PREFACE TO THE SEVENTH EDITION

According to a reliable and conservative estimate some half billion words are published annually on medical subjects in the journals of English speaking countries alone. Much of the mass of scientific writing turned out by the laboratories and clinics comes within the scope of this book, at least for review. With each succeeding revision we became increasingly conscious of the hopelessness of trying to cover so great an expanse of medical literature. Even those whose interests are largely confined to one or another special field are inundated and complain that they often find it hard to keep their heads above the swelling tide. We ourselves now marvel at the intrepid not to say reckless spirit in which this book was conceived and its first edition written. Though we are not abject in our apology we fully realize and regret the insufficiency of the last revision. There was a disconcerting gap between its text and the more recent advances in physiology and related branches of scientific medicine, which made us acutely aware of the necessity of calling upon others for help. This we have done and our colleagues have responded magnificently and most generously to our appeal. We have been extremely fortunate in gathering together for this edition a galaxy of contributors, each of whom is outstanding in the field which his contribution covers. We believe that this, the seventh, is the most comprehensive and authoritative edition since the inception of the book twenty five years ago. We wish to extend our most cordial thanks to our colleagues for this happy outcome which the excellence of their contributions has brought about.

The names of the contributors are listed alphabetically on page ii.

The section on Circulation, Chapters 14 through 28, has been rewritten, mainly by Dr. Donald E. Gregg and his associates.

Chapters 1 to 13, on the *Physiology of the Blood*, and those numbered 44 to 49 and 51 to 55, all inclusive, have been revised or rewritten by members of the staff of the Department of Physiology, and of the Banting and Best Department of Medical Research, University of Toronto. Professor C. H. Best has exercised general supervision over these chapters.

More specific reference to the contributions of the several authors will be found in the Table of Contents.

PREFACE TO FIRST EDITION

Physiology is a science in its own right and the laboratory worker who pursues his researches quite detached from medical problems need offer no apology for his academic outlook. Indeed some of the most valuable contributions to medical science have been the outcome of laboratory studies whose applications could not have been foreseen. Nevertheless, we feel that the teacher of physiology in a medical school owes it to his students, whose ultimate interest it must be conceded is in the diagnosis and treatment of disease, to emphasize those aspects of the subject which will throw light upon disorders of function. The physiologist can in this way play a part in giving the student and practitioner a vantage point from which he may gain a rational view of pathological processes.

We have endeavored to write a book which will serve to link the laboratory and the clinic, and which will therefore promote continuity of physiological teaching throughout the pre-clinical and clinical years of the under-graduate course. It is also hoped that when the principles underlying diseased states are pointed out to the medical student and he is shown how a knowledge of such principles aids in the interpretation of symptoms or in directing treatment, he will take a keener interest in physiological studies. When such studies are restricted to the classical aspects of the subject apparently remote from clinical application, the student is likely to regard them only as a task which his teachers in their inscrutable wisdom have condemned him to perform. Too often he gains the idea from such a course, that physiology is of very limited utility and comes to believe that having once passed into the clinical years, most of what he has crammed for examination purposes may be forgotten without detriment to his more purely medical studies. Unfortunately, he does not always realize at this stage in his education how great has been the part which physiological discoveries have played in the progress of medicine and that the practice of today has evolved from the "theories" of yesterday.

Many physiological problems can be approached only through animal experimentation. Advances in many fields, most notably in those of carbohydrate metabolism, nutrition and endocrinology, bear witness to the fertility of this method of research. On the other hand, many problems can be elucidated only by observations upon man and physiology has gained much from clinical research. The normal human subject as an experimental animal possesses unique advantages for many types of investigation and in disease, nature produces abnormalities of structure and function which the physiological laboratory can imitate only in the crudest way. Within recent years the clinical physiologist, fully realizing these advantages and the opportunities afforded by the hospital wards, has contributed very largely to physiological knowledge. In many instances clinical research has not only revealed the true nature of the underlying process in disease but has cast a light into some dark corner of physiology as well, several examples of clinical investigation which have pointed the way to the physiologist could be cited. In the last century, knowledge of the processes of disease was sought mainly in studies of morbid anatomy, biochemistry was in its infancy and many of the procedures now commonly employed for the investigation of the human subject had not been devised. Today, the student of scientific medicine is directing his attention more and more to the study of morbid physiology in his efforts to solve clinical problems. This newer outlook has borne fruit in many fields. It has had the beneficent result of drawing the clinic and the physiological and biochemical laboratories onto common ground from which it has often been possible to launch a joint attack upon disease. We feel that this modern trend in the field of research should be reflected in the teaching of medical students, and have therefore

given greater prominence to clinical aspects of the subject than is usual in physiological texts

In order to understand the function of an organ it is usually essential to have a knowledge of its structure. For this reason we have followed the plan of preceding the account of the physiology of a part by a short description of its morphology and, in many instances of its nerve and blood supply. The architecture and functions of the central nervous system are so intimately related that some space has been devoted to a description of the more important fiber tracts and grey masses of the cerebrum, cerebellum and spinal cord.

We wish to thank our colleagues in physiology, biochemistry and anatomy whom we have drawn upon on so many occasions for information and advice, without their generous help the undertaking would have been an almost impossible one. We are also deeply grateful for the unstinted assistance which we have received from our friends on the clinical staff, several of whom have read parts of the text in manuscript or in proof. We wish especially to acknowledge our indebtedness to Professor A. M. Wynne, who has written the section on the oxidizing systems of living cells to Dr J. K. W. Ferguson for his collaboration in the preparation of Chapter 33, and to Professor C. B. Weld and Dr E. T. Waters whose stimulating criticisms and sound counsel have been invaluable.

Finally, we wish to thank our secretaries Miss Mabel Cory and Miss Dudley Martin, who have spent so many tedious hours in preparing the manuscript for the press, in checking the references and in compiling the index.

SECTION ONE
The Blood and Lymph

1

THE PHYSIOLOGICAL PROPERTIES, PHYSICAL
CHARACTERS AND COMPOSITION

Outline of the Functions of Blood

In animals whose bodies are composed of many cells (Metazoa) the blood serves those purposes, which for unicellular organisms (Protozoa) are carried out by the fluid medium, the salt or fresh water, which surrounds them and bathes their surfaces. For example, an organism such as the amoeba acquires oxygen by diffusion directly from the environment into the interior of the cell. Similarly the carbon dioxide diffuses outwards. The processes of nutrition and the excretion of the products of the cell's metabolism are accomplished in a manner equally simple. Food is taken in through the cell membrane either in solution or as particulate matter, and waste products pass into the surrounding medium. Other requirements of this organism, such as the maintenance of an optimum temperature and the proper degree of moisture, are dependent on the immediate (internal) environment, the *milieu interne* of Claude Bernard.

The elemental needs of each cell in a multicellular individual from the most primitive type to the highest vertebrate are the same as for the unicellular organism, yet in the evolution of the higher forms the cells composing their bodies have become farther and farther removed from immediate contact with the outside world. Myriads of cells have become packed together, and the deeper ones could not possibly satisfy their needs after the direct and simple fashion of the unicellular forms. The more primitive multicellular types overcame the difficulty by the development of canal systems which opened to the exterior and through which the ocean waters flowed freely in

and out, bringing oxygen and aliment to the more deeply lying cells and bearing carbon dioxide and other excretory products away. Thus the first attempt at a circulation, was an open one. As higher forms evolved the circulation became closed and the waters of the environment no longer flowed and ebbed through the body. No longer could the interchange of the respiratory gases and the absorption of nutriment be carried out in this direct and simple way. Yet the vessels of this closed circulatory system were filled with a fluid which took the place of and fulfilled the duties of the watery environment of the more primitive types. The blood and other body fluids may be looked upon as that environment which has become enclosed within the bodies of the higher forms, and has undergone certain modifications in its composition to meet the requirements of the more specialized cells which it bathes.

The similarity between the compositions of sea water and blood which has been stressed by the researches of Macallum lends support to these views on the evolution of the blood.¹ This brief account will also serve as an introduction to a consideration of the functions of the body fluids, since their duties are to satisfy in the same way as did their prototype, the requirements of the individual cells.

¹ Sea water of today differs from blood serum in having a total salt concentration of about 3 per cent, a much higher concentration of magnesium and a lower concentration of potassium. But Macallum points out that the sea water of the geological period when the ancestors of mammalian forms adapted themselves to a terrestrial life was probably closely similar in its inorganic composition to blood serum.

1 *Respiratory* The transport of oxygen from the air in the lungs to the tissues, and of carbon dioxide from the tissues to the lungs

2 *Nutritive* The conveyance of food materials, glucose, amino acids and fats from the alimentary canal to the tissues

3 *Excretory* The removal of waste products of metabolism, e.g., urea, uric acid, creatinine, etc

4 *The maintenance of the water content of the tissues* Though the blood itself is contained within vascular channels, a constant interchange of fluid through the vessel walls takes place. This fluid which has left the blood vessels and come into direct contact with the tissue cells is known as the tissue or interstitial fluid. It closely resembles the blood plasma in chemical composition, and is identical with lymph. Through the medium of the transuded fluid the final stage in the transportation of oxygen and food materials to the tissues and the first stage in the journey of CO_2 and waste products from the tissues are made.

5 *To regulate body temperature* The body owes its ability to regulate its temperature (ch 52) largely to the water of the blood and tissue fluids. Water possesses three qualities which fit it pre-eminently to fulfil this purpose.

a *The specific heat* of water is considerably higher than that of any other liquid or solid. On account of this great heat storage power of water, sudden changes of body temperature are avoided and even a cold blooded animal such as the frog has, due to this purely physical quality, some ability to maintain a relatively constant body temperature against transient fluctuations in environmental temperature. A man of average weight develops 3000 Calories in 24 hours. This amount of heat is capable of raising the temperature of his tissues (which are largely water) only about 32°C . Heat elimination (radiation, etc.) is able to keep pace with heat production and the body temperature varies but slightly within normal limits. But it has been pointed out by L. J. Henderson that if the tissues had the low heat storage capacity (spec. heat) of most substances, an amount of heat equal to 3000 Calories would raise the temperature of the tissues and fluids of the body by from 100° to 150°C .

b *High conductivity* The thermal conductivity of water is greater than that of any other ordinary liquid. The advantage of this in the dissipation of heat from deeply situated regions of the body is obvious.

c *High latent heat of evaporation* More heat is required for the vaporization of water than for that of an equivalent amount of any other liquid. One cubic centimeter of water requires about 0.6 Calories for its vaporization. This figure is 50 per cent higher than that of water's closest competi-

tor. Fluid is being constantly lost from the body through evaporation from the lungs and skin. A large amount of heat is lost in the process.

These physical properties of water which make it ideal as a heat regulating medium are enhanced by other purely physiological factors. The mobility of the blood and the readiness with which it may be quickly redistributed in the body, combined with the unique physical properties of the fluid itself, render it so highly efficient as a regulator of body temperature. The blood may in a moment be brought from deeper to superficial regions and spread out in fine vessels over a broad area just beneath the skin, and in this way will greatly increase the radiation of heat. At another instant, in order that heat may be conserved, the fluid is drawn from the surface areas and collected in the deeper parts of the body—internal organs, muscles, etc.

6 *Protective and regulatory* The blood and lymph contain certain chemical substances of a complex nature, antitoxins, lysins, and other antibodies, which are the basis of the body's defense against injurious agents of various kinds. The circulating fluids are also the vehicle by which the hormones of the different ductless glands are brought into direct contact with the cells of the tissues.

The Composition of Blood

The blood is a highly complex fluid in which solid elements are suspended—the *corpuscles* or *blood cells*. Its specific gravity varies between individuals from 1.050 to 1.060 and its viscosity from 5 to 6 times that of water. If blood is centrifuged before it has had time to clot, or if clotting is prevented by special means (ch 12), the solid elements are thrown down and separated from the fluid portion. The latter is called the *plasma* and contains *proteins*, as well as many organic and inorganic substances in solution—nutritive and excretory materials, antibodies and hormones, and other substances of an unknown or imperfectly known chemical constitution. The specific gravity of plasma is normally around 1.027 but varies with its concentration in protein. The cells constitute about 46 per cent of the volume of human blood, the plasma 54 per cent. Small variations above or below these values are commonly encountered.

The specific gravity of a small sample of blood or of plasma may be measured by the method of Phillips, Van Slyke and associates. A series of small bottles is set up containing copper sulfate solutions varying by small equal increments (0.004) in specific gravity. A drop of blood or plasma is allowed to fall gently from the tip of a

* The specific heat of a substance is defined as the number of calories required to raise 1 gram of the substance 1°C .

TABLE I I

Inorganic constituents of plasma, red cells and whole blood, milligrams per 100 cc. average values

	Sodium	Potassium	Calcium	Magnesium	Chlorine	Iodine	Iron	Copper	Phosphate	Sulfate	Total Base cc. N/10 NaOH
Plasma	340	20	10	2.7	370		0.2				160
Cells	20	410	0	6.0	190		100.0				
Whole blood	190	220	5.2	4.0	250	0.01	50.0	0.1	3.0	2.0	

The concentrations of these various inorganic constituents are also commonly expressed as milliequivalents (m eq.) per liter. Thus serum contains 100 mg. of calcium per liter. The molecular weight of Ca is 40.07. So being divalent its milliequivalent is 20.03. The concentration of calcium in serum is therefore $\frac{100}{20.03} = 4.9$ milliequivalents per liter. Sodium is monovalent and has a molecular weight of

23, serum therefore contains $\frac{3400}{23} = 147.8$ m eq. per liter.

medicine dropper into each of a number of the bottles whose solutions are within the expected specific gravity range of the blood or plasma sample. The drop of blood or plasma, upon entering the solution, becomes coated with a film of copper proteinate and remains suspended, neither rising nor falling for a few seconds, if it is of the same specific gravity as the solution, thus, since the specific gravity of the solution is known, that of the blood or plasma is indicated.

In the following outline are given the constituents of the blood, grouped upon a physiological basis:

*Whole blood**A. Cells*

- (1) Red corpuscles or erythrocytes
- (2) White corpuscles or leucocytes
- (3) Platelets or thrombocytes

B. Plasma

- (1) Water, 91 to 92 per cent
- (2) Solids, 7 to 9 per cent
 - (a) *Proteins*, 7 per cent. Serum albumin, serum globulin and fibrinogen.*
 - (b) *Inorganic constituents*, 0.9 per cent. Sodium, calcium, potassium, magnesium, phosphorus, iodine, iron, copper, etc.
 - (c) *Organic constituents* (other than (a) and (d)): Nonprotein nitrogenous substances, (urea, uric acid, xanthine, hypoxanthine, creatine and creatinine, ammonia and amino acids) neutral fats, phospholipids, cholesterol, glucose.
 - (d) *Internal secretions, antibodies and various enzymes*, (amylases, proteases, lipases, esterases, etc.)

* Plasma from which the fibrinogen has been removed through clotting (ch. 12) is spoken of as serum.

INORGANIC CONSTITUENTS

The concentration of the plasma to the various inorganic materials is given in table I I.

It will be noted that the plasma is relatively rich in sodium and calcium but poor in potassium and magnesium whereas in the cells conditions are reversed. The cells show a relatively high concentration in potassium and magnesium, but are lacking in calcium and have a low concentration of sodium (human). In the blood of some species sodium is absent or present only in traces. Except for a minute amount of iron in the plasma, this element is confined to the red cells and the greater part of it is attached to the hemoglobin molecule (ch. 6). It has been suggested that the small quantity of nonhemoglobin iron in the erythrocyte is bound loosely with the lecithin of the cell stroma (p. 71), (see also chapter 8).

Phosphorus

Phosphorus exists in blood in four main forms. One of these is *inorganic phosphorus* (orthophosphate). The three other phosphorus fractions are in *organic* combination and are as follows:

1 *Ester phosphorus*, e.g., diphosphoglycerate, adenosinetriphosphate, hexose phosphates, glycerophosphate.

2 *Lipid phosphorus*, e.g., the phosphatides lecithin, cephalin, sphingomyelin.

3 *Nucleic acid phosphorus*.

According to Kay the nucleic acid phosphorus in normal human blood is negligible. It is derived from the nuclei of white cells and the reticulum of the reticulocytes. In abnormal blood containing a large number of leucocytes, reticulocytes or nucleated red cells this fraction may however constitute a considerable proportion of the total phosphorus.

The inorganic phosphorus (3 mg per 100 cc) is according to most observers about equally distributed between cells and plasma. The quantity of organic phosphorus in blood is many times greater than the inorganic. In whole blood it amounts to from 35 to 40 mg per 100 cc and the greater proportion of this is in the cells.

The inorganic and ester fractions are extracted from blood by the precipitation of the proteins with trichloroacetic acid and filtering. The phosphorus contained in the filtrate is spoken of as the acid soluble phosphorus. Upon extraction of blood with alcohol ether the lipid phosphorus is obtained. The phosphorus of blood is therefore separable into two classes:

- (1) *The acid soluble which includes*
 - (a) Inorganic phosphorus
 - (b) Ester phosphorus
- (2) *Alcohol ether soluble, i.e., organic phospholipid phosphorus*

The ester, or organic acid soluble phosphorus is obtained by determining the total acid soluble P and subtracting from it the inorganic phosphorus. Of the ester phosphorus, all of which is intracellular, about one quarter is hydrolyzable by bone phosphatase (ch 59). The hydrolyzable portion is mainly adenosinetriphosphate, and the nonhydrolyzable part mainly diphosphoglycerate. Since the nucleic acid phosphorus is negligible in normal blood, the acid soluble + the alcohol ether soluble phosphorus equals the total phosphorus as determined by wet ashing.

In the following table is given the distribution of inorganic, ester and lipid phosphorus in normal blood.

Phosphorus in whole blood

Milligrams per 100 cc, average figures	
1 Total phosphorus	40
2 Total acid soluble—90 per cent in cells	27
3 Inorganic—in cells and plasma	3 ⁴
4 Ester (2-3)—practically all in cells	24
5 Lipid (1-2)—in cells and plasma	13

The phosphorus compounds of the blood and tissues play an important role in maintaining the electrolyte equilibrium within the red cells and in regulating the acid base balance. Diabetic acidosis, for example, and the acidosis induced by the ingestion of ammonium chloride, are accompanied by increased excretion of phosphorus in the urine and a pronounced reduction of the organic acid soluble phosphorus in the blood cells. Reverse changes occur in alkalosis, the reduction in the chloride of the blood following pyloric obstruction, and the alkalosis caused by overbreathing are associated with a reduction in the urinary

excretion of phosphates and a decrease in the inorganic and ester phosphorus of the blood. In renal insufficiency, the inorganic phosphorus in the plasma and cells and the ester phosphorus (diphosphoglycerate) in the cells are greatly increased. The inorganic and ester phosphorus are reduced in rickets but a rapid increase accompanies the healing process. The inorganic phosphorus is diminished after the injection of insulin and in hyperparathyroidism (ch 59). In anemias associated with high reticulocyte counts and in leukemia, the concentration of ester phosphorus in the blood is increased. The inorganic phosphorus is increased in some forms of tetany.

ORGANIC CONSTITUENTS (OTHER THAN ORGANIC PHOSPHORUS)

Plasma Proteins

The concentration of total protein in the plasma and the proportions of the three fractions—albumin, globulin and fibrinogen—vary from species to species but under ordinary conditions of health remain relatively constant between individuals of the same species.

Serum globulin can be separated by "salting out" into two fractions—*euglobulin* and *pseudoglobulin*, or into three fractions— α , β and γ globulins—by electrophoresis. The euglobulin is thrown out of solution by saturation with NaCl half saturation with $MgSO_4$, or one third saturation with $(NH_4)_2SO_4$, it is insoluble in water. The pseudoglobulin is not "salted out" by NaCl but is thrown down by saturation of its solution with $MgSO_4$ or half saturation with $(NH_4)_2SO_4$. It is soluble in water.

The electrophoretic separation of proteins is based on the difference in electric charges of various proteins and consequently their different rates of migration in an electric field. In addition to the "salting out" and electrophoretic procedures two other methods are available. (a) Cohn's chemical fractionation method which utilizes the different solubilities of the proteins and the sensitivity of the solute to variations in ionic strength in ethanol concentration and in metallic ions. (b) The ultracentrifugation procedure which separates proteins on the basis of their differences in density.

α , β and γ globulins have isoelectric points of 5.1, 5.6 and 6.0 pH, respectively. It is questionable whether these fractions are distinct chemical entities. It is more probable that they are merely artificially produced as a result of the methods of treatment employed. In other words, it is likely that serum globulin is a single large molecule which is split into two or three separate parts by

⁴ In infants and young children, the inorganic phosphorus is from 1 to 3 mg per cent higher than it is in adults.

laboratory manipulation. Yet however this may be, the γ globulin is more intimately associated with antibody production, and undergoes an increase in many acute and chronic infections.

Pseudoglobulin contains 85 per cent α globulin and 15 per cent γ globulin, whereas, euglobulin contains less α but more of the β and γ globulins.

The several electrophoretic fractions of plasma protein are not pure, all contain lipid and carbohydrate material combined probably as prosthetic groups. The albumin fraction also contains bilirubin (ch. 6). Approximately 75 per cent of the carbohydrate and all of the lipid, bound to protein, is found in the α and β globulin fractions. The role played by the lipoprotein complexes in atherosclerosis is discussed elsewhere in the book. Other substances, e.g., calcium, phosphorus, sulfonamide drugs and the dye T 1824 (p. 17) are bound to the albumin fraction (see fig. 11).

Fibrinogen has been isolated and prepared in crystalline form. X-ray diffraction studies indicate that its molecule is structurally similar to such fibrous proteins as collagen and myosin (see ch. 53). The molecular weights of the plasma proteins are given on p. 7.

The total plasma protein can be calculated from the specific gravity of the plasma by means of line charts, or by using the formula $P = K(S - A)$, where P is the plasma protein in grams per 100 cc, S the specific gravity and K and A are constants with values of 364 and 1.006, respectively. Thus, if the specific gravity is 1.026, the protein in grams per 100 cc is $7.28 = 364(1.026 - 1.006)$.

The values of total protein and of the different fractions in human plasma are given in the following table.

Protein fractions in human plasma

Fractionation by Electrophoresis grams/100 cc	Fractionation by Salt ing out with Sodium Sulfate grams/100 cc
Total protein 6.03-6.72	Total protein 6.0-8.0
Albumin 3.32-4.04	Albumin 4.3-5.0
Total globulin 2.23-2.39	Total globulin 1.1-3.1
α globulin 0.70-0.84	Euglobulin 0.1-0.4
β globulin 0.74-0.81	Pseudoglobulin 1.0-2.7
γ globulin 0.66-0.70	Fibrinogen 0.2-0.3
Fibrinogen 0.31-0.43	Albumin/globulin (A/G) ratio 1.50

FIG. 11 Dyed electrophoretic and corresponding density pattern of human sera.

100 cc in dog, cow and goat respectively) (see fig. 11).

PATHOLOGICAL VARIATIONS IN SERUM PROTEINS. The several protein fractions of plasma may change in value independently of one another, and either with or without alteration in the quantity of total protein, in several pathological states the albumin and globulin fractions may change in opposite directions, i.e., a fall in albumin accompanied by a rise in globulin.

The fibrinogen concentration is increased in pregnancy and menstruation, in tissue injury of various kinds, in parathyroid overdosage, acute infections, malaria and several other conditions. This fraction is markedly reduced in animals after hepatectomy or severe liver damage and in several diseases involving the liver. In rare instances it is congenitally considerably below normal or absent.

In hemorrhage a loss of all fractions of plasma protein occurs, their concentrations are also diminished as well, since the blood volume is at first made good by the passage of a saline solution or one of low protein concentration from the tissue spaces into the blood stream. In extensive burns, on the other hand, especially during the following few days all fractions are reduced as a result of the leakage of blood fluid from the de-

In some animals the globulin is equal to or exceeds the albumin. Of the three fractions fibrinogen is always in lowest concentration and it is considerably lower in human plasma than in that of some animals (e.g., 0.54-0.72-0.60 gram per

nuded surface and into the tissues in the region of the burned area, but since the lost fluid is usually relatively low in its content of protein, the protein concentration of the plasma tends towards an increase. In *cirrhotics of the liver*, *chronic hepatitis* (depressed synthesis by liver), *chronic infections*, the albumin fraction is reduced.

In *nephrotic* and *nephritic conditions* (due to loss of albumin in the urine) and in severe *malnutrition* (owing to the low intake of the necessary amino acids for protein synthesis) the albumin fraction is also reduced. As a result of the diminished concentration of albumin, the oncotic pressure of the plasma tends to fall, less water is held in the vessels and, as a consequence, the plasma volume is reduced. As a consequence of these changes, the globulin, though not raised absolutely, shows an increased concentration. In any condition associated with a loss of water from the blood (*dehydration*, *anhydremia*, p. 25), though no change may occur in the absolute amount, i.e., in the total quantity in the blood, the concentrations of all fractions will show an increase. In order to determine whether an absolute reduction or increase in one or other of the plasma proteins exists, it would be necessary to measure the total plasma volume (ch. 3) as well as the concentration of the particular fraction. The γ globulin shows an absolute increase in *multiple myeloma*, *cirrhotics of the liver*, *subacute yellow atrophy of the liver*, *acute hepatitis* and *acute nephritis*, *leukemia*, *tuberculosis*, *scarlet fever* and in *acute and chronic infections*. In liver disease the α globulin is also increased, and in later pregnancy the concentration of β globulin, which contains a high percentage of lipid, is raised. Prothrombin appears to be a β globulin. This fraction serves to bind a considerable proportion of the plasma cholesterol, carotene and phospholipids of the plasma, and is increased in the later months of pregnancy. The isoagglutinins (anti A and anti B, and anti Rh, ch. 5) are associated with the γ and β globulin fractions of the plasma.

ORIGIN In the *embryo*, the mesenchyme cells, through a process of secretion or by the actual solution of their substance, furnish the fluid (embryonic plasma) which floats the primitive blood cells (ch. 11). The albumin fraction is formed earlier than the other proteins which do not appear in the plasma of the chick embryo until after the 14th day of incubation.

In the *adult*, five possible sources of the plasma proteins have been suggested—namely, disintegrating blood cells (red or white), the general tis-

sue cells, reticuloendothelial cells of spleen, bone marrow, etc., and the liver.

It is now well established that the liver is the site of the production of plasma albumin, this fraction undergoes a pronounced reduction in conditions which depress hepatic function. It is thought that the Kupffer cells are especially concerned in the manufacture. The albumin fraction (but not the globulin) in the plasma of dogs can be reduced and maintained at a subnormal level by intravenous injections of a solution of gum acacia (p. 50). In these experiments the hepatic cells become swollen and vacuolated. The fall in serum albumin is therefore considered to be due, in part at least, to the failure of the liver to make good the normal "wear and tear" of serum albumin (which amounts to several grams daily), though, possibly, there is also a withdrawal of albumin from the plasma to the liver as a compensatory response to rectify the increase in oncotic pressure caused by the presence of acacia in the circulation.

The evidence points definitely to the liver as the site of fibrinogen production since, as mentioned above, the concentration of this fraction is reduced by liver damage or hepatectomy. When the liver returns to a healthy state after injury has been induced by an agent such as phosphorus or chloroform, the fibrinogen level also returns to normal. Following slight liver injury or during the repair of a hepatic lesion, which might be expected to stimulate the functional activity of the organ, the fibrinogen may be actually higher than normal.

The origin of serum globulin has not been definitely settled. Elman and Hefetz succeeded in reducing the albumin fraction in the serum of dogs by dietary measures to 50 per cent of the normal. No reduction was observed in the serum globulin. The livers of the animals showed pronounced histological and chemical changes, the water content of the hepatic tissue was increased, the cells became vacuolated. This was accompanied by severe depletion of hepatic protein.

On the contrary, the experiments of Miller and his associates who perfused the intact livers of rats with blood containing lysine labeled with isotopic carbon (C^{14}) indicate that the liver furnished about 80 per cent of the serum globulin. The remainder is supplied by extrahepatic tissues, the greater part of which, if not the whole, are derived from the lymphocytes (White and Dougherty, ch. 10). The conflict between the results of the experiments of Elman and Hefetz and those

of Miller and associates may be explained perhaps by the great functional reserve of the liver, hepatic lesions in the experiments of the former being insufficient to cripple its globulin producing function

There is experimental evidence that the adrenocorticotrophic hormone of the pituitary through its action on the adrenal cortex affects the manufacture of β and γ globulins. Injections of this hormone or of adrenal cortical hormones into rats causes within 24 hours a rise in β globulin of 30 per cent, and in γ globulin of from 70 to 80 per cent (White and Dougherty)

FUNCTIONS 1 Fibrinogen is essential for the clotting of the blood (ch 12)

2 All three proteins serve to maintain the osmotic pressure (p 26) of the blood. The large molecules of the proteins do not pass readily through the normal capillary membrane. The osmotic pressure which they exert amounts to, in man, between 25 and 30 mm Hg. The pressure which each fraction exerts is inversely related to the size of its molecule and directly related to its concentration in the plasma. The molecular weight of fibrinogen is over 200,000 and its concentration is low, it therefore contributes little toward the total osmotic pressure. Albumin is in the highest concentration and its molecule has the least weight (70,000-75,000). The osmotic pressure of the plasma, therefore, depends largely upon this fraction. The molecular weight of serum globulin is between 150,000 and 190,000 and its concentration is considerably less than that of albumin. In equivalent concentrations, serum albumin has an osmotic activity 2.4 times that of serum globulin (Keys), it furnishes about 80 per cent of the oncotic pressure of the plasma.

3 Viscosity. The proteins give a certain viscosity to the blood which is a factor in the maintenance of the normal blood pressure.

4 They aid in the regulation of the acid base balance of the blood (ch 13)

5 Stability of the blood (see p 61). The globulin and fibrinogen fractions influence the tendency of the corpuscles to adhere to one another and form rouleaux or clumps.

6 Trephones. Carrel has shown that the leucocytes prepare substances from the plasma proteins which are essential for the nourishment of tissue cells grown in cultures. These substances he has termed trephones.

7 Immune substances (antibodies) which react with the antigens of several microorganisms, e.g., diphtheria, typhoid and streptococcal infections,

and the viruses of mumps, influenza and measles, are associated with the γ globulin. γ Globulin, separated from the other fractions, is used as a means of artificially immunizing against measles, infectious hepatitis, rubella and poliomyelitis. Certain other antibodies, the isoagglutinins A and B, are present in the γ and β fractions. As might be expected, the globulin fraction of the serum tends to increase during the process of immunization against the infective diseases mentioned above.

8 They serve as a reserve of protein upon which for a time the body draws during fasting or when the protein intake is inadequate.

Plasmapheresis. The importance of the plasma proteins is demonstrated by this procedure which consists in bleeding an animal and returning the red cells suspended in Locke's solution to the body. A state of shock results, followed by death when the total protein is reduced to between 1 and 2 per cent. No ill effects result however if the cells are suspended in serum before they are reintroduced. When depletion of the proteins is not carried to the point where fatal shock ensues, a marked rise in protein concentration occurs within 15 minutes which indicates that during this time a store of preformed protein is drawn upon for the replacement of the protein which has been removed. The regeneration is slower after this, though fairly rapid for the first 24 hours. It becomes progressively slower during succeeding days. The proteins are restored to the normal level in from 2 to 7 days, provided that the diet contains a sufficiency of high quality protein. Plasma proteins themselves have been found to be best for this purpose, the proteins of liver run a close second.

In more chronic plasmapheresis experiments, edema commences when the total protein concentration reaches a value of 5.5 per cent and albumin a concentration of 2.5 per cent.

The Nonprotein Nitrogen (NPN) or Noncoagulable Nitrogen of Blood

By the term nonprotein nitrogen is meant the nitrogen of those substances, e.g., urea, uric acid, creatinine, etc., listed on page 8. They may be extracted from blood or plasma by treating either of these with a reagent, such as trichloroacetic acid,

* Gamma globulin obtained from any normal person usually contains sufficient immune bodies for protection against measles and infectious hepatitis, but for protection against rubella (German measles), poliomyelitis, whooping cough, chicken pox and mumps, an active immune globulin can be obtained only from subjects convalescent from the particular disease.

TABLE 12*

which precipitates the proteins, filtering and determining the nitrogen in the filtrate. These substances are in part absorbed with or derived from the food, and in part are the waste products of tissue catabolism. The total NPN of whole blood amounts to from 28 to 40 mg per 100 cc. It constitutes from 1 to 2 per cent of the total nitrogen of the blood. Its concentration in the cells is nearly double that in the plasma. The proportions of the different constituents are given in table 12.

The term undetermined nitrogen embraces the nitrogen of ammonia, purines, and other non-protein substances of unknown or undefined nature.

PATHOLOGICAL VARIATIONS The NPN of blood at any given level represents the balance struck between nitrogenous materials formed in the intermediary metabolism of ingested and tissue protein and the excretion of these products in the urine. In renal insufficiency, therefore, the nonprotein nitrogen is elevated, and in certain cases may be ten times the normal. On the other hand, a rise in the NPN occurs in conditions which are associated with excessive tissue catabolism, such as infections, fevers, thyrotoxicosis, starvation or severe malnutrition. It is also increased following hemorrhage into the stomach or upper intestinal tract. In the later months of pregnancy the NPN is reduced. The reduction has been attributed to the diversion of nitrogen to

the growing fetus and the reduction of protein catabolism in the maternal tissues.

The chief conditions associated with an elevation of the NPN of the blood are

Adrenal insufficiency
Dehydration
Hemorrhage into the gastrointestinal tract
Infectious fevers: lobar pneumonia
Intestinal obstruction
Parathyroid intoxication (in animals)
Peritonitis
Renal insufficiency

Cholesterol

(See also chapters 39 and 49) This sterol is present in serum in the free form and as cholesterol esters. The normal value for total serum cholesterol is not known exactly, it varies from 100 to 250 mg per cent. The esterified cholesterol is about 72 per cent of the total and this ratio varies within a rather narrow range. Its concentration is increased in several diseases, notably in hypothyroidism and lipid nephrosis and in some cases of atheromatosis. Keys and his associates found that within fairly wide limits (2 to 3 grams cholesterol weekly) the content of the sterol in the diet exerted little effect upon the serum cholesterol.

THE RED CELLS OR ERYTHROCYTES

The Size, Shape and Structure of the Red Cell

Human erythrocytes are disk shaped, non nucleated elements having a mean diameter of 7.2μ ($6-9\mu$ see fig 2 1) and a thickness of about 2.2μ ($2-2.4\mu$) at the thickest part, i.e., near the circumference, and about 1μ at the center. As a result of osmotic changes¹ and the consequent passage of water into the cell, the diameter increases with a shift in the acid base balance of the blood toward the acid side. The cell is therefore slightly larger in venous than in arterial blood, its diameter is increased by about 0.5μ in muscular exercise and reduced by forced breathing. The central portion of the cell is much thinner than its edges, which appear heaped up into a circumferential mound around a central depression. This construction gives it a biconcave contour or a roughly dumbbell outline when viewed edgewise (figs 2 1 and 2 2).² The average area of a red cell is $120\mu^2$ and the volume $85\mu^3$.

¹ These are the mean dimensions of the cell measured in dry films. In the fresh state the diameter is larger by about 0.5μ . There is considerable variation between the diameter of the smallest and largest cells found in a sample of normal blood. The range for dried films is shown in figure 2 2.

² Hartridge has pointed out the advantage of this design for the transport of oxygen. Of all geometrical figures the sphere is the one in which its center is equidistant from all points upon its surface. The adoption of this form by the red cell would therefore have ensured the diffusion of oxygen to all parts of its interior at equal rates. But a sphere has the disadvantage of possessing the smallest surface in relation to its mass. A thin disk on the other hand, presents an almost maximal surface area in relation to its bulk, yet in such a shape all parts on the surface are not equally distant from its center, the ends are further removed than the sides. The shape of the red cell—a thin disk with elevated rounded edges—is a compromise between these two forms. It secures the advantages of equal and rapid diffusion of oxygen to its interior and a relatively large surface area for the absorption of the gas.

The biconcave form also gives the red cell a mechanical advantage, in that the changes in volume which the cell undergoes from time to time can be effected with a minimal amount of tension being placed upon the cell membrane. The membrane covering the concavity of the cell moves

There has been in the past a tendency to regard the erythrocyte as almost a dead cell, because of its low oxygen consumption, and its lack of a nucleus. However, it should be noted that the erythrocyte carries out metabolic processes, and it does have a finite, though low, oxygen consumption. It is therefore probably better to consider it as a very specialized type of living cell.

The framework, or stroma of the red cell, comprises somewhat less than 5 per cent of the wet weight of the cell. The major constituents of the stroma are lipids and an insoluble protein. The former is mainly made up of cephalin, lecithin and cholesterol, the latter is albuminlike. Almost half of the lipids are bound to the protein, and a lipoprotein complex called elenin has been isolated from the stroma by Calvin and his coworkers. Elenin seems to contain at least the A, B and Rh antigens. (In general, the antigenic nature of the erythrocyte appears to be a property associated with the stroma.) Hemoglobin makes up about 30 to 34 per cent of the wet weight of the cell. This corresponds to an extremely concentrated solution of the proteins, and means that the hemoglobin molecules are packed very tightly into the interior of the erythrocyte.

The erythrocyte contains the enzymes of the glycolytic system, catalase, carbonic anhydrase, all of the glutathione of the blood, as well as other enzymes and organic and inorganic salts. Potassium is present in high concentration, relative to sodium.

When a drop of freshly drawn normal blood is placed on a glass slide and examined under the microscope, many of the erythrocytes will be seen to group themselves together with their broad surfaces in contact, like a pile of coins. Groups of cells arranged in this way are called rouleaux (sing., *rouleau*). The normal discoid shape of the erythrocytes is a requisite for rou-

leaux or in "like the bottom of an oil can" as the cell increases or diminishes in volume.

³ Though very widely accepted, this sex difference has probably been overemphasized. Some workers have found a maximal difference of only 1 per cent in favor of men.

leaux formation, the property being lost if the cells as in congenital hemolytic jaundice, assume a more globular form. Rouleaux formation does not occur in the circulation under normal physi-

FIG 21 Diagram showing dimensions of the red cell

ological conditions, the moving cells showing little or no tendency to cohere.

'Sludged blood' In certain abnormal states, e.g., tissue injury and shock, the cells of the circulating blood show a pronounced tendency to stick together and form large clumps or masses which move slowly and clumsily through the small vessels—arterioles and capillaries. This sludged blood, as it is termed by Knusel, who has made an extensive study of the phenomenon, has a deleterious effect upon the general circulation. Normally the blood moves through the minute vessels in stream lines. The cells remain

FIG 22 Red cell diameter distribution curve for healthy men (after Price-Jones)

FIG 23 Diagram showing composition of the red cell

FIG 24 Description in text

discrete showing little tendency to cohere. The propulsive force of cardiac systole is transmitted throughout the vascular system with the minimum dissipation of energy. Stream lining is abolished in sludged blood, a large proportion of the energy is wasted in giving a rolling or rotary motion (angular acceleration) to the massed cells. Sludged blood is thought in some instances to be a factor in thrombosis (ch 12)

Number

The average number of red cells in man is around 5,000,000 per cu mm for males and 4,500,000 for females, but 6,000,000 is not a very unusual figure for a robust young man and 5,500,000 for a healthy young woman.² Slight variations in the number of red cells, amounting to about 5 per cent, occur throughout the 24 hours. The count is lowest during sleep, becomes elevated after arising and increases gradually throughout the waking hours. At birth and in infancy the red cells are somewhat more numerous than in later life, but the earlier figures of 7,000,000 and 8,000,000 for the newborn child have not been confirmed by later work. Destruction of a large proportion of the extra cells occurs within the first 10 days, but for a few days the red cell count shows a progressive fall, for some weeks after this the count remains considerably above that of the adult.

The destruction of large numbers of erythrocytes shortly after birth and, as a consequence, the liberation of excessive amounts of hemoglobin into the plasma has been held to be the cause of the physiological jaundice of the newborn, in whom the bilirubin content of the plasma (ch 33) is from 3 to 5.5 mg per cent. The infant's red cells are said by some to be more fragile than

those of the adult, yet it is questionable, in view of the revised figures for red cell counts in the newborn, that excessive hemolysis plays a very important part in the production of the jaundice. Again, others deny that the red cells at birth are unduly fragile. Immaturity of the excretory function of the liver probably plays the dominant role.

The total number of red cells in the human body estimated upon the basis of 5,000,000 per cu mm is about 33,000,000,000,000 which gives a total red cell area exposed to the plasma of between 3500 and 4000 sq meters. Lamons has made the interesting observation that in the species which he investigated (cat, rabbit, dog and man) the surface area of the individual corpuscles and the corpuscular count varied in opposite directions, so that the cell area per cu mm of blood was nearly the same in all—7.24, 7.55, 7.52 and 7.35 sq cm for the four species in the order given above. The quantity of hemoglobin per sq cm of red cell area is also about equal in all mammalian species.

PHYSIOLOGICAL VARIATIONS IN THE NUMBER OF RED CELLS

Increase in the number of red cells occurs under the following conditions:

I. HIGH ALTITUDES. It has been known for many years that the inhabitants of mountainous regions, especially where the elevation above the sea is 10,000 feet or more, have constantly a much higher red cell count than persons living at sea level. The natives of some regions in the Peruvian Andes where the altitude is 14,000 feet or more, have a red cell count 30 per cent above the normal (over 7,000,000 per cu mm). Not only the natives, but travellers sojourning even for a short time at these altitudes undergo an almost immediate increase in the number of their red cells. The corpuscular increase is directly proportional to the altitude, as may be seen from table 2 I.

It is perhaps necessary to point out here that an increase or a decrease in the red cell count does not of itself inform one of an increase or decrease in the red cells of the body as a whole. The red cell count gives only an estimate of the *number of cells per unit quantity of blood* (p. 17). A reduction in the amount of plasma or of the water of the blood, for instance, would cause the *proportion* of red cells in the specimen to be increased. But neither the immediate nor the permanent increase in number of red cells at high altitudes is due simply to a reduction in fluid and a greater concentration of the blood, for estimations of the

TABLE 2 I

Altitude in Thousands of Feet	Corpuscles in Millions per Cubic Millimeter
0.7	4.5
4.4	5.2
12.0	6.8
15.6	7.8
18.2	8.3

From Barcroft after Hingston. In this table the altitude (in thousands of feet) multiplied by 0.225 gives a figure which approximates the increase in red cell count (in millions per cu mm) above that at sea level. In this instance the count at sea level was 4,250,000.

total volume of blood in the body (see ch 3) prove that there is an *absolute* increase in the number of circulating cells. How is the *immediate* increase brought about? It is obviously impossible to account for such a rapid rise in the red cell count by a greater production of cells by the bone marrow, and it is at once suggested that large masses of cells are packed away from the general circulation—in a 'storehouse' of some kind—but are quickly mobilized upon demand. When the functions of the spleen are considered (ch 8) it will be seen that this organ serves as a reservoir for red cells and is responsible for the sudden increase in their number which occurs early in the process of acclimatization to high altitudes.

The *permanent* and great elevation of the red cell count, which is a characteristic feature of the blood of natives and other persons after acclimatization to the rarified atmosphere, cannot be explained in the same manner, for the number of cells which the spleen can put into circulation is limited. Under these circumstances there is, actually, an increased manufacture of erythrocytes by the blood forming organ—the bone marrow. The cells which are formed by the overstimulated marrow are discharged into the general circulation at a somewhat immature stage of their development. They are spoken of as *reticulated cells* or *reticulocytes* since their protoplasm shows a delicate filigree or reticulum which stains with basic dyes. The ultimate cause of the corpuscular increase (a physiological polycythemia) is undoubtedly the lowered oxygen tension of the atmosphere, and consequently of the blood, since animals placed in an hermetically sealed cabinet and subjected to lowered oxygen tensions exhibit similar blood changes.

2 **MUSCULAR EXERCISE** and certain EMOTIONAL STATES cause a temporary increase in the number of red cells as a result of an outpouring of concentrated blood from the spleen. This may be looked upon as an emergency measure and, like that which occurs at high altitudes, is the response of the body to the tissues' call for oxygen.

3 **WIGHTENED ENVIRONMENTAL TEMPERATURE** also causes a liberation of red cells from the splenic reservoir.

4 **OTHER CONDITIONS** which tend to lower the oxygen tension of the arterial blood cause a rise in the number of circulating red cells. As in the response at high altitudes two factors are concerned, e.g., a discharge of blood from the spleen

* Though this can be demonstrated in experimental animals it does not appear to be an important feature in man.

FIG 25 Showing reticulocyte response to altitude (after Barcroft)

and other reservoirs, and a greater production of cells by the bone marrow.

Reduction in the number of red cells occurs at high barometric pressures e.g., when the oxygen tension of the blood is higher than the normal. Animals, for example, living in deep mines have a lower red cell count than those at sea level.

ALTERATIONS IN THE NUMBER OF RED CELLS IN PATHOLOGICAL STATES

Increase in the Number of Red Cells—Polycythemia

Increase in the total number of red cells occurs as a compensatory measure in several pathological conditions and then represents apparently the response of the bone marrow to low oxygen tensions in the arterial blood. A red cell concentration of 7,000,000 or more per cu mm of blood is not unusual in the following conditions:

1 **EMPHYSEMA** (p 518) and other chronic diseases which interfere with the oxygenation of the blood in the lungs (anoxia), e.g., tracheal stenosis, pneumothorax, tumor of the lung, pulmonary tuberculosis and pulmonary arteriovenous aneurysm.

2 **CONGENITAL HEART DISEASE** (ch 25)

3 **ASTHMA & DISEASE**, a condition associated with dilation and marked hypertrophy of the right heart, sclerosis of the pulmonary arteries and their branches with consequent obstruction of the blood flow through the lungs. There is extreme cyanosis, emphysema, dyspnea, and attacks of asthma are common accompaniments. The bone marrow is hyperplastic.

4 **CHRONIC CARBON MONOXIDE POISONING**

5 **CHEMICALS** e.g. chronic poisoning

arsenic phosphorus and manganese gum shellac and certain aniline dyes

6 REPEATED SMALL HEMORRHAGES the polycythemia then represents an over response of the bone marrow to the successive blood losses

POLYCYTHEMIA VERA (synonyms erythremia splenomegalic polycythemia Vasquez Osler disease) Unlike the preceding types the polycythemia is not secondary to any known pathological condition. The disease appears to be primarily centered in the red bone marrow which is greatly increased in amount and is hyperplastic, extending into the shafts of the bones to displace the fatty marrow and packed with normoblasts and mature erythrocytes. Megaloblasts are absent or very scarce. The number of red cells in the circulating blood may be as high as 14 000 000 per cumm and a count as high as 20 000 000 has been reported. The total blood volume is greatly increased. The viscosity of the blood is of course greatly elevated. The concentration of hemoglobin in the individual cells and the chemical and physiological properties of the pigment are normal. The size shape and general features of the red cells as a rule show nothing unusual and the number of reticulocytes is not greatly increased.

The chief features shown by the disease apart from those of the blood itself are cyanosis (ch 33) dyspnea on exertion enlargement of the spleen hemorrhages and a familial tendency. Death may occur from thrombosis of the portal vein or a cerebral vessel. The circulation rate (ch 28) is slowed and the diffusion rates of oxygen and CO_2 (ch 31) through the pulmonary epithelium are reduced although during rest the oxygen saturation of the arterial blood is usually normal. The renal blood flow and the filtration fraction (ch 34) are increased whereas the plasma flow is decreased. The oxygen saturation of the blood is reduced however during exercise. Owing to the great increase in hemoglobin concentration the actual quantity of oxygen in the blood is greater than normal. If the polycythemia were a compensatory reaction brought about by the lowered rate of diffusion of oxygen through the pulmonary epithelium one would expect that breathing air with a high pressure of oxygen would be of benefit but this is not the case. Exposure in a chamber to a high oxygen tension for several days does not effect a reduction in the number of red cells. The reduced circulation rate may result in some way from the fact that the blood contains such a large load of oxygen that the tissues can obtain their quota from a smaller quantity of blood than normally. On the other hand the reduced circulation rate may be due primarily to vasoconstriction in some

part of the circulation. Some believe that narrowing of the caliber of the vessels of the bone marrow and the resulting low oxygen tension produced thereby provide the stimulus for the overproduction of blood cells. Studies of blood lactic acid concentration in polycythemia vera following muscular exercise lend support to the idea that a sluggish blood flow through the tissues is a causative factor. In normal persons and in the secondary types of polycythemia mentioned above a rise in blood lactate occurs whereas in polycythemia vera exercise causes a fall. This anomaly could be explained upon the basis of a high resting blood lactate as a result of a slow blood flow and the accumulation of lactic acid in the ischemic tissues. Exercise would then by causing vasodilation and a freer oxygen supply in the contracting muscles tend to reduce the concentration of the metabolite in the blood. That this is the probable explanation is indicated by the observation that vasodilation induced by heat also causes a fall in blood lactate in this disease. The phenomenon appears to be of fundamental significance and not simply the result of the high erythrocyte concentration because it is not abolished when the red cell count is brought down to normal by treatment with phenylhydrazine hydrochloride a drug which has been employed in controlling the disease.

Polycythemia can be produced in dogs by the daily administration of cobaltous chloride (8 mg daily for 2 or 3 weeks). The high red cell count thus induced is reduced to normal by feeding with whole beef or hog liver or by the daily injection of ascorbic acid. The effect of liver suggests the presence of an hepatic hormone possessing a depressant action upon bone marrow activity. Radioactive phosphorus (P^{32}) has been used lately with success in the treatment of the disease.

The observations of Schafer have thrown a new light on the pathogenesis of polycythemia vera which may show a way to the rational treatment of the disease. In experiments upon dogs he found that excision of the carotid sinus and the aortic nerves caused the development of polycythemia and hypertension in 40 per cent of the animals. Removal of the paravertebral chain of sympathetic ganglia was followed by a gradual return of the erythrocyte count to normal. A similar result followed paravertebral sympathectomy in a patient suffering from polycythemia. The polycythemic response to removal of the influence of the carotid sinus and aortic nerves is possibly due to constriction of the vessels of the bone marrow the anoxia caused thereby acting in the usual way to stimulate its hemopoietic function.

Reduction in the number of red cells below the normal is known as anemia. The causes and varieties of anemia are manifold and will be considered in chapter 9.

An apparent decrease or increase in the number of red cells occurs under certain conditions which upset the water balance of the body. It has already been pointed out that the red cell count gives merely an estimate of the proportion of cells to plasma. There may, for instance, be undue retention of water in the body, and the plasma or its watery constituents may then be increased (hydremia or hemodilution). The blood is diluted, and the number of red cells per unit of blood is reduced, yet there is no absolute decrease in the number of circulating cells. Conversely, a loss of plasma or of merely the water of the blood (anhydremia or hemoconcentration) will increase the red cell count, i.e., the blood becomes more concentrated although the total number of red cells in the body is not altered. Therefore in conditions associated with extreme dehydration (p. 24) of the body the number of red cells per unit of blood is increased.

A practical point to be remembered when counting the red cells or in determining the packed cell volume is that their number may be relatively increased or decreased by purely local alterations in blood concentration. Pronounced dilation of the capillaries of the region of skin from which the sample has been taken will cause a local slowing of the blood stream and congestion of the part. The loss of fluid from the vessel into the tissues and the clumping of corpuscles which may result from the greater capillary pressure will give a false estimate of the number of red cells. On the other hand, pressure made upon the part by the examiner in order to hasten the flow of blood from a skin puncture may express fluid from the tissues which will dilute the red cells in the specimen. Moreover, even under ordinary physiological conditions the concentration of red cells may vary considerably in different parts of the circulation. The proportion of red cells in the capillaries is greater as a rule than in the heart and larger vessels, by around 12 per cent, but in certain states associated with slowing of the peripheral circulation concentration of red cells in the capillaries may increase the disparity. Trapping of plasma in the peripheral vessels may occur in other conditions and will tend to reduce the concentration of cells in the capillary areas below that in the general circulation. These are also important points to bear in mind in estimating the blood volume by the dye method (p. 17).

Estimation of red cells. The concentrations of red (or white) cells may be obtained by counting them directly after suitable dilution beneath the microscope as in the method of Thomas Zeiss. The instrument used for this purpose is called a *hemacytometer*. The reader is referred to texts on laboratory methods for details. The relative volumes of

red cells and plasma are determined by means of a specially devised centrifuge known as an *hematocrit*. The blood, rendered noncoagulable, is drawn into a graduated capillary tube, placed in a centrifuge and revolved at a speed of 3000 r.p.m. 30 to 60 minutes. At the end of this time the original blood will be found to have separated into a clear colorless column of plasma and a red column—the corpuscles. The lengths of the two columns are read off by means of the graduations on the tube. The normal proportions of plasma and corpuscles in human blood are about 54 (53–56) and 46 (44–47) respectively. That is the volume of cells (*packed cell volume*) is 46 per cent of the total volume of the specimen of blood. The average volume of the individual erythrocytes is obtained by dividing the packed cell volume by the figure for the red cell count. It is important to use an anticoagulant such as heparin that does not cause shrinkage or swelling of the cells.

Variations in Size, Shape and Structure of the Red Cells

Under physiological conditions little change in shape of the red cell occurs, though a few fragmented cells may be found in normal blood. These are, as will be seen later (ch. 8), simply remnants of senile cells which have undergone a natural disintegration in the blood stream. A slight change in volume, about 7.5 per cent occurs, due to osmotic changes incident to the respiratory cycle (ch. 20). The red cells at birth and in early infancy are larger than in adult life. This as well as the higher cell count is responsible for the high packed cell volume (54 per cent) of the infant's blood.

In disease, the red cell is subject to many changes in size, shape and structure. The examination of the blood and the identification of the various forms of abnormal cells is an important means employed in diagnosis of the different anemias (ch. 9). Only the more outstanding abnormalities can be touched upon here. The least pronounced departure from the normal blood picture is an increase in the number of *reticulocytes* (see frontispiece). These young red cells resemble the ordinary cells in every way except that after *supravital staining* (alcoholic solution of brilliant cresyl blue added to blood in the fresh state) a fine reticulum of basophilic material can be seen in the cytoplasm. The reticular material is of cytoplasmic origin, probably γ globulin, and does not represent nuclear remains. A reticulum of similar nature may sometimes be seen in cells in which the nucleus is still intact. In normal human blood the reticulocytes are from 0 to 2 (av. 0.5).

per cent of the total red cell count * They are increased after hemorrhage, at high altitudes (p 511, by exercise, in acholuric jaundice (p 77) and in pernicious anemia, especially following specific treatment (p 82) of the latter condition and during the blood crises A rise in the reticulocyte count indicates an increased activity of the blood forming tissue—the bone marrow—which as a result of a specific stimulus turns out a larger number of young cells The maturation of the red cells, that is, the change from reticulocytes to erythrocytes, has been estimated to take from 10 to 24 hours There is evidence that the thyroid gland liberates a principle which hastens the maturation of reticulocytes

The next stage in the life of the red cell is represented by the *normoblast*, which appears in the blood in several different types of anemia This cell, as its name implies, is normal in size and shape, possesses the usual amount of hemoglobin, but contains a nucleus The bone marrow normally holds large numbers of these immature cells, but in health they do not reach the general circulation In pernicious anemia and other severe types of anemia large, pale, nucleated cells are seen resembling white cells (lymphocytes, ch 10) They represent a very primitive stage in the development of the red cells, they are termed *megaloblasts* The megaloblast contains a small, sometimes a negligible amount of hemoglobin Its protoplasm also contains a diffuse or punctate arrangement of basophilic material Hemoglobin is acidophilic, so these cells may stain with acid as well as with basic dyes This phenomenon of dual staining, which may also be shown by other abnormal cells, is known as *polychromasia* Other cells of various sizes and shapes may be seen in the anemias Shrinkage of the contents of the red cell with wrinkling of its limiting membrane, as may result from immersing the cells in a hypertonic solution, is termed *crenation* In pernicious anemia, in particular, the presence of cells of unequal sizes (*anisocytosis*) and of deformed outline (*poikilocytosis*) is common The poikilocytes may

* These cells are more numerous in rabbit's blood, being from 3 to 3.5 per cent of the total red cell population The blood of certain other species, also shows a relatively high count

assume the most bizarre forms, mulberry, flask or hammer shapes may appear Erythrocytes with a globular form (*spherocytes*), or of an elliptoid or crescentic shape (*elliptocytes* and *sickle cells*) are found in certain types of anemia Pauling, Itano, Singer and Wells have found that in sickle cell anemia the red cells contain an abnormal type of hemoglobin and they suggest that the formation of certain bonds between the abnormal molecules causes a distortion of the cell These distorted more rigid cells, are destroyed more rapidly than the normal cells *Macrocytes* and *microcytes* are terms denoting cells of usual structure and without nuclei, but larger and smaller respectively than the normal erythrocyte In certain conditions, e.g., lead poisoning, fine dots of basophilic material, probably a porphyrin (ch 6) appear throughout the cell, giving it a stippled appearance This abnormality is known as *punctate basophilia* (see frontispiece) In certain types of anemia rings or twisted strands of basophilic material may be seen near the periphery of the cell These are derived from the nucleus and are known as *Cabot's rings* At other times small nuclear fragments—*Howell-Jolly bodies*—are present in the cytoplasm

BLOOD VOLUME: BODY WATER: WATER BALANCE

Blood volume estimations are of value in many clinical conditions associated with a loss or gain of fluid by the body, or for the purpose of checking the results of corpuscular and hemoglobin estimations. It is also sometimes of interest to know, in experimental investigations and in metabolic studies in man, the total amounts of certain blood constituents, e.g., protein, calcium, sodium, etc., as well as their concentrations.

Methods for the Estimation of Blood Volume

DIRECT METHOD

The first attempts to measure the total quantity of blood in the body were made upon animals by Welcker (1854). His method consisted in taking a small measured quantity of the animal's blood and diluting it to 1 in 100 with normal saline.

The animal was then bled, and after the blood had ceased to flow, its vessels were washed out and the muscles minced and extracted with water. Water was then added to the collected fluid—blood and washings—until its color matched precisely the tint of the original diluted blood specimen. The total collected fluid divided by 100 gave the blood volume.

This method was also employed upon decapitated criminals (Bischoff) in order to obtain a value for the blood volume of man, but since its applicability was obviously very limited, in direct methods were later devised.

INDIRECT METHODS

Several methods are available for the determination of the blood volume during life. The carbon monoxide method developed by Grehant and Quinquand for animals and modified by Hal dane and Smith for man, has been largely supplanted by the dye method.

The dye method was originally devised by Kuth, Rowntree and Geraghty. The degree of dilution in the plasma of a known amount of dye injected into the circulation is employed as the

basis of calculation. The color of the stained plasma is compared in a colorimeter with that of a standard dye solution of known concentration. There are several qualifications required of a dye before it can be considered suitable for blood volume measurements. In the first place, of course, it must be innocuous. It must not diffuse too rapidly from the blood stream, it must color only the plasma and not be adsorbed by the cells of the blood nor by the walls of the blood vessels. It must not change color itself after entering the blood, nor cause the liberation of pigment from the red cells (hemolysis) and it must be capable of mixing evenly and thoroughly with the plasma. If it lacked these qualifications, the colorimetric readings obviously would be un dependable.

The dye most commonly employed is a blue dye, T 1824 (Evans blue). Evans blue has the advantage that the error due to any discoloration of the plasma by hemoglobin (hemolysis) is minimized. This dye is also eliminated very slowly (48 per cent per hour) from the circulation. It remains in the circulation because it combines with protein although this combination apparently is not strong, for the two can be separated by paper electrophoresis.

In making an estimate of blood volume a sample of plasma is obtained before the dye is injected. Then a known amount of the dye is injected intravenously and blood samples are obtained at 10 or 20-, 30, 40, and 50 minute intervals after the injection. The concentration of dye in the plasma is measured. Because the dye leaves the circulation to some extent, it is necessary to determine the fall in concentration of the dye with time. By extrapolating back to zero time from the curve of concentrations, the concentration of the dye at zero time can be computed and this is used to calculate the blood volume. Because T 1824 leaves the circulation slowly, in normal persons it is usually possible to obtain a reasonable estimate of the blood volume from a sample taken 10 minutes after the dye has been injected, but under conditions when mixing is slow, the extrapolated values are preferable. From the con-

centration of dye in the sample and the amount of dye injected, the dye dilution and hence the plasma volume can be computed

If either lipemia or hemolysis is present, the dilution method with T-1824 is not satisfactory unless a lengthy dye extraction procedure is used. Also, as we have seen, in many instances the disappearance rate of the dye from plasma must be known if an accurate plasma volume measurement is to be achieved. Another disadvantage is that repeated injections may cause some discoloration of the conjunctivae and skin.

Plasma volume may also be estimated by the injection of albumin "tagged" with I^{131} . This is not affected by hemolysis or lipemia, nor does it stain the tissues, but it also has the disadvantage of requiring information concerning its disappearance rate. Measurements of plasma volumes by the use of T-1824 and by means of I^{131} albumin give similar results. Another procedure has been developed using a dextran fraction which leaves the circulation very slowly. This method has the advantage of requiring only two blood samples, one of which is a control. It is unaffected by lipemia or hemolysis, employs a colorless material and requires no highly specialized equipment for its estimation.

These various procedures give an estimate only of the plasma volume. In order to obtain the value for the total blood volume, the proportion of cells to plasma must be determined by means of the hematocrit. If the packed cell volume thus obtained is, for example, 45 per cent, the plasma volume is therefore 55 per cent. Thus the total blood volume can be calculated from the plasma volume and the hematocrit reading.

In calculating the blood volume from the plasma volume and the hematocrit reading it is necessarily assumed that the proportion of red cells to plasma is the same throughout all parts of the vascular system, but experimental evidence is strongly against such an assumption. In capillaries the proportion of red cells to plasma may be considerably less or more than in the larger vessels. To eliminate the error of unequal distribution of red cells throughout the circulation, methods have been devised for the estimation of the total circulating red cell volume. These use the dilution of injected red blood cells which have been "tagged" with radioactive iron (Fe^{59}), radioactive chromium (Cr^{51}) or radioactive phosphorus (P^{32}). In the method of Hahn, as modified by Gibson and his colleagues radioactive iron (Fe^{59} or Fe^{55}) is incorporated into ferric ammonium citrate, which is injected into a donor belonging

to group O (ch 5). Newly formed cells take up the iron and appear in the circulation in 24 hours, reaching a maximum in 21 days.

From 70 to 100 ml of the donor's blood (30 to 40 ml of red cells), having a radioactivity of from 2500 to 3000 counts per minute per ml (determined by Geiger counter), are injected intravenously or intraarterially into the subject. The quantity of donor's blood injected will depend upon the volume of red cells which the recipient is expected to have, but injections between 70 and 100 ml cover a range of red cell volumes of from 1500 to 2500 ml.

Between 10 to 20 minutes are allowed to pass after the injection in order for thorough mixing of donor's and recipient's cells to occur. Samples of 15 ml of recipient's blood are then taken and are followed at 10 and 20 minute intervals by two more samplings. Two milliliters of donor's blood are diluted to 100 ml, 10 aliquots are then prepared. The recipient's blood samples are centrifuged at 3000 r.p.m. for 30 minutes. Donor and recipient samples are wet ashed and the iron deposited electrolytically on copper. The radioactive iron in the two samples is determined by means of a Geiger counter, the calculation of the circulating red cell volume is made from the following equation:

$$V_{rr} = \frac{CD \times V_{aD}}{V_{aR}}$$

where V_{rr} is the red cell volume, CD the number of milliliters of donor cells injected, V_{aD} the radioactivity of the donor's cells and V_{aR} the radioactivity of the recipient's cells.

In order to determine the total blood volume the plasma volume is measured by the dye method and the result added to the value for the circulating red cell volume.

This method is based on two assumptions—(a) that none of the radioactive iron escapes again after being taken up by the erythrocytes, and (b) that all the labelled cells became mixed with the recipient's cells equally throughout the circulation. Only the principle of the method can be given here, for details the reader is referred to the original papers.

Radioactive iron can be used in tests carried out over a long period of time because it persists in the cells and the blood remains radioactive for much longer than when radioactive chromium or phosphorus are used. The methods employing Cr^{51} and P^{32} are simpler to use than the one just described because the labelling of the red blood cells with these materials can be done *in vitro*.

Since it is thus possible to use red blood cells from the individual on whom the test is to be made, the problem of cell compatibility does not arise. All determinations of blood volume, whatever method is used, are made with the patient recumbent and under basal conditions some 12 to 14 hours after a meal. The loss of the dye or other material into the tissues at the site of injection must be avoided since this of course will vitiate the results which, since the plasma would be less deeply stained, would be too high. Care must also be exercised to prevent evaporation of fluid from the samples after they have been drawn. Other wise the concentration of the particular test material in the plasma would be raised and the readings (which would indicate a lower degree of dilution) would be too low.

Normal Values for Plasma and Whole Blood Volumes as Obtained by Different Method

In normal subjects, blood makes up roughly 7 per cent of the body weight, with plasma volume a little over 4 per cent and red cell volume about 3 per cent. The plasma volume of adult males is about 40 ml, the red cell volume about 29 ml, and the whole blood volume in the neighborhood of 70 ml per kg of body weight. The blood volume of a man of average weight (70 kg) is therefore around 5 liters. The blood volume in terms of body weight shows considerable variation from person to person. Changes in body density alter this relationship of blood volume to body weight. The relationship between blood volume and body height shows a similar variability. The most constant relationship is found between a combination of body weight and the cube of body height (fig 31).

Body Water (see also ch 4)

The blood volume and its variations cannot be considered entirely apart from the fluid content of the body as a whole. Blood volume regulation is largely a question of balance between the fluid within the vessels and in the tissues. When conditions arise which tend to lower or raise the volume of blood, counter forces come into play which restore the normal level. When circulating fluid is lost, the vessels replenish themselves from the extravascular spaces. On the other hand, any tendency for the blood volume to rise is met by a discharge of the excess fluid into the tissues and later from the body in the urine. So, a balance is struck, and in health the blood volume is maintained remarkably constant. For example, after the intravenous injection of a large

FIG 31 Ratio of measured blood volume to total body mass plotted against body density (X 53 men, O 26 women). Note that the blood content is 92.8 ml per kg in hypothetical body of density 1.097. BV was computed from measured PV and hematocrit with correction of the latter to the over nil cell concentration of the circulating blood.

quantity of saline the volume of circulating fluid (although raised temporarily) is brought back to normal within 30 minutes or less. On the other hand the loss of blood fluid, as by hemorrhage, immediately calls into action processes which may, in a very short time, replenish the blood volume. When an animal is bled to death, at a not too rapid rate the blood which is withdrawn is found after a few minutes of bleeding to have become diluted—clearly demonstrating the promptness with which fluid (water and salts) has been absorbed into the vessels.

The total volume of the water of the body varies among species but in man has a mean value of approximately 65 per cent (about 10 per cent less for women) of the body weight (it is about 65 per cent in the dog and about 73 per cent for guinea pigs and rabbits). It is difficult to establish proper mean values for body water, because its total volume is related to the mass of the lean tissues of the body rather than to the body weight. In an obese person it is a much lower percentage of the body weight than in one who is lean. The values, therefore, vary widely both between persons and different species of animal in accordance with their fatness or leanness.

The total volume of the body water can be determined by injecting into the blood stream a

known amount of water containing deuterium or tritium, or antipyrine which becomes uniformly distributed throughout the body fluids (intracellular and extracellular), and then determining its concentration in a sample of serum. Tritium labelled water may be more conveniently measured than deuterium labelled water because of the radioactivity of tritium. A further method using N acetyl 4 aminoantipyrine has also been described.

The water content of various tissues, in average percentages, is given in the following table

	per cent
Muscle (striated)	75
Skin	70
Connective tissues	60
Adipose tissue	20
Bone (marrow free)	25-30
Blood	
Plasma	90
Cells	65
Kidney	80
Liver	70
Nervous tissue	
Gray matter	85
White matter	70

The *extracellular fluid* which comprises the blood plasma, the tissue or interstitial fluid, lymph and the fluid in the serous cavities, amounts to about 24 per cent of the body weight, the plasma water constitutes only about 4 per cent of the body weight. The fluid within the cells, the *intracellular fluid* amounts to 41 per cent of the weight of the body, or about two times the extracellular fluid. The skeletal muscles contain about half, the skin about $\frac{1}{2}$ and whole blood only about $\frac{1}{10}$ of the total body water.

In general, the intracellular fluid has a high concentration of potassium and a low concentration of sodium, whereas the extracellular fluids contain relatively large amounts of sodium and small amounts of potassium.¹ In most cells chloride is also in low concentration or is absent, the red blood cells and the cells of the gastric glands are notable exceptions. Substances, such as su-

¹ In the case of muscle at any rate, this distribution of Na and K between intra- and extracellular fluids may be altered in pathological states involving the excessive loss of potassium from the body, e.g. severe and prolonged diarrhea, hyperactivity of the adrenal cortex or the administration of desoxycorticosterone (ch. 58) when muscle potassium is largely replaced by sodium. Increased concentration of K in the serum and other extracellular fluids occurs in adrenal cortical insufficiency, in oliguria or anuria, during tissue breakdown or anoxia, following major surgical operations, and in dehydration.

crose, mannitol, inulin, thiocyanate and to a large extent chloride, when introduced into the body, become uniformly distributed throughout the extracellular fluids, but do not enter the cells in important amounts and, since they are not metabolized and are not excreted too rapidly, can be employed to estimate the volume of the extracellular fluid in the living animal. When, for example, a known amount of thiocyanate, is injected into the blood stream and sufficient time allowed for equal distribution to occur, the volume of the extracellular water can be calculated from the concentration of the solute in a sample of serum. Radioactive sodium or chloride may also be employed for such determinations, but since these solutes are not excluded from all types of cells they are not as dependable as thiocyanate or sucrose, especially if absolute values are sought. The extracellular fluid is visualized as occupying a space of the determined volume, and according to the solute used in the estimation it is customary to speak of the *thiocyanate space*, *sucrose space*, etc.

The values for the total body water and the extracellular water being known, the intracellular water is found by subtraction (see table below)

Body water	
Body Water	Percentage of Body Weight
A Extracellular	
In plasma	4
In interstices	15
In hollow viscera eye, etc	5
B Intracellular	41

When calculating intracellular water in this way it is well to appreciate that some of the methods for determining extracellular fluid volume, because they measure only the volume of fluid into which the test substances can freely diffuse, exclude a certain amount of fluid outside cells, such as eye humors, cerebrospinal fluid and secretions of glands whereas these fluids are usually included in the estimation of total body water.

The characteristic distribution of sodium and potassium between blood plasma and tissue fluid is shown in table 3 I. Determinations of the extracellular fluid volume, total tissue water content and sodium space permit one to obtain information regarding shifts of ions or water across cell boundaries. It is probable that changes in electro-

lyte concentration are primary and that shifts in intracellular water occur secondarily to such changes. The entrance or exit of water thus depends on the balance of ions inside and outside the cell water passing freely across the cell boundary. The balance of ions inside and outside the cell, with a high potassium concentration inside and a high sodium concentration outside, is best explained by postulating an active process—a sort of "sodium pump"—which excludes, or even extrudes sodium from the cell. The precise way in which sodium is kept out of the cell is not known, but the process requires energy. The immediate energy source is probably adenosine triphosphate or some related compound, and either glycolysis or oxidation may provide the further energy required. The 'sodium pump' may become less efficient under circumstances when energy supply is reduced, as, for example, when the blood supply to a tissue is blocked or when there is some metabolic insufficiency. One can think of changes in intracellular water, therefore, as being related to changes in the molar concentrations of intracellular or extracellular electrolytes, and one way in which an imbalance could be brought about would be through some change in the 'sodium pump'. Intracellular water under ordinary conditions is a rather fixed quantity, and the fluid of blood is also kept relatively constant. A loss of one fourth of the body water is usually fatal.

Under physiological conditions the interstitial fluids show the greatest changes. In dehydration the proportion of the total water from extracellular and intracellular compartments varies with the manner in which the negative water balance is produced. When, for example, the dehydration is caused by sucrose diuresis, about 85 per cent of the excreted water is derived from extracellular and 15 per cent from intracellular sources. Whereas, in dehydration resulting from water deprivation, the water loss is from 57 to 67 per cent intracellular (Painter and associates).

Hyaluronic acid. Although practically none of the extracellular water is chemically bound, that is to say, substances are dissolved in it readily, and it can be entirely separated from colloidal materials by ultrafiltration, and although free movement and rapid changes of distribution are permitted its physical state does not appear to be that of a simple solution of electrolytes and protein bathing the cells: it is held in the tissue spaces by a gelating substance. The latter has been identified chemically as a mucopolysaccharide and called *hyaluronic acid*. This substance also enters into the formation of the cement sub-

TABLE 3 I
Concentrations of base in the water of blood plasma
and in the water of muscle tissue
(After Gamble, Ross and Tisdall)

	Per 100 cc Plasma	Per 100 cc Plasma Water	Per 100 cc Muscle Tissue	Per 100 cc Muscle Water
	mg	cc 0.1 N	mg	cc 0.1 N
Na ⁺	330	157.7	80	45.8

Total		171.5		182.1

Water of blood plasma is taken as 91 per cent by volume and water of muscle tissue as 76 per cent of weight.

stance binding cells together, and into the production of other gel like materials e.g., vitreous body, jelly of the umbilical cord, etc. The physiological significance of this material is dealt with in another place.

Water Balance

In health, except when new tissue is being formed, the body's intake of water obviously must balance the output. When the output exceeds the intake, the body's water content is reduced and the body is then said to be in negative water balance, dehydration results. When, as during growth, convalescence from an acute illness or in pregnancy, new tissue is being formed or for a time after a subject has been placed upon a reducing diet, the water balance is positive, the intake exceeding the output, i.e., water is retained.

The antidiuretic principle of the hypophysis constitutes part of the mechanism regulating the volume of body water. In dehydrated states, increased amounts of the pituitary hormone are excreted in the urine (ch. 56).

THE WATER INTAKE

Body water is replenished in two main ways (a) by the ingestion of liquids, semisolid and solid food (cooked lean meat, for example, is from 65 to 70 per cent water), and (b) by the water formed in metabolism through the oxidation of the hydrogen of the food or of the body tissues themselves. Water is absorbed mainly from the small intestine, to a smaller extent from the large intestine, and in small amounts only from the stomach. The following is from H. W. Brown and Brown compiled from the data of Magnus-

Levy gives the quantities of water produced by the metabolism respectively, of the three main food stuffs and of alcohol

100 grams of fat	yield 107.1 grams water
100 grams of starch	yield 55.1 grams water
100 grams of protein	yield 41.3 grams water
100 grams of alcohol	yield 117.4 grams water

Water is also formed in the tissues through the polymerization or synthesis of various compounds, i.e., through a metabolic process the reverse of hydrolysis. An ordinary mixed diet yields as a result of oxidative processes from 300 to 350 grams of water daily, or about 14 grams per 100 Calories. When no food or drink is taken, the body materials themselves are utilized for this purpose, the glycogen, protein and fat supplying important quantities of water. The camel's hump, for instance, which is largely composed of fat, is a reservoir for large amounts of water, and the clothes moth kept in a desiccator and fed upon perfectly dry food lays eggs which are 80 per cent water.

For the adult, the amount of water from all sources and under ordinary circumstances which must be ingested daily is around 2500 cc. or about 1 cc. per Calorie of food intake. This usually means that about 1000 cc. of water as such or in beverages must be drunk in order to maintain the water balance.

The water intake under conditions of average temperature, humidity and diet is summarized in the following table:

Solid and semisolid food	1200
Oxidation of food	300
Drinks (water, milk, coffee, beer, etc.)	1000

The volume of body water is held constant through a nicely balanced adjustment between intake and output. The intake is regulated mainly by the sensation of thirst.

Even a slight fall in the total volume of body water arouses thirst. This is caused by the inhibition of salivary secretion and the consequent drying of the oral mucosa, as well as by the rise in the osmotic pressure of the blood. Thirst can be aroused experimentally by the intravenous injection of a hypertonic solution. The subject of thirst is dealt with more fully in chapter 43. In experiments on dogs Robinson and Adolph found that when the animals had ready access to water they drank when they had lost water to the extent of 0.5 per cent of their body weight. The

amount of water drunk was just sufficient to replace that which had been lost. It is hard to conceive what signaled the cessation of drinking, for it occurred while the water was still in the stomach, that is before it had been absorbed.

THE WATER OUTPUT

Water is lost from the body in the feces, urine and saliva and by the evaporation of water from the skin and lungs. The daily loss through these several channels is given in the following table for a man of average size at light occupation in a temperate climate:

Skin (at average temperature and humidity)	500
Expired air (at average temperature and humidity)	350
Urine	1500
Feces	150
Total	2500

Under usual conditions of air temperature (23–25°C), humidity and diet, the heat lost from the lungs and the surface of the body by the evaporation of water amounts to about 24 per cent of the total heat production. The measurement of this *insensible water loss* under standard conditions may therefore be employed as a basis for the determination of the basal metabolism (ch. 44).

The loss in the saliva is negligible under ordinary circumstances but may be considerable in mouth breathing (as a result of evaporation) and in those addicted to the spitting habit.

The water lost through the skin and lungs varies greatly with the temperature and relative humidity of the atmosphere and with the extent of the muscular exercise indulged in. At ordinary temperatures slight secretion by the sweat glands is not perceived since the sweat evaporates as quickly as it is formed. This *insensible perspiration*, as it is called, includes the loss of a greater amount of water by evaporation from the moist tissues beneath the skin, this loss is quite apart from the actual secretion of sweat (ch. 52). The diffusion of water through the skin and evaporation from the surface under ordinary comfortable conditions of room temperature and humidity is around 1 mg. per cm² of skin surface in a period of 10 minutes. The rate of diffusion is little different for living or dead skin and whether sweat glands are present or absent. The amount of the *insensible perspiration* has the average value given above but may be many times this value, when the air is

hot or the body temperature raised the rate of evaporation of water from the tissues beneath the skin is much more rapid, the secretion of sweat is also likely to be more active, but owing to the higher rate of evaporation a larger quantity of sweat is secreted before it becomes evident. Relative humidity and air movement also influence the rate of evaporation. So in humid, still atmospheres sweat secretion is more evident though it may be no greater than in a drier atmosphere when evaporation is more rapid. Large quantities of sweat are secreted as a result of muscular exercise or when, as in the tropics, the temperature is high. In hot climates the daily secretion may amount to 3000 cc daily and in very torrid atmospheres it may be as much as 10 liters. When heavy work is done in a hot environment, sweat may be secreted at the rate of 2 liters per hour. This necessitates the drinking of an equal quantity of fluid in order to maintain the normal water content of the body, since the intake must equal the output.

At ordinary temperatures the inspired air contains negligible quantities of water whereas the expired air is almost saturated with moisture. Any condition which increases the pulmonary ventilation therefore increases the water lost by this route.

The Relation of the Electrolyte Concentration and Tissue Changes to the Volume of Body Water

The isotonicity of the body fluid which depends mainly upon its concentration in sodium and chloride is maintained constant largely by the retention or elimination of water, the kidneys playing the primary role in this regulation. A loss of salt is accompanied by a loss of water and the ingestion of salt is followed by water retention. Thus it is possible to increase the volume of body water in normal persons to the point where edema occurs by the administration of large amounts of sodium bicarbonate and to cause the discharge of nephritic or cardiac edema by the reduction or withdrawal of salt from the diet. In the latter instance, only sufficient sodium chloride is available for the production of a more limited amount of isotonic fluid. The fundamental factors controlling the total volume of body water are not clearly understood. The hypothalamus is important in regulating the osmotic pressure of extracellular fluid through its influence on the liberation of antidiuretic hormone by the posterior pituitary gland and hence its influence on water retention by the kidney (ch 34). There must be, however, some means of regulating the absolute

amount of body water. It is felt that the basic factor in this control is the regulation of sodium excretion by the kidney. Since the transplanted kidney can still regulate body water, this regulation must be finally effected by something carried in the blood. The adrenal cortex undoubtedly is important in this regulation through its influence on the reabsorption of sodium, but other factors must also be involved since even in the absence of the adrenal cortex some regulation of body water can still occur. What starts the chain of events that leads to alterations in renal activity is not clear. Circulatory changes are important. Factors leading to a reduction in circulating blood volume, venous return or cardiac output appear to reduce the excretion of salt and water, whereas factors increasing blood volume or the venous return and cardiac output increase the excretion of salt and water. Whatever the precise initiating factor, it would seem that there must be a mechanism sensitive to changes in the absolute amount of body water as well as one sensitive to changes in the concentration of electrolytes. The details of this mechanism are unknown.

Changes in the diet can bring about changes in the total body water. Protein is laid down in the body with water (about 3 grams of water per gram of solid). During growth or convalescence from wasting diseases retention of water therefore occurs, i.e., the intake of water, including that derived from solid food, exceeds the output. Fat is laid down with a minimal amount of water (only that in the protein of the connective tissue framework), the deposition of glycogen is accompanied by a small storage of water.² Water retention therefore follows a sudden change from a high fat to a high protein diet, and to a less degree from a fat diet to one high in carbohydrate. A change from a diet high in carbohydrate or protein to one high in fat is followed by the loss of water.

Reduction of the caloric value of the diet below the energy requirement is accompanied for a time by the retention of water. During the first week or so on a reducing diet the subject's weight may for this reason show little or no change, the fat catabolized being replaced by water. In a prolonged fast after the fat stores have been depleted protein is also partly replaced by water, the muscles of animals dying of starvation showing a marked reduction in the proportion of protein.

² Zuntz concluded from his experiments that 3 grams of water were laid down with each gram of carbohydrate. But his results have been questioned and are not now generally accepted.

DEHYDRATION

When the output of water exceeds the intake, the body's water content obviously will be reduced. That is, the body is in negative water balance and the condition known as dehydration results.

Causes of Dehydration

Dehydration may result from

1 *Water depletion or primary dehydration* (a) *Simple deprivation of water* from whatever cause shipwreck, desert travel, dysphagia, extreme weakness, mental patients refusing to drink, etc. Under such circumstances, though there is an effort to conserve the stores of body water, through a reduction in the amount excreted by the kidney, in the sweat and by other routes, some water is always lost though none be drunk. Dehydration occurs more quickly in fever or if the environmental temperature is high.

b *Excessive water loss* may result from persistent vomiting (e.g., pyloric or intestinal obstruction) prolonged diarrhea, or the excretion of large quantities of urine or sweat, especially when accompanied by a restricted water and salt intake. In the acute diarrheas of infants, dehydration and loss of weight may occur very rapidly.

In water depletion the osmotic concentration of the extracellular fluid rises, water is drawn from the cells, and both extracellular and intracellular compartments shrink. Extreme thirst is experienced.

2 *Reduction in the total quantity of electrolytes* *salt depletion or secondary dehydration*. The electrolyte concentration of the body fluids, both extracellular and intracellular, is maintained constant through the elimination or retention of water. That is, a reduction or increase in the total electrolytes, which comprise chiefly the basic radicles Na (extracellular) and K (intracellular) and the acid radicles HCO_3 and Cl, is accompanied by a corresponding decrease or increase in the volume of body water. The sum of the basic elements and acid elements of course must balance. Loss of Cl can be made good by the retention of H_2CO_3 and a rise in plasma bicarbonate. Excreted base, however, can be replaced only by basic substances supplied in the food. The total concentration of electrolytes in the body fluids is therefore dependent upon the stores of total base. For example, in pyloric or high intestinal obstruction (p. 712) fluid is secreted in large quantities into the gastrointestinal tract. The fluid may be vomited or may collect and remain in the dilated

part of the canal above the obstruction. (The latter occurrence is the rule in the rabbit which can not vomit.) In either case the secretion of large quantities of gastric juice entails a loss of blood chloride. A similar chloride loss is induced in animals by means of a gastric fistula fashioned by sectioning through the pylorus, stitching the stomach opening to the abdominal wall and allowing the gastric juice to drain to the exterior. In the foregoing instances the chloride depletion causes at first no ill effects, the normal concentrations in electrolytes of the blood and tissue fluids being maintained for a time by the retention of CO_2 , and, as a consequence of this, an increase in bicarbonate. The compensation for the Cl loss leads however to alkalosis which is then countered by an increased excretion of base in the urine. This of course is accompanied by diuresis, marked dehydration results.

On the other hand, the continued loss of pancreatic juice (p. 633) to the exterior causes an immediate depletion of base plasma bicarbonate is reduced. In the adjustment of the acid base balance the excess of acid radicles is excreted in the urine, this again entails a loss of water. Similarly, the ingestion of acid producing salts causes a depletion of base, which is used for the neutralization and excretion of the acid radicles. Such salts therefore act as diuretics and dehydrating agents.

In salt depletion the extracellular fluid is hypotonic, water enters the cells so that the volume of intracellular fluid is maintained whereas the extracellular fluid (especially the interstitial) is reduced.

Clinically the failure to ingest sufficient salt or the leaching of salt from the body of a seriously ill patient by glucose infusions is a not uncommon cause of salt depletion.

3 *The injection of hypertonic solutions* into the blood stream. When a strong sugar or salt solution is injected, the temporary rise in the osmotic pressure of the blood causes a flow of fluid from the tissues into the vascular system until equilibrium is reestablished. The blood volume is increased, but is soon returned to normal by the loss of the excess material into the tissues and its eventual excretion via the kidney and bowels. A net loss of body water results.

Effects of Dehydration

(a) *Loss of weight* due to the reduction in tissue water as well as to the actual breakdown of body substance which occurs in the effort to furnish water for the maintenance of physiological processes. Fat and carbohydrate stores are first drawn

upon for this purpose and later, protein (b) *Disturbances in acid base balance*, usually toward the acid side. The diminished quantity of circulating fluid (loss of plasma water, anhydremia) and the consequent depression of oxidative processes in the tissues is held responsible for the excessive production of acid metabolites, e.g., lactic acid. The slowing of the renal circulation also leads to a reduced excretion of urine and the retention of acids (e.g., phosphoric) which under normal circumstances are eliminated. (c) *Rise in the non-protein nitrogen of the blood*. (d) *Rise in plasma protein concentration* and of chloride though there is no absolute increase. There is an absolute increase in blood sugar, especially when the stage of exhaustion approaches. (e) *Rise in body temperature* as a result of the reduction in circulating fluid (see ch. 52). (f) *Increased pulse rate and reduced cardiac output*. (g) *Thirst*. This occurs in water depletion but not in salt depletion, it will be discussed in chapter 43. Any fall in the water content of the tissues is reflected in the glandular activities especially of the salivary glands. Secretion is suppressed, the mouth and throat become dry. In dehydration thirst is extreme and the mouth parched. (h) *Dryness, wrinkling and looseness of skin* and a pinched expression to the features result from the loss of subcutaneous fat and of water from the deeper layers of the skin. Other manifestations are, reduced intraocular tension and recession of the eyeball and, in infants, depression of the fontanelle. (i) *Exhaustion and collapse*.

WATER INTOXICATION

When an animal is given large quantities of water by stomach tube, especially if urinary secretion is reduced by the administration of pituitrin, the tissues become "water logged," serious symptoms ensue, e.g., depression of temperature, vomiting, convulsions and coma which shortly end in death. Similar effects also follow in man if large quantities of water are given to a patient with nephritic edema or, if in a subject of diabetes insipidus, pituitrin be administered while the water intake is maintained at the usual level (see ch. 56). The manifestations of water intoxication are believed to be due to the dilution of electrolytes in the body fluids, and the damage caused thereby to the tissue cells.²

² Excessive concentration of electrolytes in the tissue fluid with consequent hypertonicity, as occurs in shipwrecked sailors if they drink sea water (which has a concentration in salts about three times that of serum) causes an equally deleterious effect upon the tissue cells. This appears to be the cause of death.

Adrenalectomy reduces the renal response to water drinking, and thus increases the susceptibility to water intoxication. This susceptibility is reduced by the administration of desoxycorticosterone, of 17 hydroxy 11 dehydrocorticosterone, or of thyroid hormone. A similar protective action is exerted by these principles upon normal animals.

In water intoxication, the protein and chloride of the plasma are diminished and the extracellular water decreased. The water retained in the body enters the cells of blood and tissues which become swollen. It is not possible to account for the reduction in plasma chloride by increased renal excretion for both adrenalectomized and normal animals actually excrete less salt than usual; apparently the salt is diverted from extracellular to intracellular fluids.

There is no danger from excess fluid being retained in the body through water drinking, for the sense of thirst and its appeasement nicely control the quantity ingested, but the artificial administration of inordinate amounts of water in the form of glucose solution, especially after surgical operations when there is some tendency toward anuria, may cause serious disturbances in water metabolism. The effects of an excess of body water induced in this way can be corrected readily by the administration of hypertonic saline.

When there has been prolonged ischemic injury of tissues, as occurs following tourniquet application and subsequent release, large amounts of sodium are soaked up by the injured tissues. In ischemic shock in mice, as much as $\frac{1}{2}$ of the total extracellular sodium may be lost into the injured region. The uptake of sodium by the injured cells causes its level in the extracellular fluids to fall. Normally, the kidney would respond to this reduction in the electrolyte concentration by excreting more water and electrolyte homeostasis would be maintained. But instead, there is renal retention of water and the sodium level of the interstitial fluid and plasma remains low. Infusions with sodium chloride are effective in promoting survival in this condition, but colloid or glucose solutions not containing sodium chloride are ineffective.

Factors Governing the Interchange of Fluid between the Tissues and the Vessels

According to Starling's view (which is generally accepted) the physical factors which determine the flow of fluid from the tissues into the blood stream as well as in the reverse direction—from

the vessels to tissue spaces—are the *osmotic* and *hydrostatic pressures* of the fluids in the two situations

OSMOTIC PRESSURE

Osmosis is diffusion through a membrane separating water—or an aqueous solution—to which the membrane is permeable, from another aqueous solution to whose dissolved materials the membrane is impermeable. Such a membrane that permits the passage of water or of some substances in solution but acts as a barrier to the molecules of certain other substances, is called *semipermeable*.

If an aqueous solution of cane sugar be placed in a vessel and a layer of water poured gently upon its surface the two liquids will remain separate for a time. Gradually, however, sugar molecules will diffuse upward and intermingle with the water molecules whereas many of the latter will pass downwards into the sugar solution. The diffusion process which due to the random movement of the molecules and quite independent of gravity or convection currents will continue slowly until the concentrations of the two types of molecules become equal throughout all parts of the liquid. If now instead of allowing free diffusion between the two solutions to take place they be separated by a membrane semipermeable with respect to the sugar molecules, equal and free diffusion cannot occur since water molecules can cross the membrane into the sugar solution but sugar molecules cannot pass out; the volume of the solution is bound to rise. The water molecules diffuse in both directions but their concentrations in pure water being higher than in an aqueous solution a greater number will strike the water side of the membrane

and more will pass through into the sugar solution than in the opposite direction, water therefore gradually accumulates on the sugar side of the membrane and dilutes the solution. If the compartment containing the solution of sugar is enclosed by rigid walls and connected with a manometer the pressure that develops can be measured. This pressure since it is caused by osmosis is called the *osmotic pressure*. A manometer (fig. 32) designed for the measurement of osmotic pressures is called an *osmometer*. Osmosis when related to the transfer of water across cell boundaries is called *endosmosis* or *exosmosis* according to whether water passes into or out of the cell.

Theoretically the transference of water through a semipermeable membrane if unopposed by any other force would proceed indefinitely although at a progressively slower rate and cause infinite dilution of the osmotically active substance on the other side. The volume of the solution would continue to increase and the osmotic pressure would not cease to rise until the concentrations of water molecules on the two sides of the membrane were equal. However owing to the presence of the molecules of the dissolved substance such equalization can never be fully attained. But the rise in pressure itself by opposing diffusion of the water molecules into the solution after a time automatically brings osmosis to a standstill.

Great pressures are capable of being developed by osmotically active substances. A 10 per cent solution of cane sugar for example can produce an osmotic pressure of over 6 atmospheres which is a pressure equivalent to that exerted by a column of fluid between 170 and 200 feet high.

Semipermeable membranes vary greatly with respect to the materials that they will or will not allow to pass. Erythrocytes for example are permeable to water but not to hemoglobin and the plasma proteins and are more permeable to chloride and bicarbonate ions than to potassium and sodium ions. Even the red blood corpuscles of different species vary considerably with respect to their relative permeability to these two cations but generally speaking blood cells as well as other cells are more pervious to K^+ than to Na^+ . The capillary membrane on the other hand permits the passage of all substances of small molecular size dissolved in the plasma and has only a limited permeability to the plasma proteins. The capillary wall of the renal glomerulus lets through very little protein. Artificial membranes such as those made of a precipitate of copper ferrocyanide or of collodion also vary in their permeabilities.

Osmotic pressure measurements give an estimate of the tendency for the diffusion of water to occur across a semipermeable membrane. The *osmotic pressure* is a result of the diffusion process not a cause of it.

Osmosis is important in many physiological

FIG. 32 As the pressure rises in the chamber it opposes the inward diffusion of the water molecules.

processes in both animal and plant life, e.g., the excretion of urine, the interchange of materials between the interiors of the blood cells or tissue cells and their surroundings, the flow of sap in plants, as well as the regulation of the blood volume. The fluids of the body contain various electrolytes and organic materials in solution. Semi-permeable membranes of various types possessing different selective permeabilities, such as the cell wall, the vascular endothelium, the renal epithelium, and the membranes lining the serous cavities and the alimentary tract, are interposed between fluids with different concentrations of osmotically active substances.

Isotonic, hypertonic and hypotonic are terms employed to denote the osmotic activity of a solution relatively to that of some other solution. If, for example, two salt solutions of equal strength are separated by a semipermeable membrane, neither will develop an osmotic pressure; they are said to be *isotonic*. If the solution on one side of the membrane be stronger, the net amount of water passing to this side will therefore be greater and the solution here is said to be *hypertonic*. The weaker solution from which there is a net transference of water is termed *hypotonic*.

In physiology these terms are used most commonly to indicate the osmotic activity of a solution as compared with that of the body fluids. For example, excised organs or sections of tissue upon which experiments are to be performed are kept moist and viable by a saline solution isotonic with the tissue fluid. Shrinkage of the cells through the loss of water (as would result from the use of a hypertonic solution) or swelling by endosmosis (as would occur if the solution were hypotonic) is thus avoided. Similarly, in order to prevent either shrinkage or swelling of the red blood cells, they must be suspended in a solution, such as plasma, that is isotonic with the fluid in their interiors. See Hemolysis, chapter 7.

HYDROSTATIC PRESSURE

The other important factor in the interchange of fluid between the blood and the general body fluids according to Starling's hypothesis is the hydrostatic pressure within the capillaries, i.e., the blood pressure, and its relation to that of the extravascular fluids.

THE RELATION OF OSMOTIC TO HYDROSTATIC PRESSURE IN THE INTERCHANGE OF FLUID ACROSS THE CAPILLARY MEMBRANE

The walls of the capillaries (generally throughout the body, as already mentioned) permit the free passage of water and substances of small

molecular size dissolved in the plasma, e.g., glucose, inorganic salts, urea, etc.

Obviously this must be so, otherwise essential nutritive materials could not reach the tissue cells and waste products could not enter the blood stream to be excreted. But the capillary wall is largely impermeable to the large molecules of the plasma colloids. To this partial impermeability the osmotic activity of the plasma is due. Since the albumin has the smallest molecule of the three plasma proteins, it escapes through the vessel in relatively greater amounts than do the globulin and fibrinogen fractions.

By the use of ^{131}I labelled albumin, it has been found that the amount of plasma protein passing through the capillary wall into the interstitial fluid is considerable, amounting to more than the total protein of plasma each day. The rate of return of protein from interstitial fluid is very important in the maintenance of plasma protein levels. The lymphatic system plays a major role in this return (ch. 4).

The manner in which osmotic and hydrostatic pressures act in regulating the interchange of fluids between the tissues and the muscles may now be seen. The blood at the arterial end of a capillary has a pressure, let us say, of 30 mm Hg (this is an arbitrary figure and will vary according to the activity of the part). This is a force driving the water and the dissolved crystalloids through the capillary membrane. But the hydrostatic pressure of the tissue fluid on the outer side of the membrane offsets in part, that within. The pressure of fluid in the tissue spaces is difficult to determine but it is considerably less than that in the capillaries. It probably varies considerably in different regions, being low in those containing much loose areolar tissue. But for illustration let it be assumed to be 10 mm Hg. The hydrostatic pressure, therefore, which is effective in forcing fluid out of the vessel (filtration pressure) is only the difference between the pressure within and that on the outside of the vessel, namely, 20 mm Hg. But the osmotic pressures of the plasma and tissue fluids must be taken into account. In the plasma it amounts to about 25 mm Hg. The tissue fluids have a lower protein content and consequently a lower osmotic pressure. The latter amounts to about 15 mm Hg. Owing to this disparity of 10 mm Hg between the osmotic pressures of plasma and tissue fluid, there would be a net transference of water and diffusible substances inwards across the capillary membrane if such transference were unopposed by any other force. But a net hydrostatic pressure of 20 mm

FIG. 33 Illustrating the relation of hydrostatic and osmotic pressures in the regulation of the interchange of fluid between the vessels and the tissue spaces

Hg is set against it at the arterial end of the capillary leaving a balance amounting to 10 mm Hg which serves to filter water, salts, etc., and a little protein out of the plasma. Now as the blood flows rather slowly through the capillary and loses water in this way by filtration, the protein concentration, and consequently its osmotic activity, rises. Coincidentally with the progressive rise in osmotic activity the hydrostatic pressure declines, until at the venous end of the capillary there is a balance of net osmotic pressure over net hydrostatic pressure. Water accompanied by freely diffusible materials is therefore absorbed into the circulation. This picture of filtration at the arterial end of the capillary and absorption at the venous end is going on continually at the periphery of the vascular bed. But it is subject to considerable variation, not only in the same capillary from time to time but in different parts of the peripheral circulation at any moment (see fig. 33).

As the blood flows through the capillary, as a result of the passage of water outwards there is a consequent rise in the concentration of protein

Blood	Tissue fluid
Hydrostatic pressure 30 mm Hg	Hydrostatic pressure 10 mm Hg
Effective hydrostatic pressure 20 mm Hg	
Osmotic pressure 25 mm Hg	Osmotic pressure 15 mm Hg
Effective osmotic pressure 10 mm Hg	
Driving force $\rightarrow$ 10 mm Hg (20 - 10)	

changes whereby larger molecules are being broken down into smaller ones, other molecules are removed or built up into larger ones. In this way alterations in molecular concentrations and in the diffusibility of the constituents of the tissue fluids with consequent variations in osmotic relationships are occurring ceaselessly. The actual exchange of water across the capillary wall is rapid. Studies with deuterium and tritium labelled water indicate that in one minute an amount equal to the total plasma water is exchanged.

Under any circumstance in which the blood volume is increased or diminished either the hydrostatic pressure or the osmotic pressure or both are altered, and it is through such changes that the blood fluid is restored automatically to its previous level. After hemorrhage, for example, the hydrostatic pressure is lowered in the capillary area but the osmotic pressure is unchanged. Fluid will therefore be absorbed from the tissue spaces. Moreover, constriction of the capillaries tends to reduce, dilation to increase the capillary pressure. Therefore, the capillary constriction which follows a severe hemorrhage will slow the filtration rate at the arterial end of the capillary and increase absorption of interstitial fluid at the venous end. Again, when water is drawn from the blood, in consequence of excessive loss of fluid by the kidney, sweat glands or bowels, concentration of the plasma proteins will result. The increased osmotic pressure of the plasma will then hasten the rate of absorption from the tissues. The intravenous injection of large quantities of isotonic saline, on the other hand will have the twofold effect of diluting the colloids and temporarily increasing the hydrostatic pressure. The excess fluid in consequence is rapidly eliminated from the blood stream into the tissues and later through the kidney and bowels.

Alterations in Blood Volume

Many factors are concerned with the regulation of blood volume, the pressure of blood in the capillaries, the concentrations of poorly diffusible substances on the two sides of the capillary wall, the available capillary surface, the permeability of the capillaries and the total capacity of the vascular bed.

REDUCTION OF THE BLOOD VOLUME

This may result from

1. A loss of whole blood as in hemorrhage
2. Reduction in the total number of red cells, as a result of increased destruction or diminished production (see anemia ch. 9)

Metabolic processes in the tissues bring about

3 Loss of plasma alone from the vessels as in burns or shock from other causes (ch 28)

4 Loss of blood water This is called *anhydremia* and is simply a part of a general dehydration and so results from the same causes as the latter

In the reduction of blood volume resulting from hemorrhage, the concentration of the blood in cells and protein is lowered, since a watery fluid enters the vessels from the surrounding tissues

When the blood volume is lowered as a result of a loss of plasma, the red cell concentration is increased (hemoconcentration) but the protein of the plasma is little altered

In *anhydremia* both the protein concentration of the plasma and the red cell count are raised. The concentration of plasma protein may increase by 50 per cent or more. The viscosity of the blood is therefore raised, and it flows sluggishly from an opened vein. If the *anhydremia* persists, the red cell count and the protein concentration tend to fall again. Then an estimation of the blood concentration may fail to give a true index of the extent of the blood volume reduction

Acute exposure to cold causes a moderate loss of water from the blood to the tissues (chiefly skin muscle and probably liver), the total water content of the body remaining unaltered. It is not altogether clear by what means this movement of water is brought about. It is, however, an important factor in the regulation of body temperature (ch 52). The work of Barbour and others furnishes evidence of a nervous element in the mechanism. Animals in which the cord had been divided in the upper thoracic region when placed in a cold bath did not respond in the normal fashion. Concentration of the blood did not result and the temperature of the body fell to that of the environment. The control is exercised evidently through vasomotor nerves. More prolonged exposure to cold (6-12 weeks) increases blood volume in experimental animals

Posture The blood volume of the human subject after 30 minutes or so in the erect posture is some 15 per cent less than that in recumbency. A fluid of low protein concentration leaks from the vessels of the lower limbs into the extracapillary tissues, as a result apparently of the increased hydrostatic pressure in the capillaries of these parts

INCREASE IN BLOOD VOLUME

(1) *High temperatures* In hydrated subjects, exposure to a high temperature leads to an increase in blood volume. This increase reaches a maximum in about 7 days after which it may re-

turn toward normal. The extracellular fluid volume increases also, although initially the greater part of this increase is reflected in the elevated plasma volume. In the first few hours after exposure to heat the changes are slight and inconsistent

(2) *Muscular exercise* The effect of a bout of vigorous exercise in man is to decrease the plasma volume. The magnitude of this decrease may be exaggerated when measurements are made by the dye method because of a change in the optical properties of the plasma. However the protein concentration of the plasma, and the red cell count increase. The increase does not seem to be progressive. Some elevation in blood volume may occur with muscular training. This can be demonstrated in dogs but in men accustomed to hard physical work, the red cell volume in relation to height and weight is only slightly increased over that of sedentary individuals

(3) *Emotional excitement* in animals and in man causes an increase in blood volume

(4) *Pregnancy* In pregnant women the blood volume though somewhat variable increases on the average by 20 to 30 per cent, though in the last few weeks of pregnancy tends to fall again. There is an increase in plasma volume and in interstitial fluid. Associated with this is a retention of sodium. Restriction or the administration of salt reduces or increases respectively, the volume of extracellular fluid. The increase in plasma volume in pregnancy combined with a lower protein concentration of the plasma is responsible, in part at least, for the edema of the lower limbs which commonly occurs in the pregnant state

(5) *Congestive heart failure* As a result of the retention of sodium the extracellular fluid undergoes a pronounced increase

(6) *The administration of desoxycorticosterone* causes a retention of salt and, as a consequence, a rise in the volume of plasma and interstitial fluid. This depends on the salt load. Aldosterone is much more active than desoxycorticosterone in its effect on sodium retention. It helps to keep in equilibrium the fluid volume and sodium retained, fluid retention varying directly with that of sodium

SUMMARY OF THE PATHOLOGICAL STATES ASSOCIATED WITH ALTERATIONS IN BLOOD VOLUME

Reduction

(a) *Hemorrhage* (loss of whole blood), (b) *burns* (loss of plasma), (c) *dehydration* (loss of water),

(d) *pernicious anemia* (reduction in red cells, with a moderate increase in plasma), (e) *certain chronic anemias other than those of the pernicious type*. In these the total volume of red cells is only slightly or moderately reduced and this is to a large extent compensated for by an increase in plasma above the normal standard. The total blood volume is therefore, as a rule, not greatly below normal as calculated upon the basis of weight or of surface area. (f) *Obesity*. The blood volume per kilogram of body weight is much reduced but is normal when considered in relation to the body surface. (g) *Myxedema* (reduction of both red cells and plasma but mainly of the former).

Increase

(a) *Polycythemia vera* (increase mainly of red cells but also of plasma), (b) *cirrhosis of the liver* (increase of plasma), (c) *leukemia* (increase in white cells and plasma), (d) *splenomegaly with anemia—Banti's disease* (increase in plasma), (e) *hyperthyroidism* (equal increases both in red cells and plasma), (f) *congestive heart failure*.

It should be pointed out that the proportions of red cells and plasma may vary from the normal though the total blood volume remains unaltered. With regard to the blood volume and the proportion of cells to plasma there are therefore nine possible blood states. Rowntree has introduced the following descriptive terminology. A normal blood volume he terms *normovolemia*. If the ratio of cells to plasma is normal as well, he calls the condition *simple normovolemia*, but a decrease or increase in the number of cells in relation to plasma is termed *oligocythemic* or *polycythemic normovolemia* respectively. *Hypovolemia* and *hyperolemia* are corresponding terms for reduced and increased blood volumes, each of these is divisible into simple, polycythemic and oligocythemic forms (see fig. 34).

FIG. 34 The nine possible combinations of whole blood, plasma and red cell volumes (after Rowntree)

THE EFFECTS OF HEMORRHAGE

When more than 30 per cent of the blood volume is lost rapidly, the body is usually unable to repair the loss unaided and, unless transfusion is restored to, death results. In a healthy man the loss of 30 per cent or less of his blood cells readjusting mechanisms into play which may bring the blood volume back to the normal level within a remarkably short time, 500 cc or so of blood drawn for transfusion purposes are said to be replaced within an hour or so. The restoration of the blood to its previous concentration in erythrocytes, however, takes about 7 weeks on the average. This time may be shortened considerably by the administration of iron and a diet containing a liberal quantity of high quality protein. Fowler and Barer found in a study of 200 blood donors that, after the removal of 550 cc of blood, the average fall in hemoglobin was 2.3 grams per 100 cc. Regeneration of hemoglobin occurred at the rate of 0.049 gram per cent for men and 0.040 gram per cent for women per day.

The protective mechanisms which automatically come into action after hemorrhage are several and may be divided into two groups—*immediate or early* and *delayed*.

Immediate or Early Effects

If the loss of blood is large, especially if it is of sudden occurrence and from an artery, there is a prompt fall in blood pressure as a result simply of the reduction in circulating fluid. If not too great, the fall in pressure is salutary since it helps to prevent further bleeding. A moderate loss of blood 10 per cent of the total amount produces little or no drop in pressure. This is especially true if the blood is lost gradually and if it comes from a vein, i.e., beyond the peripheral resistance. Under these circumstances compensatory mechanisms easily maintain the pressure of blood at its normal height. Three main compensations relating to the vascular system occur: (a) reduction in the capacity of the vascular bed; (b) increased peripheral resistance; (c) fluid entry from the tissues. These will be dealt with later.

Clotting of the blood (ch. 12) which occurs within a few minutes serves to close the opening in the blood vessel. The blood tends to clot more rapidly than usual after a severe hemorrhage. The initial drop in pressure, when such occurs, aids the formation of the clot. Stanching of the bleeding is also furthered in the case of an artery by the retraction and contraction of the middle fibromuscular coat of the vessel, as well as by the

curling up and crenation of its endothelial lining. Platelets are deposited on the injured surfaces and agglutinate to form a plug or a base of attachment for the clot. Some disintegrate also and liberate a vasoconstrictor substance, serotonin, or 5-hydroxytryptamine which is a material aid in hemostasis (ch 12). These factors, together with the fall in blood pressure, may be sufficient to stanch the flow of blood from an artery as large even as the popliteal. Clot retraction, which also depends on platelets, leads to the formation of a firmer plug.

In small vessels the opposed endothelial surfaces become sticky and coherent.

Increase in the heart rate. This is almost invariably an accompaniment of a severe hemorrhage and is one of the most valuable signs of concealed, i.e., internal bleeding; this sign is not seen, as a rule, in moderate blood losses or in slow bleeding. It is brought about through carotid sinus and aortic reflexes (ch 21 and 32) initiated by the fall in blood pressure. Reduction in blood flow through the vessels of the medulla with the consequent anoxemia of the cardiac centers may be an additional factor. Adrenaline liberation (ch 58) may possibly play a part. Although the nature of the compensation provided by the increase in heart rate is not clear in view of the reduced venous return, it is possible that the increase in heart rate may lower the central venous pressure and hence improve the pressure gradient in the veins. This would improve venous return over what it would otherwise be.

Release of blood from blood reservoirs into the circulation. helps to restore the circulating blood volume. These reservoirs are skin, liver, lungs, spleen and the splanchnic venous vessels. The blood from the spleen is richer in cells than the circulating blood. Its reservoir function in some animals is great, but in man it is not of such importance.

Increased respiration. The anoxia of the chemoreceptors of the carotid and aortic bodies caused by the reduced blood flow is probably responsible for the increased rate and depth of breathing. When the blood loss is more profound, and consequently the oxygen want more urgent, long deeply drawn inspirations, and expirations of a sighing character ensue (air hunger), or periodic breathing of a Cheyne-Stokes type may develop (p. 500). Gasping respirations precede death.

Reduction in capacity of the vascular bed and redistribution of the blood. When the flow of blood has been stopped or considerably lessened by a complete or partial closure of the wound in the

vessel the blood pressure, if this had fallen, rises again. This is the result mainly of a readjustment of the capacity of the vascular system whereby it is made to conform more nearly to the lessened volume of blood. It is this reduction in the vascular capacity which prevents the initial fall in pressure when the loss of blood is gradual. It is effected by the reflex narrowing of innumerable small vessels (vasoconstriction) in regions such as the skin, mucous membranes, intestine and other parts not immediately essential to life. If the hemorrhage has not been too severe the reduction in the capacity of the vascular bed may result in maintenance of an adequate venous return and consequent maintenance of cardiac output and of arterial blood pressure. If the hemorrhage is somewhat greater, then the venous return and cardiac output may fall but the blood pressure may be maintained by an increase in peripheral resistance along with a reduction in the capacity of the arterial vessels. If the hemorrhage is still greater, then the arterial blood pressure will fall and may be restored by restoration of blood volume through the entrance of fluid into the blood vessels from the tissues. The vascular response is called into play by the underfilled state of the arteries and large veins feeding the heart (see vascular reflexes, chapter 21).

The vasoconstriction is not confined to the small arteries and arterioles but extends to arteries and veins (Heymans) and vasomotion of metarterioles (ch 15 and 26) and precapillary sphincters is enhanced. These latter vessels also show increased reactivity to mechanical stimulation and to adrenaline (Zweifach and associates). The level of adrenaline and probably also of noradrenaline in blood is increased following hemorrhage. This probably plays a part in the vasoconstriction. These measures whereby the blood remaining in the vascular system is confined to a smaller space are of the utmost importance; they enable the essential centers in the medulla to be supplied with blood under adequate pressure to sustain their vitality. Also a greater quantity of blood than would otherwise be possible is brought to the heart to supply its muscle, fill its cavities and maintain the circulation. The withdrawal of blood from the less important parts of the body is responsible, however, for some of the characteristic manifestations of hemorrhage, notably the pallor of the skin and mucous membranes, and the coldness of the body surface. The cerebral anoxia causes sensations of giddiness or faintness, flashes of light or ringing in the ears (tinnitus). The metabolic changes occurring as a

result of hemorrhage or fluid loss are anserobic in type and in the later stages, at all events, may be a consequence of reduced blood supply to tissues, although it is possible that other factors may be involved in the early changes. The rise in blood pressure at this stage is conducive to fresh bleeding. There is danger of the clot becoming dislodged.

In very severe hemorrhage, the hypernormal phase of capillary reactivity gives place to one of reduced capillary responses as the irreversible stage of hemorrhagic shock supervenes. The minute vessels tend toward dilation and become unresponsive, though the larger vessels still remain constricted.

Delayed Effects

Replacement of the lost fluid. This, it has already been mentioned, commences almost upon the instant that the blood is lost, but takes a variable length of time, depending upon the extent of the blood loss, to become complete. It occurs as a result of the low hydrostatic pressure within the capillaries. Fluid from the tissues moves into the vessels and dilutes the blood. The corpuscular concentration is therefore reduced and since fluid is entering the capillaries directly from the tissues and not by way of lymphatics, less protein is returned with the fluid from the tissues and for a short time after hemorrhage the protein content of the plasma is markedly depressed. Very soon, however, the concentration of protein in the plasma shows a rise again as a result of the mobilization of protein stores probably from the tissue stores. Calvin found, that in dogs 50 per cent of the plasma protein removed by bleeding was restored within 4 hours. The extreme thirst which the subject of acute hemorrhage suffers is the call of the tissues for fluid and indicates that their own stores are being drawn into the under-filled vessels. The administration of water will therefore aid the body in recovering its water balance and replenishing the blood volume.

Replacement of the blood cells finally occurs through the increased activity of the blood-forming organs. This takes several days or weeks, the rapidity of the process depending to a large extent upon the nutrition and recuperative power of the individual and upon the diet. While the repair process is in progress reticulated cells are found in increased numbers in the blood.

In summary, following hemorrhage, if the loss of blood is not great, the circulatory effects of a reduction in blood volume may be compensated by vasoconstriction with decrease in the capacity

of the vascular system. Thus the venous return, cardiac output and hence arterial blood pressure, may be maintained. If the loss is greater, the venous return and cardiac output may be reduced somewhat, but the arterial blood pressure may still be maintained by increasing the resistance to outflow from the arteries by vasoconstriction, especially of arterioles. If the loss is greater still, then the venous return and cardiac output will be reduced to such a degree that the increase in peripheral resistance may be insufficient to maintain the arterial blood pressure. The vascular compensations are brought about through reflexes initiated by the stimulation of stretch receptors in the blood vessels, principally in the carotid sinus and aortic arch, but possibly also in the great veins and right atrium. Further compensation comes as a consequence of arteriolar constriction and of increased vasomotion in the terminal vascular bed. As a result of arteriolar vasoconstriction, the blood pressure in the terminal vascular bed as a whole is reduced. As a result of increased vasomotion, the hydrostatic pressure in the true capillaries of the terminal vascular bed is reduced. With the fall in hydrostatic pressure in the capillary vessels, fluid entry into the capillaries from the interstitial spaces is increased and the blood volume tends to be restored. Since relatively less fluid reenters the circulation by way of lymphatics, the protein reentry will be less in relation to the fluid and the blood becomes more dilute. Protein is restored relatively quickly thereafter and a still slower restoration of red blood cells occurs.

THE LYMPH AND TISSUE FLUIDS

Structure of the Lymphatic System

The lymphatic system commences peripherally as a meshwork of delicate vessels (lymph capillaries) which drain the tissue spaces. This is a one-way system, the lymph within it moving toward the great veins. By the confluence of small vessels larger ones are formed which, receiving tributaries along their course, gradually swell in size, and finally form the right lymphatic and thoracic ducts. These pour their lymph into the blood stream by way of the right and left subclavian veins, respectively. The system is a closed one, its vessels possessing complete walls formed of endothelial cells. Small nodes (lymph nodes or glands) are interposed in the course of the larger lymph channels. These vessels, upon reaching the gland, break up into finer channels which, plunging into the node, open into the arnues of its cortex. After passing through the gland the lymph is collected again on the other side by fine vessels which soon re form into a few larger trunks. The glands are placed at strategic points along the lymph routes, e.g., the elbow and axilla, knee and groin in the case of the upper and lower limbs, and at points in the abdomen, thorax and neck where several lymph vessels join. Lymph vessels are situated in skin, in subcutaneous tissue, in the fascial planes of muscles, in the linings of the respiratory, gastrointestinal and genitourinary tracts, and in the capsule and septa of the liver. Those in the intestinal villi are known as *lactals*.

In the walls of the abdominal cavity the lymphatics are most abundant on the under surface of the diaphragm, where the greatest lymphatic absorption of colloidal material and minute particles takes place. The respiratory movements hasten absorption from the abdominal cavity, probably by varying rhythmically the intra-abdominal pressure. Absorption also takes place into lymphatics of the omentum. Phagocytes play an important role in absorption through both the diaphragm and omentum. Absorption through the parietal peritoneum is slight and is mainly through the blood capillaries, which absorb only

crystalloid solutions. The lymphatic system of the heart consists of intercommunicating plexuses lying beneath the epicardium and endocardium, and within the myocardium. Lymphatics are also present in the areolar tissue underlying the peritoneum and pleurae. They are absent from the central nervous system. In the lung the lymphatics extend no further than the respiratory bronchioles, the alveoli being devoid of lymph capillaries. Because of the poor lymphatic supply to the alveoli, or of its difficulty in penetrating the alveolar wall, protein is not readily absorbed from the interior of alveoli into the lung lymphatics. Water passes readily into the lung capillaries however because of the low pressure within them. The lymphatic system can be considered as taking some part in the regulation of the general circulation although this has not been worked out in detail. For example, if there is an increase in pressure in the pulmonary system there is also a greater pulmonary lymph flow. This fluid can move to a limited extent through lymphatic channels to the systemic circulation. Such a shift would tend to lessen the elevation in pulmonary pressure.

The skin is supplied richly with lymph capillaries. The lymph vessels in the deeper layers of the skin are so abundant, according to McMaster, that the skin cannot be punctured anywhere without tearing them, and since the flow of lymph along these vessels is relatively rapid foreign material injected into the skin soon reaches the regional lymph nodes. An injection into the skin is therefore, to a large extent, an injection into the lymphatic system. This is not true for all materials, but protein, so injected, is received by the blood mainly by way of the lymphatics. After destruction of the lymphatics from a region, subcutaneously injected protein does not appear in the blood for a long time and when it is detectable it is only in very small amounts.

The permeability of the lymph capillaries is increased by many agencies e.g., sunlight, warmth, and by mechanical or chemical stimula-

FIG 41 Diagram to indicate the relation of the lymphatic system to the circulatory system

tion histamine is particularly effective. Their walls may become so permeable that they can scarcely be considered as channels walled off from the surrounding tissue spaces.

Lymphatic tissue has a great capacity for regeneration and very active proliferation of lymphatics occurs in an inflamed region.

The Nodes as Defense Barriers

The lymph nodes must be looked upon as important structures for the defense of the blood against the invasion of bacteria or other injurious agents travelling by the lymph paths. When an infection of a part—a finger for instance—lying distal to a gland occurs, the latter becomes inflamed as a result of the localization therein of some of the bacteria or their toxins carried in the lymph. The gland swarms with motile cells (phagocytes) which attack and destroy the invading organisms. In this way a barrier is raised against the passage of deleterious agents, particularly bacteria, into the blood stream. In the case of the limbs at any rate it appears that no material can pass from the tissues to the blood stream via the lymph without filtering through the lymph nodes. The effectiveness of the nodes as filters has been clearly demonstrated by Drinker and his associates. The popliteal and iliac lymph nodes of dogs were perfused with solutions containing virulent streptococci (200 000 000 colonies per cc). After perfusion lasting for over an hour the fluid collected from the thoracic duct was found to be sterile. After the node itself has been attacked by the microorganisms it may then serve as a source from which the blood stream becomes infected. Though highly efficient as filters for bacteria the nodes appear to offer but slight hindrance to the

passage of viruses. There is evidence that the lymph nodes contribute towards the body's defense in another way, namely, by the production of antibodies.

Barnes and Trueta have shown that bacteria pass from the tissues to the blood solely by the lymph stream and that even toxins and venoms of large molecular weight (over 20 000) are not carried into the blood if the lymph vessels have been blocked. These observations in part explain the success which has followed the immobilization of infected parts in plaster; this procedure might be expected to reduce to a minimum the lymph flow from the inflamed region and thus to confine the infective process.

The Composition of Lymph

The lymph of the small peripheral lymph vessels and the fluid of the tissue spaces are closely similar in composition and both resemble the blood plasma. Drinker found that it varied under different conditions from 0.3 to 4.0 per cent in mammals. The higher figure, however, is unusual; concentrations between 0.5 and 0.7 per cent were found for human leg lymph.

Our views concerning tissue fluid, although largely conjectural and based chiefly on fluid exudates, are probably correct. The protein content of lymph is lower than that of plasma as lymph forms from tissue fluid. The total quantity of mobilizable protein in interstitial fluid about equals the entire protein of the plasma. The protein of lymph is derived from this mobilizable mass of tissue fluid protein which varies, of course, with the amount of protein leaking from the capillaries. Differences in the amount of protein and fluid leaving the circulation and in the amount of fluid reabsorbed by the capillaries as well as differences in the volume flow of lymph, will alter the protein content of the lymph. The amount of protein passing from the plasma into the tissue fluid is related to the surface area of the functioning capillaries and may not necessarily be ascribed to differences in the permeability of the capillaries. Electrophoresis shows the proteins of lymph to be qualitatively identical with the plasma proteins. The protein concentration in thoracic duct lymph, as a rule, is considerably higher than in peripheral lymph, but the lymph flow from the thoracic duct appears to be less than the total flow from several organs or regions. In hepatic lymph, the protein concentration, which is about $\frac{2}{3}$ the concentration in plasma, varies inversely with the lymph flow. This suggests

that the rates of exit and reabsorption in liver may be important in producing the relatively high concentration of protein in hepatic lymph. However, labelled albumin exchanges more rapidly between plasma and hepatic lymph than between plasma and intestinal lymph, and still more rapidly than with the lymph of skeletal muscle. Most of the normal components of liver lymph seem to come chiefly if not entirely from blood plasma, with the exception of glucose which is present in higher concentration in liver lymph than in blood plasma. In anaphylactic or peptone shock, heparin, released from the liver, passes into the blood mainly by way of lymph pathways. Lymph contains prothrombin (p. 110) and clots slowly. It contains large numbers of white cells, mostly lymphocytes, but relatively few red cells. The number of leucocytes varies from 1000 to 20,000 per cu. mm. in thoracic duct lymph of the dog and averages 550 per cu. mm. in peripheral lymph. In peripheral lymph there are from 300 to 13,000 erythrocytes per cu. mm. The lymph flowing from the thoracic duct since it comes largely from the intestine and liver, will vary in composition in accordance with the digestive processes. Its protein content is under ordinary circumstances from 2 to 4.5 per cent. Within 1 or 2 hours after a meal containing much fat the thoracic duct lymph appears milky. The lacteals and the fine lymphatics of the mesentery, being loaded with globules of absorbed fat, are seen as glistening white streaks. The fatty acid of thoracic duct lymph is increased by the ingestion of fat,

on a fat-free diet it is about the same as in the fasted animal.

The composition of plasma and peripheral lymph (i.e., lymph in the subcutaneous vessels of the limbs or neck) are compared in table 41.

It will be noted that calcium and total phosphorus, which are in part bound with protein, are in lower concentration than in plasma; the other constituents with the exception of protein and amino acids are in higher concentration.

The Formation, Pressure and Flow of Lymph

After what has been said with regard to the forces concerned in the regulation of the fluid interchange between the capillaries and the tissues little need be added in explanation of lymph formation. The two processes are interrelated and similar in nature. Any condition which increases the outpouring of fluid from the capillaries into the tissues will tend to increase the flow of lymph. The lymph capillaries are much more permeable than the blood capillaries and although the tissue spaces, i.e., the clefts between groups of tissue cells, are separated from the lymphatic system in an anatomical sense, the walls of the latter vessels are so permeable that they offer little impediment to the movement of either protein or crystalloids. It has been stated already that of the fluid which transudes from the blood at the arterial end of the capillary much of the water is reabsorbed at the venous end. The protein, however, passes into the lymph. The lymph capillary is therefore

the special channel whereby protein is returned (in a round about way) to the blood. It is also concerned with the absorption of other colloids, or of particulate matter which may be introduced into the tissue spaces. Although in mammals the extravascular circulation of the entire plasma albumin takes place in about 20 hours, in the frog, in which the blood capillaries are more permeable to protein than those of mammals, the entire protein of the plasma passes from the blood and back again to blood *via* the lymph system, some 50 times in 24 hours.

Under ordinary conditions the pressure of the thoracic duct lymph is very low but if the duct is obstructed in the dog, a pressure of 15 cm. of water develops. The rate of flow along the human thoracic duct (as measured in cases of duct fistulas) is from 1 to 1.5 cc. per minute. Cain and his associates found an average flow of 0.46 cc. per minute in the thoracic duct, of which more than half, about 0.26 cc., was contributed by the lymph vessels of the liver.

The pressures in the peripheral lymph vessels during rest run from 0 to 6 cm. of water according to different observers using various species of animals. In inflammatory states and during activity the pressure in the larger lymph vessels of the part rises considerably above the resting value. Also when a lymph vessel becomes obstructed, the pressure on the distal side (i.e., toward the finer vessels) of the obstruction increases, the vessel becomes distended on this side and collapsed on the proximal side. The lymph pressures decrease from the periphery toward the more central channels, and are higher on the distal side of a lymph node (mesenteric) than on the proximal side. In the lymph capillaries of the mouse ear pressures up to 27 cm. of water were found by McMaster, the latter figure exceeds that usually found by most observers in the larger lymph trunks of other animals.

Obilitation of the lumen of the finer lymph vessels by a high pressure in the tissues is provided against by the fastening of the walls of the vessels by fibrillae to the surrounding tissue cells. When edema fluid collects and the tissue pressure rises, the fine lymphatics do not collapse, but, on the contrary, their lumens become wider (McMaster).

The mechanism governing the passage of tissue fluid into the lymph vessels is obscure, although the action of the pulse in the blood vessels of the part appears to play a part. McMaster and his associates have demonstrated the importance of a pulsatile flow in the vessels of the perfused

rabbit's ear, in the spread of vital dyes through the tissues and in the formation and flow of lymph.

Enlarging the capillary surface by vasodilation, or increasing the number of patent capillaries increases the leakage of protein from the circulation. This happens when infusions of saline or dextran are given. The protein of tissue spaces is returned to the blood by the lymph. If the thoracic duct lymph does not reenter the circulation the plasma proteins may decrease by 15 to 30 per cent in 3 hours. It seems probable that the exit of protein from blood vessels and the efficiency of its return by lymphatics will be important factors in the regulation of fluid interchange modifying the balance of forces across the capillary wall.

Functions of the Lymphatic System

- 1 A primary function of the lymphatic system is to return protein to the blood from the tissue spaces.

- 2 The lymphatics have a role in the redistribution of fluid in the body, being capable of shifting fluid from one part of the circulatory system to another.

- 3 The lymphatics remove particulate matter, bacteria etc. from tissues.

- 4 The lymph flow helps in maintaining tissues. The ligation of lymph vessels in the heart may give rise to myocardial degeneration, in the kidneys it may accelerate the development of hydronephrosis when the ureters are tied, and in the liver it hastens the degenerative changes that follow bile duct ligation.

Conditions Which Increase the Lymph Flow

- 1 INCREASE IN CAPILLARY PRESSURE AS A RESULT OF VENOUS OBSTRUCTION. Landis and Gibbon found that in man filtration from the capillaries showed a definite increase when the venous pressure rose above 12 or 15 cm. of water. The rate of filtration from the capillaries was directly proportional to the increase in venous pressure (fig. 4.2). At a given venous pressure the filtration rate increased rapidly at first but gradually slowed and finally ceased. This falling off in the filtration rate is ascribed to the rise in extracapillary pressure, due to the fluid accumulation, which opposes the hydrostatic pressure within the capillary. The accumulation of extracellular fluid is therefore greater in regions which are loose in texture and where the skin is readily stretched. In persons with firm, resistant skin, edema, for the same reasons, is later in making its appearance.

FIG. 4.2 Showing rates of filtration produced during 30 minutes by venous pressures between 20 and 80 cm. water (after Landis and Gibbon)

and is less pronounced than in those with loose, flabby skins, as when weight has been lost rapidly.

Increased pressure in the veins of the portal area, as may be produced by obstructing the portal vein or the hepatic veins, causes increased filtration into the tissues of the abdominal viscera and a great increase in the volume of lymph flowing along the thoracic duct.

Increase in arterial pressure, on the other hand, does not increase filtration in animals until the pressure reaches around 300 mm. Hg.

2 INCREASE IN CAPILLARY SURFACE, i.e., increase in the filtering surface. This increases the leakage of protein and fluid. It is due to factors causing distension of the capillary vessels: (a) increase in capillary pressure, (b) increase in the local temperature, (c) infusion of fluid.

3 INCREASED PERMEABILITY OF THE CAPILLARIES. (a) A sufficient rise in temperature may increase capillary permeability.

(b) *Capillary poisons.* Peptone increases the flow of lymph from the thoracic duct probably as a result of its injurious effect upon the abdominal

capillaries. The increased flow occurs after removal of the liver so injury to the hepatic vessels is not essential. Other substances which increase lymph flow in this way are extracts of strawberries, crayfish, mussels, leeches, histamine and foreign proteins. To what extent this is due to a change in permeability and to what extent it is a consequence of capillary dilation is not known.

(c) *Reduced oxygen supply* to the tissues (oxygen want), increases lymph flow probably because of dilation of blood vessels but possibly also through damage to the capillary endothelium.

4 HYPERTONIC SOLUTIONS. The intravenous injection of a concentrated solution of glucose, sodium sulphate or sodium chloride causes an increased flow of lymph from the thoracic duct. These substances in concentrated solution though they permeate the capillary wall exert an osmotic effect until equilibrium between the extravascular and intravascular fluids is reestablished. Water enters from the tissue spaces particularly of the muscles and subcutaneous tissues of the limbs, which in consequence show a fall in volume, the brain shrinks. The removal of fluid may actually extend to the fluids within the cells which undergo shrinkage, and general desiccation of the tissues may result. The blood volume for the time is greatly augmented the excess fluid for the most part being accommodated in the capacious capillary and venous areas of the abdomen. The viscera—liver, kidneys, spleen and intestines—increase in volume, due to the distension of their vascular beds and a great outpouring of fluid as well as of protein occurs, which swells the volume of lymph in the thoracic duct. In this way these substances produce a redistribution of fluid.

The injection of isotonic saline will also increase the passage of protein and fluid from the capillaries and increase lymph flow. This too is probably a consequence of the distension of blood vessels. Protein is returned from the tissue fluid by the lymphatics. The concentration of protein in the returning lymph is higher than would be expected if the saline had caused dilution of the lymph. Sometimes the total plasma albumin actually increases. However if the infusion is large, the protein return is not as great as the protein leakage. So with larger infusions (greater than 2% plasma volume) the protein loss from the blood vessels to the interstitial spaces may be increased.

The effect which hypertonic solutions have upon the movement of tissue fluids had extensive appli-

edema during the first World War Sir A. E. Wright introduced the practice of packing wounds with salt crystals or irrigating them with a hypertonic salt solution. This causes an outward flow of lymph and tissue fluid, which results in the mechanical removal of the bacteria and their toxins from the tissues bordering the wound.

5 INCREASED FUNCTIONAL ACTIVITY When a gland or muscle enters into activity an increase in lymph flow occurs which starts a little after the commencement of the secretory or contractile response, but is nearly synchronous with the increased metabolism resulting from the activity. The increased flow is ascribed to (a) formation of metabolites which increase the osmotic effect of the tissue fluids and cause more fluid to leave the vessels (b) vasodilation, increased capillary pressure and increased fluid and protein leakage.

During rest the flow along the lymph vessels of the muscles and subcutaneous tissues is slight, and the protein content of the lymph is high. During activity the protein concentrations fall since less transuded water undergoes reabsorption into the blood and more is carried away by the lymph channels. This may occur even though the leakage of protein from the vessels is greater. The contracting muscles exert a pumping effect upon the lymph, driving it along the vessels. The rhythmical movements of the intestinal wall are thought to exert a similar effect in promoting the flow in the fine lymphatics of the submucosa. However, during fat absorption, lymph formation and its movement in the thoracic duct does not seem to be influenced by intestinal motility.

6 MASSAGE AND PASSIVE MOVEMENT act to a certain extent like muscular activity. They augment the blood flow, capillary pressure and capillary surface and so increase lymph formation. The manipulations and movements of the muscles serve to propel the lymph along the lymphatic channels.

Edema (See also p. 575)

Edema is the term applied to an excessive accumulation of fluids in the tissue spaces, and is due to a disturbance in the mechanisms of fluid interchange, which have been considered in the preceding pages.¹ Instead of there being a perfect balance struck between the inward and outward flow of fluid through the capillary membrane absorption is exceeded by transudation. The particular factor or factors of the mechanism that are disordered are not always clear, and a satisfactory explanation of all forms of edema cannot be given.

But from previous discussions it is evident that the following factors will tend to increase the volume of interstitial fluid: (a) reduction in the protein concentration of plasma. Edema commences when the albumin fraction has fallen to between 2.5 and 3 per cent, (b) a general or a local rise in capillary blood pressure, (c) increased permeability of the capillary membrane, (d) increase in the filtering surface as when the capillaries dilate, (e) obstruction of the lymph channels.

There is a tendency for the accumulation of edema fluid to progress so far and then become stationary provided the conditions producing it remain constant, for as we have seen, when the tissue fluid pressure reaches a critical level its opposition to the force driving fluid from the vessels prevents further transudation. It should be appreciated too that plasma, as a source of edema fluid, has definite limitations and unless the total extracellular fluid is increased, a generalized edema cannot be very severe.

Since edema is only a symptom of some primary condition it may have a variety of causes, according to the particular disease with which it is associated.

1 Cardiac edema In congestive heart failure there is both an increase in extracellular fluid and salt retention (ch. 25). It is clear that the volume of extracellular fluid can be reduced by restriction of the salt intake or by the administration of diuretics which remove both water and salt. Or it can be discharged by improving cardiac action, as by administering digitalis, lanatoside, or other suitable drug.

2 Mechanical obstruction of veins When the main veins leading from a part are obstructed by new growth, fibrous tissue, as in cirrhosis of the liver, thrombosis, etc., increased transudation of fluid occurs. This is due in part to the rise in intracapillary pressure and an increase in the filtering surface, but the permeability of the capillary wall may also be increased as a result of the impaired blood supply or, as in the case of new growth, probably by the production of toxic substances as well.

3 Edema due to renal disease In chronic nephritis edema is not usually pronounced unless the heart is failing, however, in the nephrotic syndrome it is an outstanding feature. In nephrosis a reduction in plasma protein as a consequence of the loss of protein in the urine leads to the passage of an abnormally large volume of fluid from the capillaries throughout the body. This in turn is probably responsible in some way

for renal retention of salt and as a consequence of this, retention of water

4 Inflammatory edema In this type several factors combine to produce the fluid infiltration of the tissues. Increased capillary pressure occurs, due to dilation of the vessels and local slowing of the blood stream as well as to thrombosis and obstruction of the returning veins. There is an increase in the filtering surface too and the lymphatics for a variable distance from the inflammatory area are obstructed as well. The capillary walls are also seriously damaged by the bacterial toxin or other injurious agent, so that a fluid with a high protein content escapes from the vessels. The edema is localized to an area of varying extent surrounding the injured site. Certain analgesics, e.g., aspirin, morphine and Demerol, tend to reduce the edema of simple inflammation.

5 Giant edema This is a localized noninflammatory edema which comes on with great rapidity and involves the loose areolar tissue in such regions as the hands, face, external genitalia or larynx. It occasionally runs in families. Little is known definitely regarding the mode of its production. A histamine-like substance liberated at the site of the edema is apparently the immediate cause. The remote exciting cause is frequently a foreign protein consumed in the diet which apparently gains access to the blood stream in a more or less unchanged state for the attack often follows a particular food to which the subject is susceptible, and is sometimes accompanied by gastrointestinal disturbances. The effects are therefore of an anaphylactoid nature and constitute one type of allergy. This type, also termed *angioneurotic edema*, is allied to the very localized edemas which constitute the condition known as urticaria and which as suggested by Lewis are caused by the liberation of a histamine-like substance in the skin.

6 Edema caused by malnutrition or by toxic substances Edema may occur in the anemias or in conditions in which the general nutrition of the body suffers. When the diet is deficient in vitamins or there is too little fat or protein in the diet edema may occur, as in beriberi, scurvy, "war edema" or in the faulty nutrition of infants. In animals edematous conditions have actually been induced by general underfeeding, or by a diet deficient in fat and soluble vitamins or by one deficient in protein alone. The factors responsible for the increased transudation in these cases are not always clear, but in others there is a marked lowering of plasma protein which alone is sufficient to account for the edema. In many instances, on the other hand, hypoproteinemia does not occur.

In such cases the lack of some essential amino acid may be the determining factor. A simple explanation has been offered by Henschel and his colleagues, namely, that owing to the loss of tissue on the famine diet the extracellular fluids (plasma and interstitial fluid) show an apparent increase, that is, though not showing an absolute increase, they are greater than normal in relation to body weight. Henschel and his colleagues in experiments upon a group of normal young men on a semi starvation diet found that although the absolute volume of extracellular fluid remained fairly constant at the value observed before the subjects were put upon the experimental diet, it increased gradually to about 40 per cent above normal when considered in relation to body weight, edema appeared when the relative increase in volume reached from 8 to 10 per cent above normal, which is approximately the same as the increase in volume of interstitial fluid at which other types of edema appear.¹ Increased capillary permeability due to impaired nutrition of the vascular walls was the main cause of the starvation edema in the Netherlands during the last war. In some cases of nutritional edema excretion of an antidiuretic substance has been reported.

Certain chemical substances such as arsenic, salts of heavy metals and the toxins of certain infectious diseases such as diphtheria, acute nephritis, etc., are known to act as capillary poisons and apparently cause edema in this way. An interesting type of a toxic edema is that which may be produced in animals by the injection of hemato porphyrin (ch. 6). This substance appears to sensitize the tissues towards light rays and the edema occurs only after exposure. Histamine causes local edema at the point of injection by inducing capillary dilation and increased permeability of the membrane.

¹ When the subcutaneous tissues are involved these appear swollen and leave the imprint of the thumb when it is pressed into the skin (pitting). Dropsy (hydrops) is an old fashioned term which is applied to edema as defined above or to a free collection of fluid within one of the body cavities, e.g., the thorax or the abdomen. *Hydrothorax* is also applied to the former of these conditions and *ascites* to the latter. *Anasarca* is a more or less generalized edema involving the subcutaneous tissues.

It is important to remember that the term edema applies to a gross collection of extravascular fluid. The bulk of tissue fluid fluctuates widely in health, and in pathological states may be very considerably increased before the increase is evident clinically. When for example, a normal person stands for a time the extravascular fluid of the legs increases, and the immersion of a limb in a hot bath hastens the rate at which fluid transudes from the vessels—the limb volume rises as a result, largely, of fluid accumulation in the tissues. Drury and Jones found that edema appeared when the increase in fluid increased the volume of the leg by 8 per cent.

7 *Edema due to lymphatic obstruction* Obstruction to the outflow of lymph from the tissue spaces may cause pronounced edema, even though the venous channels and the capillary vessels are unaffected. Edema of this nature is readily produced in frogs by compression of the lymph channels alone. It is more difficult to produce edema in this way in higher animals, but if the obstruction is complete edema occurs in them also. Edema of this nature is seen in infections with the filarial parasite which finds its way into the lymph vessels of the limbs and blocks their lumens with the production of the condition known as elephantiasis. The pleural cavities depend for the absorption of a fluid upon the lymph channels, and accumulations of fluid may occur here as a result of lymphatic obstruction. The edema associated with carcinoma is due chiefly to the filling of the lymphatic channels with cords of cancer cells as well as to venous obstruction caused by the pressure of the growth. The "milk leg" of the puerperium is in part due to lymphatic obstruction. The tissue fluid in these types of edema has a relatively high concentration of protein.

8 *Heat edema* The effect of heat upon capillary permeability has been mentioned (p. 33). Excessive heat may actually lead to edema in man. It occurs in the tropics and occasionally in so called temperate zones during an intense heat wave. In crease in blood volume, enlargement of the filtering surface as a result of the opening up of fresh capillaries and the rise in capillary pressure incident to the dilation of capillaries previously patent, are also factors in the production of this type of edema.

TRANSFUSION: THE BLOOD GROUPS

The materials employed for restoring the blood volume to normal are (a) whole blood, (b) plasma or serum, (c) solutions of colloids, e.g., gum acacia, isinglass, dextran, polyvinyl pyrrolidone, etc., (d) solutions of crystalloids, e.g., saline or glucose solutions

Whole Blood¹

Theoretically, whole human blood is, of course, the ideal transfusion fluid. The improvements and simplification of technique in recent years and the advance in knowledge of blood incompatibilities have made blood transfusion immeasurably safer and available under circumstances which hitherto would have been insuperable. It is used not only in cases of emergency such as severe hemorrhage or wound shock, but in several other conditions which are included in the following list:

Hemorrhage

Anemias especially, aplastic anemia and hemolytic disease of the newborn, agranulocytosis and hemorrhagic diseases e.g. hemophilia and purpura hemorrhagica

Shock (wounds, burns)

Malnutrition in infants, marasmus acute intoxications

Septic conditions, septicemias

The red cells of the transfused blood survive

¹ Within recent years stored blood (or plasma) is being used to an ever increasing extent. Blood collected from the dead has been employed in Russia, but cadaver blood for obvious reasons has not found general favor. Placental blood or blood removed by venesection from cases of congestive heart failure has also been used, but the blood of healthy donors is preferable. The blood is preserved at a temperature of around 1°C after dilution with a citrate dextrose mixture in the proportions of 5 parts of blood, 1 part of 3.2 per cent citrate solution and 6.5 parts of 5.4 per cent dextrose solution. Kept in this way blood remains suitable for transfusion for about twenty days. These so-called blood banks have the advantage that a quantity of blood already prepared for transfusion can be obtained at a moment's notice. But there is also the great disadvantage that any blood not used within the time limit must be discarded.

and carry out their functions for several weeks (around 80 days on the average) after their injection. For this reason whole blood is greatly superior to any other transfusion fluid in any condition in which the respiratory capacity of the blood has been greatly reduced, e.g., very severe hemorrhage or hemorrhage in an anemic person, CO poisoning, etc. It is also more effective in traumatic shock than plasma, serum or other blood substitutes. The use of blood as a transfusion fluid, nevertheless, is hedged about by hazards both to the recipient and to some extent to the donor. On this account it is the preferable procedure only when adequate facilities for guarding against these dangers are available, otherwise some blood substitute should be used. The safeguards which must be taken are:

1 The donor must be healthy in every way. Several cases have been reported of disease having been transmitted by transfused blood. Syphilis, malaria and acute diseases have been reported to have followed blood transfusion. In some instances the transmission in the transfused blood of a particular foreign protein of dietary origin, to which the recipient but not the donor is sensitive, has caused an allergic reaction.

A very serious hazard today is the transmission in the donor's blood of a dangerous type of infectious hepatitis. This disease, when contracted through blood transfusion, is called homologous serum jaundice or hepatitis. It closely resembles the agent, apparently a filtrable virus which is responsible for the infectious hepatitis, which is seen in both sporadic and epidemic forms.

2 Too rapid transfusion of blood is dangerous, especially in children or undersized persons, for the sudden increase in circulating fluid may cause serious embarrassment to the right side of the heart. In an adult, the usual transfusion rate is from 100 to 200 cc per hour, which causes little cardiovascular effect, even though the blood volume is considerably increased. At high rates of transfusion the venous pressure may rise unduly, the cardiac output may increase sharply, and an

excessive amount of work may be demanded from the heart. Rapid infusion of fluid into animals causes death from cardiac failure, preceded by an abnormal rise in venous pressure and pulmonary edema. The total quantity injected varies from about 500 to 1500 cc or more, according to circumstances and the size of the patient.

3 One of the unpleasant and disturbing but rarely dangerous effects of transfusion is the rise in temperature which follows a short time after injection, unless great precaution is exercised in preparing the blood and the necessary apparatus. This pyrogenic action which has been more prominent in infusions and materials other than whole blood is due to substances (*pyrogens*) of unknown but probably protein nature, formed in the distilled water used in the preparation of the blood substitute, in the material itself or contaminating the transfusion apparatus. These fever-producing substances are thought to be in most instances of bacterial or viral origin. Therefore, though every possible care has been taken in their preparation, all artificial transfusion materials must be submitted to a reliable test upon rabbits for pyrogenic action before they can be accepted for clinical use.

4 An ever present potential danger in the use of whole blood is incompatibility. The donor's blood must always be tested for its compatibility with the blood of the recipient. Normal plasma contains substances which have the power to cause the clumping together (agglutination) and subsequent disintegration (hemolysis) of the foreign corpuscles of another species. Agglutination also results when bloods of two persons belonging to certain blood groups are mixed. The bloods are then said to be incompatible and transfusion under such circumstances will lead to very serious if not fatal results.

The Blood Groups

In the early years of this century, Landsteiner and others found that the blood from different persons could be divided into four groups, which we now call groups A, B, AB and O. The basis for this terminology, and for part of the differentiation lies in the antigenic nature of the red cells of the donor. In the next few decades, other blood types were found, notably the M and N types. The discovery of the Rh factor late in the 1930s stimulated more interest in blood groups, and within the past few years many more have been found. The clinical importance of these varies greatly.

TABLE 51

Group	Cells Contain Isoagglutinogens	Serum Contains Isoagglutinins
O	O	α and β
A	A	β (anti B)
B	B	α (anti A)
AB	A and B	Neither

THE A-B-O GROUPS

Reactions. The presence of agglutinin* A on cells will cause them to react with certain serum agglutinins,² anti A or α , in such a fashion that relatively large numbers of these cells stick together, i.e., agglutinate. The nature of this reaction is similar to that between any antigen and its antibody. Similarly, cells with agglutinin B will react with anti B or β -agglutinins. Cells with both A and B agglutinogens will be agglutinated by either agglutinin; cells with neither A nor B (i.e., type O cells) will not be agglutinated by either agglutinin. The α - or β -agglutinins occur naturally in human serum and the mechanism of their production is unknown. In the serum of persons with cell type A β -agglutinins occur in the serum of persons of type B, there are α -agglutinins; type AB blood contains no agglutinins, and type O blood contains both agglutinins. The relationships are summarized in table 51. Obviously, if the serum from a person of type A is mixed with the cells of a person of type B agglutination will occur. If such a serum is added to type O cells, no agglutination will occur. Other reactions resulting from mixing cells and sera of other blood types are shown in table 5.2.

Determinations of Groups

By the use of two antisera, one containing only α -isoagglutinin, and the other containing only β -isoagglutinin, it is possible to determine to which of the four blood types a given sample of

* An agglutininogen may be defined as that part of the cell which is responsible for the reaction of the cell (i.e., agglutination with other similar cells) when it is placed in a medium containing specific antibodies directed against this agglutininogen. It is responsible for a specific antigenic action of the cell. Isoagglutinogens refer to those that react with antibodies derived from the same species as the agglutininogen.

² An agglutinin is a component of the blood serum which acts as an antibody, in that it can react with a specific part of a cell (i.e., the agglutininogen) to cause agglutination. Isoagglutinins are antibodies which react with agglutinogens from the same species as mentioned above.

— = No agglutination

blood belongs. The blood is diluted with physiological saline (0.9 per cent NaCl in water) to give about a 2 per cent suspension of red cells. A drop or two of this suspension is placed on a glass slide and mixed with one or two drops of anti A serum (containing α -agglutinin). Another sample of the cell suspension is mixed with anti B serum. Agglutination of the cells with the anti A serum only shows that the cells were of type A. If agglutination occurs with both antisera the cells must be of type AB and if agglutination does not occur with either antiserum the cells must be of type O. These reactions are illustrated in fig. 51.

TEST SERA

FIG. 51. Showing the effects of the sera of groups A and B upon the corpuscles of the several blood groups.

Agglutination usually occurs quite rapidly, especially if the slide has been warmed and is gently rocked to facilitate mixing of the cells and the antiserum. It is shown by the appearance of small clumps of cells easily distinguished with a low power microscope and usually readily visible to the unaided eye. If there is no agglutination there are no clumps formed, although there may be a tendency of the cells to move towards the center of the drop and to show up as a darker colored region of rather variable size and form in the drop. Microscopically, true clumps show up as dense, dark masses. Nonspecific congregation of the cells shows as a diffuse mass of cells without definite borders.

Suitable controls with cells of known type should always be included in any test. A failure to agglutinate may mean that a certain agglutinin is not present on the cell or it may mean that the testing serum has lost its potency through bacterial contamination, heating or other careless handling. Conversely agglutination may be seen in the absence of a specific agglutinin as a result of the production by bacterial contamination of substances which can cause the nonspecific agglutination of red cells.

Effects of Incompatible Transfusions

The reactions mentioned above it should be noted are those observed when serum and cells from different persons of the types indicated are allowed to react *in vitro*. When blood from one person is transfused into another the conditions under which the reactions take place are modified and there is therefore a possibility of a difference in the results.

If blood from a person of type A is transfused into a recipient who belongs to type B it can be readily seen that there are two possible ways by which there may be agglutination of the red cells. The β agglutinins of the donor might agglutinate the B cells of the recipient and the α -agglutinins of the recipient might agglutinate the A cells of the donor. In practice it seems that usually the isoeagglutinins of the donor do not agglutinate the cells of the recipient. This may be because the donor's isoeagglutinins are rather well diluted by the time they have mixed with the circulating blood of the recipient. There is some doubt as to whether this dilution effect is sufficient to account for the failure to react. On the other hand there is but little dilution if the isoeagglutinins by the (relatively) small amount of blood which is usually given in a single transfusion and they can readily react with the cells of the donor.

Since it is the donor's cells which are most likely to be agglutinated, it might be thought that such a reaction could be avoided by the use of type O blood. Cells of such a blood could not be agglutinated by any of the isoagglutinins, and the isoagglutinins present in the O blood might not affect the cells of the recipient, as mentioned above. The use of the term "universal donor" for type O blood has therefore come into being. Conversely, persons with type AB blood are sometimes called "universal recipients." The use of such terms is dangerous, however, and they should be discarded. Certain people of type O have a very high concentration of α or of β isoagglutinins, and even after the transfused blood is diluted in the recipient's blood stream, there may be a sufficiently high amount of α - or of β isoagglutinins to react with the recipient's cells. A second very important consideration is that such terminology fails to take into account the other blood types (see below).

If there is a transfusion of the wrong blood type (i.e., incompatible blood) a transfusion reaction may result. Symptoms vary in severity, and are probably a consequence of blockage of blood vessels by the agglutinated red cells. Such cells tend to be hemolyzed more readily than normal cells, and this hemolysis may contribute to such symptoms as severe lumbar pain, a sensation of burning of the face and tightness of the chest. There may be some degree of collapse, followed by a chill and a very rapid pulse. Hemoglobinuria and anuria sometimes occur. The renal insufficiency is thought by some to be due to a blockage of the kidney tubules with hematin, but others believe that it is caused by reduced blood flow through the glomeruli.

As a check against the possibility of transfusion of the wrong type of blood, the procedure known as "cross matching" is carried out. Cells and serum of the donor's blood and of the recipient's blood are separated, and then a suspension of the donor's cells is added to some of the recipient's serum, while another test is run in which the recipient's cells are mixed with some of the donor's serum. Both mixtures are checked to see if there has been any agglutination. Because it is most important to avoid any reaction leading to agglutination of the donor's cells, the test in which they are used is sometimes called the "major cross match." For reasons indicated above, reactions with the recipient's cells are possibly of lesser importance, so the second test is sometimes called the "minor cross match." The absence of agglutination in a simple cross matching test as

outlined should not be taken as a sufficient indication that a transfusion may be performed safely. Other blood types, especially the Rh type should also be considered, and ordinarily the simple cross match will give no indication of the possibility of trouble arising from the subgroups.

Subgroups The existence of subgroups of the A agglutinogens was recognized by von Dungern and Hertzfeld in 1911. They found that there were two distinct, but still related agglutinogens called A_1 and A_2 . This finding also indicated the existence of two types of AB cells, i.e., A_1B and A_2B . About 80 per cent of type A persons have cells of type A_1 , and these cells are usually agglutinated more strongly with a given anti-A serum than the A_2 cells which come from the remaining 20 per cent of persons in the category. Further subgroups A_3 and A_4 have been reported. The sera of persons of type A_1 or A_2B may in rare cases contain an anti- A_1 agglutinin or α_1 . Certain type O individuals also have anti- A_1 agglutinins in their sera. Rare sera from A_1 or A_2B individuals contain agglutinins (α) which react with A_2 blood. These α_2 agglutinins are not specific for A_2 , since they also react, even more intensely, with type O cells. Furthermore, they do not react regularly with A_2B cells. It has been suggested that the α_2 agglutinin is really an agglutinin directed against O cells, and that it reacts with A_2 cells only because they are mostly heterozygous type A_2O .

Inheritance of A-B-O Blood Groups

Early workers in the field felt that there were two genes which determined the inheritance of the A-B-O groups, and that group O was produced by a lack of either of the two groups. This theory was shown to be incorrect, and most workers now subscribe to Bernstein's triple allelomorph theory. This states that the inheritance of the main blood groups is by three pairs of allelomorphous genes, A, B and O, for which only one locus is provided on each chromosome of the chromosome pair. These genes cause the production of corresponding specific substances on the cell, but in practice it is sometimes easier to think of group O as representing simply the absence of A and B factors. With these three factors, it is easy to see that an individual's genetic constitution will fall into one of six categories, i.e., AA, AB, AO, BB, BO, OO. Types AA and AO will both be classified as type A, and similarly BB and BO will be classified as type B. Persons of type O must be homozygous, OO. Since each gene of the diploid pair is derived from one parent, it

TABLE 5 3

Parental Combinations	No. of Families	No. of Children in Each Blood Group			
		O	A	B	AB
O × O	1563	3772	(14)	(9)	0
O × A	2903	2707	3749	(10)	(1)
A × A	1385	556	2538	0	(2)
O × B	1456	1418	(7)	1831	(1)
B × B	554	203	(1)	1009	0
A × B	1400	605	957	771	818
O × AB	530	(8)	633	616	(3)
A × AB	455	0	533	247	312
B × AB	323	(2)	183	406	232
AB × AB	59	0	28	36	65

About 45 per cent of individuals from European stock belong to group O, about 42 per cent to group A, 10 per cent to group B and 3 per cent to group AB.

It is easy to construct a table to show the possible blood types of children from given parents. Table 5 3 shows the children from various parental combinations. There is an interesting side light to the figures which are in parentheses in this table. If one accepts the explanation that the figures which are in parentheses represent illegitimate children, and further, makes a statistical analysis of the percentage of "illegitimates" among the different blood groups, one finds that there is a higher percentage in B and AB, and a lower percentage in O, than the average. The more interesting conclusion is that B group might be associated with a greater than average degree of promiscuity. It is more likely (but less interesting) that the bracketed figures include not only illegitimates, but also a fair number of errors in blood typing, which just happened to come into the B and AB group.

Other Sources of Blood Group Substances

The agglutinogens of the erythrocytes may be looked upon as substances which are incorporated into the structure of the red cell membrane, whether or not they are isolated from the antigenic complex of which they may be a part. Certain other tissues of the body yield materials which show many of the reactions of the A and B agglutinogens. But whether they are identical atom for atom in a particular spatial arrangement cannot be stated, but certainly there must be a close similarity in their molecular architecture.

Witebsky, Landsteiner and others have found in gastric juice, saliva and other body fluids and organ extracts, materials that when added, e.g.,

to anti A sera will materially reduce the agglutinating power of that serum for A cells. Similarly, many of these materials, when injected, stimulate the production of specific antibodies. Materials from animals, such as hog gastric mucosa, have been found for A, B and some other substances. In recent years the discovery of new blood groups (see below) has been so rapid that it has not been possible to investigate thoroughly other tissues for the presence or absence of substances of a serological nature similar to those relating to the ABO groups.

These substances which have been studied show a low nitrogen content (compared to protein) and a relatively high concentration of reducing sugar and hexosamine. A considerable amount of work has been done in the isolation and purification and with respect to the chemical and physical characterization of some of these materials.

Preparations of these group specific substances are of great value when it is desired to reduce the titer or effective concentration of a certain antibody in a serum. If the appropriate substance is added (e.g., add A substance to neutralize α) to the serum it will combine with its specific antibody, and thus prevent this antibody from causing agglutination of erythrocytes.

Secretors. Studies on the amounts of blood group substances which can be recovered from body fluids have shown that although these substances are present in the fluids from most individuals, they are sometimes absent or present only in very small amounts. Persons whose saliva, gastric juice, etc. contains appreciable amounts of a specific substance are known as *secretors*, the others are *nonsecretors*. It is of interest to note that this characteristic bears a relationship to one of the newer blood factors. Secretors do not have the Lewis factor (Le^+), nonsecretors have this factor on their erythrocytes.

M, N and P factors. By injecting human red cells into rabbits, and carefully neutralizing or removing known antibodies from the rabbit antiserum thereby produced, Landsteiner and Levine were able to show the existence of a pair of antigens, M and N. With these two factors, cells may be classified as either M, N, or MN. These factors seem to be poor antigens, in that they do not stimulate the production of antibodies in human subjects. The occurrence of anti-M or anti-N in man is rare. A few years after the discovery of the M and N factors, Landsteiner and Levine reported yet another factor. Human red cells may

be characterized by the presence or absence of this factor which was designated P, but it is of little clinical importance

THE RH FACTOR

Between 1937 and 1940 Landsteiner and Wiener, working with the serum of guinea pigs that had been injected with the red cells of a Rhesus monkey, were able to show that the serum thus produced agglutinated the red cells of a large proportion of blood samples that were tested. Subsequent work showed that a new human blood factor, called the Rh (from Rhesus) factor was responsible for these reactions. About 85 per cent of Caucasians were found to have this factor on their cells, i.e., they are Rh positive. The remaining 15 per cent are Rh-negative. Later work demonstrated the existence of subgroups, which are discussed below.

In contrast to the α - and β isoagglutinins, which arise apparently without any antigenic stimulus that is definitely known, antibodies to the Rh factor arise only in consequence of the injection of an Rh antigen. In man, of course, it is only those who are Rh-negative who can develop anti Rh antibodies. Rh-positive cells given to a person who is already Rh positive would be perfectly compatible, and no antibodies would be developed. There are two ways in which this isoimmunization might take place. Firstly, there may be, in consequence of an error in blood typing, a transfusion of Rh positive cells into an Rh negative person. Ordinarily this would give no difficulty in the first transfusion, but in subsequent transfusions, after the antibodies had been built up by the recipient, a similar mistake might lead to complications. Secondly, there is a possibility of isoimmunization of the mother occurring during certain pregnancies and this gives rise to erythroblastosis fetalis.

ERYTHROBLASTOSIS FETALIS In erythroblastosis fetalis the child may be stillborn or may be delivered suffering from many of the symptoms of a transfusion reaction. Frequently symptoms do not appear until a few days after birth and may be mild. It had been thought for many years that erythroblastosis might be a result of an antigen-antibody reaction, and shortly after the discovery of the Rh factor it was shown that reactions involving this antigenic factor and an antibody were indeed the cause of many of these cases and of many hitherto unexplained transfusion reactions.

It is now thought that the sequence of events

leading up to erythroblastosis fetalis is much as follows. An Rh⁺ fetus is carried by an Rh⁻ mother (and the fetus could only be Rh⁺ under these circumstances if the father were Rh⁺) and in some unknown manner Rh⁺ fetal cells or fragments of such cells enter the maternal circulation and thus, acting as a typical antigen, stimulate antibody production. Probably only extremely small quantities of cells are required for this sensitization. The antibodies now move across the placental barrier into the fetal circulation, where they react with the fetal Rh⁺ cells to cause the observed reactions. Ordinarily, the first Rh⁺ child does not cause a sufficient rise in maternal antibody level to affect that particular child, but it may so sensitize the mother that in subsequent pregnancies, if there is an Rh⁺ fetus the antibody level developed may show an increase sufficient to injure the fetus. Several pregnancies may take place before a reaction develops. It should be noted that a transfusion, even years prior to a pregnancy, of Rh⁺ cells into an Rh⁻ woman, may severely reduce her chances of having a healthy child.

For poorly understood reasons, the incidence of erythroblastosis fetalis in cases where the mother is Rh⁻ and the child is Rh⁺ is considerably less than one would expect from the considerations just mentioned. The disease, obviously, is extremely rare where nearly all of the population is Rh⁺, i.e., in Orientals, Eskimos, American Indians, Negroes.

The treatment of erythroblastosis fetalis consists of slowly bleeding the affected infant, and at the same time replacing its blood with Rh⁻ blood. The cells in this blood cannot be agglutinated by any antibodies which are not removed by the exchange transfusion, so no transfusion reaction can occur. During the next several weeks, the transfused cells will gradually be removed from the circulation, to be replaced by the infant's own Rh⁺ cells.

Attempts to obtain a 'hapten' from Rh cells (i.e., a substance that will neutralize Rh antibodies without stimulating the production of antibodies) which could be transfused into the maternal circulation in order to reduce its titer, have not been successful.

Antibody Types

It has been found that there are different types of antibodies in anti Rh sera. Though they may all have the same specificity, they do not all agglutinate red cells under the same experimental

circumstances. One type of antibody will cause agglutination of Rh^+ cells when physiological saline is used as a diluent for the serum containing the antibodies. This type is sometimes called a complete antibody. Incomplete, or blocking antibodies, will cause agglutination of Rh^+ cells if the serum is diluted in some medium containing a high concentration of protein (20 per cent bovine serum albumin is commonly employed). Not only will they fail to agglutinate cells if the diluting medium is saline, but they will inhibit the agglutinating ability of a preparation of a complete antibody. Wiener suggests that the complete antibody is divalent, with two active, specific combining sites, and so can act as a coupling to unite the red cells, whereas the blocking antibody is monovalent, i.e., it has only one combining site. Thus one active site can combine with the antigenic sites on the red cell and so prevent the action of the complete antibody. In the presence of a high concentration of protein, another reaction allows the monovalent antibodies to be linked together, and hence agglutination may occur.

Still another type of antibody may not give agglutination in either saline medium or in a protein rich medium. The addition of an anti-human globulin (Coomb's serum) will provide antibodies which link, in turn, the antibodies which coat the red cell and thus agglutination may be brought about. It should be noted that the anti- Rh antibodies act as antibodies to the Rh^+ cells, but as an antigen in their reaction to the antiglobulin serum. Any or all of these types of antibodies may be the cause of a given case of erythroblastosis.

Nomenclature

The existence of a multitude of related subgroups of the Rh factor means that the nomenclature is complex. Two different terminologies, whose origins depend on slightly different concepts of the nature of the Rh antigens are in

general use, and this adds to the complexity. The reader is referred to the papers of Wiener and his coworkers for detailed discussion on the Rh nomenclature, and to the papers of Fisher and Race for discussion on the CDE nomenclature.

Wiener has classified the different Rh types according to their reactions with three different antisera. Table 5 4 shows these types and their reactions.

In recent years further subgroups have been discovered, and the so-called variants are detected by their reactions with particular antisera. A detailed discussion of them is beyond the scope of this book.

According to Fisher and Race, there are at least three types of antigens (and corresponding antibodies). These antigens are called C, D, E and their antibodies are anti-C, anti-D and anti-E. Factor C corresponds to Wiener's rh' , factor D to Rh_0 , factor E to rh'' . The antigenic structure of a particular cell is indicated by writing capital letters for those factors which are present, and using lower case letters for those factors which are absent, thus CDE corresponds to Wiener's Rh_0 or Rh' . A true Rh^- type would be shown as cde. It should be noted that the use of lower case letters implies not only the absence of one of the Rh factors but also the presence of a so-called reciprocal factor, the Hr factor. These will be discussed below.

Variants are indicated by superscripts added to the symbol of the antigen to which they seem to be most closely related, thus C^+ . There is evidence, too, that there is a fourth subgroup, F.

The subgroups are not of equal clinical importance. The strongest antigen seems to be the Rh_0 , or D type. Most Rh^+ cells are of the type Rh_0 , or CDE. Typing sera are frequently anti- Rh_0 , or anti-CD. It is important to note that an individual might have the rh'' , or E factor only, and so with such typing sera would appear to be an Rh^- person, though he or she would be, strictly speaking, Rh^+ . Such people should only be transfused with Rh^- blood, as transfusion with blood containing the Rh_0 (or D) factor might stimulate the formation of antibodies which could cause a severe transfusion reaction if a similar transfusion were made at a later date. On the other hand, such persons must be considered as Rh^+ , if they are to be donors. The presence of an antigen could stimulate the production of antibodies if this blood were transfused into a truly Rh^- person. Rh^- donors must be of the rh (cde) type.

TABLE 5 4

Cell Type	Antiserum			Cell Type	Antiserum		
	Rh_0	Rh	Rh''		Rh_0	Rh	Rh''
Rh_0	+	-	-	rh	-	-	-
Rh_1	+	+	-	rh'	-	+	-
Rh_2	+	-	+	rh''	-	-	+
Rh_3	+	+	+	rh_3	-	-	-

Inheritance of the Rh Factors

According to Fisher and Race, the various Rh factors are inherited as 3 (or 4, if F is included) linked genes. Since each germ cell carries its own set of Rh characteristics, the diploid genetic structure of the organism will be described by using one set of characters for the structure derived from one parent, and another set for the structure derived from the other parent. Thus the phenotype CDe would be derived from several genotype combinations, as CDe/CDe, CDe/cde, Cde/cDe, CDe/Cde, CDe/cDe.

According to Wiener, the factors are inherited as multiple allelic genes, and a person of phenotype Rh', or Rh, could have genotypes RhRh, RhRh', Rh.Rh'. The determination of the genetic structure of an individual requires the use of typing sera which will react with only one of the factors, as well as a study of the Rh types of siblings and immediate ancestors of the particular individual.

Deletions In some very rare cases, the red cells may react neither with an anti Rh serum of particular specificity nor with the antiserum directed against the reciprocal factor (see below). Race and his coworkers ascribe this to a chromosome deletion, and indicate such a phenotype thus —DE. Types having only the D antigen, and lacking both the c and e factor, have been described, i.e., —D—. Wiener suggests that individuals with such cells are homozygous for a new gene R₀, and that they have the factor Rh₀, but lack factors rh' and hr', rh'' and hr'' and br.

Other blood types With the discovery of the Rh blood groups, a great deal of interest in this whole field was reawakened. Many new blood groups have been recognized and although these are usually of little clinical importance, they may play a part in certain medico-legal questions, in some rare cases of erythroblastosis, and in some rare transfusion accidents.

Reciprocal groups In some cases, there seems to be a reciprocal relationship between two blood groups, i.e., the possession of a certain blood group implies the absence of another (reciprocal) group. An excellent example of two blood groups which bear such a relationship is found in the Rh family. The absence of a particular Rh factor implies the presence of a corresponding factor in the Hr family. If, for example, there is no rh' factor, then the hr' factor must be present or, according to Fisher and Race, the absence of C implies the presence of c. The absence of the rh''

(C) factor implies the presence of hr'' (e). Anti hr' and anti hr'' sera have been used to demonstrate the existence of such factors. One might expect that there would be an Hr₀ factor, as well as Hr factors corresponding to the Rh variants, but their existence has not yet been demonstrated. Wiener suggests that there is no necessity to postulate their existence.

A determination of the hr factors is of course necessary if it is to be determined whether a person is homozygous or heterozygous.

Other blood factors include the Kell and Cellano factors, which bear a reciprocal relationship, and the Duffy, Diego, Lewis, Lutheran and Kidd factors. Some "private" blood factors have a very high or very low incidence in the general population, and positive or negative reactions occur only in members of a particular family. Among such factors are the Levas, Graydon, Jobbins, Jay and Miltenburger.

Nonspecific agglutination Erythrocytes may also be agglutinated by substances other than the specific antibodies that have been discussed. These irregular agglutinins are of common occurrence in human sera. The so-called autoagglutinins will react with practically all human bloods to cause agglutination. Autoagglutination is characterized by a marked temperature sensitivity, and only occurs in the cold. If the system is warmed, the autoagglutinins will no longer cause clumping of the cells. An apparently related type of antibody also causes agglutination only in the cold, but will not affect all human cells. These are the cold agglutinins. Bacterial action will also give rise to nonspecific agglutination called panagglutination. This phenomenon is not seen in fresh blood, but if old or contaminated blood is used for testing, there is the possibility of obtaining a false positive test due to this process of panagglutination.

Human Serum and Plasma

Many of the drawbacks inherent in the use of whole blood for transfusion are obviated by substituting human serum or plasma. These blood derivatives when pooled from a number of donors can be transfused indiscriminately without regard for the blood groups. Furthermore, liquid plasma or serum if collected under strictly sterile conditions can be stored under refrigeration for an indefinite period. Plasma kept in the frozen state is highly recommended by Strumia and McGraw as being safer than storage in liquid form. Plasma or serum dried *in vacuo* from the frozen state (or

lyophilized) by the process of Floedorf, Stokes and Mudd is the preparation *par excellence*, especially for use in the armed services. It can be stored without refrigeration, is easily transported and the dangers of bacterial contamination or of deterioration are at a minimum. But like whole blood it may transmit the virus of homologous serum jaundice. When required for use, distilled water, equal in volume to that which had been removed in the drying process, is added to the desiccated material.

Solutions of Colloids

The limited availability of whole human blood or of its derivatives, plasma or serum, has inspired a search for a blood substitute which would resemble as closely as possible the physical properties of plasma. The requirements of an artificial transfusion material are several: (a) The molecules (or particles) of the substance must be of such a size that its solution will not leave the circulation too freely. (b) The solution must have an osmotic pressure and a viscosity approaching as closely as possible these properties of whole blood, such qualifications depend upon molecular size and shape. (c) It should be isotonic with the contents of the corpuscles. (d) It must, of course, be nontoxic and innocuous in every respect. (e) It should not hinder normal plasma protein production. In addition, the material should be readily available in large quantities, preferably cheap, capable of being sterilized by ample means, and of being quickly prepared for use. Provided a material is suitable for transfusion in the foregoing respects there appears to be no valid objection to the use of some fluid other than blood or its derivatives to fill the vessels after hemorrhage. The properties which render a fluid suitable for transfusion are physical rather than chemical. Serum or plasma apparently possesses no advantage by virtue of any biochemical characteristics which it possesses. Whole blood is superior to either of these in severe traumatic or hemorrhagic shock.

Gum acacia in a 6 per cent solution in saline was introduced by Sir William Bayliss as a transfusion fluid during the first World War and proved highly successful. The osmotic pressure and viscosity of this solution closely resemble those of plasma. The molecules of gum acacia aggregate into particles comparable in size to those of the plasma proteins and do not escape freely through the capillary membrane.

However, experience since the first World War has revealed some undesirable features of gum

acacia. Gum acacia is a polysaccharide which the body cannot metabolize. It, like other foreign materials which cannot be disposed of in other ways, is taken up by the reticuloendothelial elements of the liver and elsewhere. In animals, swelling and vacuolization of the hepatic cells have been observed following the transfusion of this material. The liver may become greatly enlarged after repeated transfusions with gum acacia and sometimes shows areas of necrosis. The hepatic function of producing plasma protein is seriously depressed, the concentration of protein in the plasma is lowered following large transfusions of gum acacia and may remain below normal for a considerable time after this blood substitute has been administered.

Isinglass (collagen prepared from the swimbladders of certain species of fish, e.g., sturgeon, hake, etc.) has been advocated by Taylor and Waters, in a concentration of 6 per cent in physiological saline, as a blood substitute. Isinglass as now prepared is free from anaphylactic or pyrogenic action. It has been used clinically and found to be effective and quite safe. It has been shown both in patients and in animals to raise the blood pressure to normal after severe hemorrhage and to maintain it at this level for several hours. After its injection the blood shows progressive dilution indicating that not only is it retained within the circulation but exerts an osmotic effect which "draws" interstitial fluid into the vessels. It does not appear to have any depressing effect upon plasma protein production by the liver and has a technical advantage over animal gelatin in being perfectly fluid at room temperature. The molecular weight of isinglass, after autoclaving, is between 18,000 and 30,000.

Animal gelatin, which is closely similar to isinglass chemically, or *dextran*, a polysaccharide with a large molecule, have been used clinically with satisfactory results. Polyvinyl pyrrolidone has also been used.

The albumin fraction of human serum as developed by Cohn, Janeway and their associates is, except for its cost, an ideal transfusion material when only a cell free fluid is required. It may be given in concentrated solution or in the same concentration as in normal plasma. *Bovine plasma*, if it could be rendered quite safe yet still retain its other qualifications for a transfusion material, would solve the problem of a physiological and relatively cheap blood substitute for those emergencies in which it is not necessary to furnish red cells. The blood proteins of another species are, of

course, intensely anaphylactogenic, and several attempts have been made to remove this property (despeccation) from bovine plasma or all human. Masson has described a method involving the use of formaldehyde and heat to despeciate calf plasma. But such procedures which denature the proteins tend at the same time to reduce their osmotic pressure to a degree which greatly lessens their value for transfusion.

Solutions of Crystalloids

The small molecules of salt or of glucose pass freely through the capillary wall. They exert a negligible osmotic effect, the injected fluid is therefore not retained in the circulation. For this reason such fluids though capable of raising the blood pressure temporarily are quite unable to maintain it for any considerable length of time. Indeed they may do serious harm, for the transfused fluid as it leaks into the tissues carries plasma protein with it. This is particularly likely to occur in the case of saline. Transudation of fluid into the tissue of the lung—pulmonary edema—may result. When, on the other hand, dehydration of the tissues and loss of blood water, as shown by the concentration of the plasma proteins, are prominent features, then the subcutaneous or intravenous injection of saline (with the addition of glucose) or water by mouth, would appear, from physiological principles, to be a logical procedure. In the dehydration resulting from chloride depletion (p 24) sodium chloride is clearly indicated. A solution of this salt serves not only to supply fluid but to replace the loss of the loss of which is such an important factor in the development of the dehydrated state. It is also of great value in correcting the hemoconcentration which results from extensive burns.

HEMOGLOBIN

See also Regeneration of Blood, chapter 8

Hemoglobin, the coloring matter of the erythrocytes, makes up about 95 per cent of the dry weight of the cell. The chief function of the red cell is to store this pigment and carry it around the circulation. About 10 grams of hemoglobin pass through the lungs per second. It takes up a comparatively large load of oxygen which it carries to the tissues. One hundred cubic centimeters of water at the temperature of the body and exposed to an oxygen pressure of 100 mm Hg absorbs a third of a cubic centimeter of the gas. One hundred cubic centimeters of blood, on the other hand, at the same temperature and pressure will take up about 20.0 cc—that is, 60 times more. The difference is due to the hemoglobin. The total amount of blood in the human body will hold approximately 1200 cc of oxygen (200 cc per liter of blood). This quantity of oxygen is used by the tissues in 5 minutes or so during rest and in a fraction of a minute during muscular exertion. In the absence of hemoglobin, the entire duty for the carriage of oxygen would have to be performed by the plasma, and in order that this should be able to absorb the necessary amount of gas, it would have to be increased at least 60 times in amount. As pointed out by Barcroft, the circulating fluid, instead of being about 6 liters or $\frac{1}{11}$ of the body weight, would then need to be over 350 liters i.e., more than five times the bulk of the solid tissues.

Besides serving as a carrier of oxygen hemoglobin plays an important role in regulating the acid base balance of the blood (ch 13), and in the carriage of carbon dioxide (ch 29).

The Chemical Constituents of Hemoglobin

Hemoglobin is a conjugated protein with a molecular weight of 68,000, it consists of an iron containing pigment portion combined with a colorless protein of the histone class called *globin*. The pigments belong to a group of compounds called *porphyrins* which possess the property of being able to combine with metals. *Heme* is the name given to the compound of iron and the par-

ticular porphyrin which is found in hemoglobin. The iron porphyrin-globin complex which constitutes hemoglobin can form a loose compound with oxygen, with the iron in the ferrous (Fe^{++}) state. Under certain conditions, it may form a more stable compound with oxygen, with the iron in the ferric (Fe^{+++}) state. A more detailed consideration of the hemoglobin structure follows.

Porphyryns are pigments which, either alone or as the basis of more complex compounds, are found throughout plant and animal life from the highest to the lowest forms. A porphyrin is the pigment basis of chlorophyll—the green coloring matter of plants. One is found as a brown pigment in the shells of many eggs, and also in the dark line running down the back of the earthworm. On the other hand, when conjugated with other substances porphyrins are the basis of the blood and tissue pigments of various animals.

The basic nucleus or framework upon which all porphyrins are built consists of four pyrrole rings

linked together in a larger ringlike structure by four methene couplings. This parent structure is called *porphin* and is shown below.

Porphin $\text{C}_{40}\text{H}_{36}\text{N}_4$

By substitution of its eight hydrogen atoms by various groups—ethyl, methyl, vinyl or propionyl

FIG 6 1

—the several porphyrins in nature are produced. In the animal body it is believed that synthesis occurs in two stages. First, substances composed of two pyrrole groups only are formed and known as *pyrromethenes*. These are of two kinds. In one form, A, in figure 6 1, the four hydrogen atoms are substituted by two methyl (CH_3) and two vinyl ($-CH=CH_2$) groups. In the other form, B, the hydrogen atoms are substituted by two methyl and two propionyl ($-CH_2-CH_2-COOH$) groups. When two pyrromethenes of the first type unite, a type I porphyrin is produced. When an A and a B form unite, type III porphyrin is formed.¹ Much smaller quantities of the type I pigment are produced in the body than of type III, but in health a constant ratio exists between the two. Type III porphyrin is the pigment of hemoglobin, myoglobin and certain respiratory enzymes. It is called *protoporphyrin* and is isomeric with *oocporphyrin*, the pale brown pigment in the eggshell of the domestic hen (see fig 6 1).

¹ A type II porphyrin might possibly be formed by the union of two B types of pyrromethenes but such has not been found in nature.

Protoporphyrins may be looked upon as pigment complexes in which the eight hydrogen atoms of the porphyrin nucleus are replaced by three of the groups mentioned above, namely by two vinyl, four methyl, and two propionyl. There are some 15 different isomeric protoporphyrins, the one present in hemoglobin being designated *protoporphyrin No 9*. Its vinyl groups are at positions 2 and 5, its methyl groups at 1, 3, 5 and 8, and its propionyl groups at 6 and 7.

Small amounts of free protoporphyrin are present in the erythrocytes and larger amounts in reticulocytes. The presence of this pigment is probably responsible for the red fluorescence exhibited by the latter when viewed under ultra-violet light.

The two animal porphyrins (I and III) remain distinct chemical entities under all circumstances, being synthesized separately and never undergoing interconversion. The conception of a "dualism of the porphyrins" was first advanced by Hans Fischer and has been supported in more modern times by Dobriner, Watson and other workers in this field.

In health, type I porphyrin and sometimes type III are excreted in minute amounts in the urine after being converted to *coproporphyrin* (p 58) Coproporphyrin I, but not type III, is excreted through the bile *Uroporphyrin* is not found in normal urine but is excreted in the urine in congenital porphyria

Metalloporphyrins Porphyrins are capable of forming compounds with various metals A pigment found in the feathers of a certain South African bird (turaco), for example, and known as *turacin*, is a porphyrin combined with copper Other metalloporphyrins have been prepared, namely, those of cobalt, nickel, silver, manganese, tin, zinc, etc ¹ Protoporphyrin combined with iron forms the metalloporphyrin of the blood pigment For instance, if an Fe atom is attached to protoporphyrin we get the iron porphyrin compound of hemoglobin This is called *heme* ($C_{54}H_{72}N_4O_4Fe$) The red heme molecules give to hemoglobin its characteristic color As we shall presently see, however, heme is not peculiar to hemoglobin but is a constituent of other respiratory substances

The atom of iron, in the ferrous state, is believed to be attached to the porphyrin group in the manner represented below

Reduced hemoglobin

Oxygenated hemoglobin (oxyhemoglobin)

In the hemoglobin molecule four heme molecules are attached to the globin molecule

¹ In chlorophyll the porphyrin is combined with magnesium

Heme is capable of combining with various proteins or nitrogenous substances, e.g., albumin, ammonia, pyridine, nicotine, etc Such compounds are called *hemochromogens* When globin is the protein with which heme is combined the resulting hemochromogen is that forming the basis of the blood pigment of vertebrate life Hemoglobin is, therefore, an iron + porphyrin + globin compound

HEMIN ($C_{54}H_{72}N_4O_4FeCl$) is the hydrochloride of heme and is prepared by heating oxyhemoglobin with glacial acetic acid and a minimal amount of sodium chloride Upon cooling, reddish brown prismatic crystals of hemin separate out The detection of these, which are frequently referred to as *Teichmann's crystals* (after their discoverer), is used as a test for blood in suspected stains When hemin is treated with caustic soda oxidized heme is obtained When the latter is treated with a weak acid the iron is split off and protoporphyrin remains Hemin or blood itself when treated with concentrated mineral acids in the presence of oxygen yields hematoporphyrin (p 58)

The Distribution of Heme in Nature

Heme is almost universally distributed throughout the animal and vegetable kingdoms Respiratory pigments with this porphyrin iron compound as their common basis are found in the lowest forms of plant life as well as in the highest species of animals

CYTOCHROME is a heme compound which is widely distributed in the tissues of plants and animals It is present in certain aerobic bacteria, in yeast cells, in the onion, in worms, molluscs, crustacea, in the muscles of the bee's wing and in many other insects and their larvae It is present in the muscles and other tissues of the large number of vertebrate species which have been examined Cytochrome plays an important part in the oxidation system in the tissues It undergoes alternate oxidation and reduction but unlike hemoglobin is not autooxidizable or only slightly so (due to component b, see below) In order to take up oxygen it requires the aid of tissue oxidase (indophenol oxidase), in order to undergo reduction it requires the presence of dehydrogenases These activate the hydrogen of organic molecules in the tissue cells which become hydrogen donors The cytochrome acts as a hydrogen acceptor In this way cytochrome, it is suggested, serves as an intermediary in the transference of oxygen (liberated from hemoglobin) to the oxidizable ma-

terials in the tissue cells. It may also through component *b* serve for the direct transference of oxygen. In the presence of cyanides, carbon monoxide (in the dark) or sulfides which poison the oxidase, the oxidation of cytochrome is inhibited. On the other hand, anesthetics which depress the action of dehydrogenases prevent its reduction. In either case the link in the chain of oxygen usage by the cells is broken.

Cytochrome is a mixture of three hemochromogens, they are referred to by Keilin as *a*, *b* and *c*. Of these only *b* is autooxidizable. The heme components of the hemochromogens are not all the same, there being two varieties. One of these is identical with that in hemoglobin, the other resembles that in chlorocruorin (see below). The nitrogenous compounds with which the hemes are combined are unknown. Cytochrome is identified in living tissues by its characteristic absorption spectrum. The cytochrome of bee wing muscle shows four absorption bands at 6016, 5665, 5502 and 5210 Å, respectively. Its oxidation and reduction can be followed in the living cell by means of the microspectroscope, the bands becoming distinct when reduction occurs but almost disappearing when the substance is oxidized.

Heme in the free state, that is, uncombined with a nitrogen compound, has been discovered in many substances such as wheat flour and oatmeal where its presence had never been suspected. The fact that heme is in one way or another of such universal occurrence has prompted Buerkert to remark, "mankind has for countless centuries been eating, all unknowingly, the outstanding constituent of his blood." It has been frequently suggested in the past that chlorophyll which also is constituted of pyrrol rings, was the primitive pigment and that animals probably derived the pyrrol grouping for the manufacture of the pigment of their bloods from this green coloring matter in their diet. It is now seen, however, that heme is a much more ancient pigment since it is found in the most elemental forms of plant life in which chlorophyll does not exist. It is pointed out, however, on page 71, that there is little evidence that either of these pigments in the diet serves as a basis for hemoglobin synthesis.

Hemoglobin itself is by no means so widely distributed as is heme and the heme compound cytochrome, for it is confined to the animal kingdom. It is found in the blood of all vertebrates and of several invertebrates, e.g., worms, a certain snail, in the larvae of some but not in the body fluids of any adult insect. The blood pigments of different vertebrate species vary in their proper-

ties, the hemoglobin of the frog, for example, possesses a spectrum and oxygen dissociation curve different from that of mammals. The variability is due to minor differences in the globins to which the heme is joined and not to different hemes, which are the same throughout the vertebrate phylum.

Though many different porphyrins exist, only one differing from protoporphyrin has been discovered in nature as forming part of a hemoglobin-like substance i.e. one in which the nitrogenous fraction is probably a globin. A hemoglobinlike pigment greenish in color, is found in certain worms and is called *chlorocruorin*. It contains this other porphyrin of unknown structure combined with iron. *Helicorubin* is a respiratory pigment found in the gut and liver of the snail. It contains the same heme as hemoglobin as shown by the fact that if its nonpigmented fraction is replaced by pyridine the pyridine hemochromogen so formed shows a spectrum identical with that of the pyridine hemochromogen derived from hemoglobin. *Chlorocruorin*, however, since its heme is different when treated similarly shows a different spectrum. The nitrogenous part of *helicorubin* is unknown but presumably it is not globin.

Hemocyanin is a respiratory pigment which in certain crustacea and mollusks (king crab, octopus and snail) takes the place of hemoglobin. It is dissolved in the circulating fluid and not confined within cells. This substance contains copper instead of iron but the metal is not combined with a porphyrin as was believed at one time. This pigment is blue when oxidized and colorless when reduced.

The Molecular Weight of Hemoglobin

The pigment proper (heme) constitutes about 4 per cent, and the globin about 96 per cent of the hemoglobin molecule. If hemoglobin contained only 1 atom of iron which has a molecular weight of 56, then since the percentage of the metal in hemoglobin is 0.334,³ as determined by direct analyses, the minimum molecular weight of hemoglobin would be $(56/0.334) \times 100 = 16,800$ approximately.

The molecular weight of the hemoglobin molecule has been established by various physical

³ This is Hufner's figure, but other investigators have obtained lower, others higher values, namely from 0.305 to 0.338 per cent. The average of values obtained by Bernhart and Skeggs in a number of analyses of hemoglobin crystallized from the pooled blood of 20 human subjects was 0.340. Using this figure in the calculations, a minimal molecular weight of 16,400 and an oxygen capacity of 1.36 ml. per gram of hemoglobin are obtained.

methods to be 66,000 to 68,000. There are 4 subunits, each containing one heme molecule, and hence there are four iron atoms in each hemoglobin molecule. Evidence suggests that the molecule is a cylinder with a height of 34 Å and a diameter of 57 Å. On the surface of one side of the cylinder there are two hemes, and two hemes are on the opposite side (not the ends) of the cylinder.

Hemoglobin constitutes about 34 per cent of the wet weight of the cell, and at this high concentration there is just sufficient space for the hemoglobin molecules to rotate freely about their three axes.

Human blood contains about 15 grams (14 to 16 grams) of hemoglobin per 100 cc. Since the proportion of iron in hemoglobin is 0.334 per cent, the quantity of the metal in 100 cc. of blood is about 50 mg. and in the total blood of the human body about 4 to 5 grams. The blood contains a small proportion of iron in addition to that combined with hemoglobin.

THE ESTIMATION OF HEMOGLOBIN IN BLOOD
Several methods are available for determining the hemoglobin concentration of blood. But whatever the method used the fundamental information sought is the oxygen capacity of the blood. This may be found directly by means of the Van Slyke apparatus or the apparatus of Barcroft or Warburg. Or, since the hemoglobin molecule contains 0.334 per cent of iron, the hemoglobin in grams per 100 cc. can be calculated from an analysis of the blood for its iron content. Thus, if the blood contains 50 mg. of iron per 100 cc., its hemoglobin concentration is $(50/0.334) \times 100 = 15$ grams (approx.) per 100 cc. and the oxygen capacity $(15 \times 1.34 =) 20$ cc. (approx.) per 100 cc.

The most convenient method for chemical use is one based upon matching a sample of diluted blood with one of a series of permanent color standards. The best known methods of this type are the *Haldane Gowers*, in which the hemoglobin is first converted to carboxyhemoglobin, the *Gowers*, in which the blood sample after dilution and full oxygenation is matched colorimetrically with a picocarmine standard, and the *Sahli* method which involves the conversion of the hemoglobin in the diluted sample to acid hematin.

Myoglobin or *muscle hemoglobin* (mol. wt. 16,700, 1 atom of iron) the pigment of muscle, resembles blood hemoglobin in its function. The protein component differs from that globin which

is found in hemoglobin. It acts as an oxygen reservoir within the muscle fiber which serves to tide the muscle over from one contraction to the next. It has a higher oxygen affinity than has blood hemoglobin and can combine with oxygen and dissociate from it with great rapidity (less than 1/100 second). Myoglobin starts to give up its oxygen at the instant that the muscle contracts. Its oxygen store is replenished during the resting state.

The Combination of Hemoglobin with Gases

OXYGEN (see also chapter 20)

Hemoglobin combines with oxygen by virtue of the iron which it contains. The attachment of the iron to the heme and to the protein molecule is very important in giving to the hemoglobin molecule its peculiar property of ready combination or dissociation with the oxygen molecule.

The iron in hemoglobin is in the ferrous (divalent) state. Heme, by itself, readily reacts with oxygen and the iron changes to the ferric (trivalent) state. The combination of the heme with globin however, brings about a great stabilization of the molecule so this increase in valence does not ordinarily take place, even though there may be a combination with oxygen.

The iron is in a hexacovalent state, with four of the bonds linking it with the planar porphyrin molecule. The resulting heme molecules (4 in number) are attached to the surface of the globin molecule by another of the covalent links of the iron. The nature of the group in the globin molecule to which the heme is attached is not yet settled, though Wyman, and Coryell and Pauling postulate that it is attached to the imidazole group of a histidine residue. The sixth covalent bond, which sticks out from the plane of the heme, is the point of attachment of the molecular oxygen. The details of the changes which take place in the various bonds upon oxygenation of the hemoglobin molecule are beyond the scope of this book, but it is interesting to note that the postulated linkage of iron with the imidazole group can be shown to provide an explanation for the 'Bohr' effect, i.e., the greater acidity of hemoglobin with oxygenation.

Since each hemoglobin molecule contains four iron atoms, it can combine with four molecules of oxygen. The oxygenation of one of the four hemes enhances the oxygen-binding capacity of the now partly oxidized molecule, so that this molecule becomes fully oxygenated in preference to other

* The estimation of hemoglobin by iron analysis is claimed by King and his associates to be the most reliable method, though even this method is not without error, for a certain small proportion of the iron in blood is not in combination with functioning hemoglobin.

hemoglobin molecules. This interaction, i.e., the effect of the oxygenation of one heme upon the ease of oxygenation of the other hemes results in a peculiar sigmoid-shaped curve if the percentage of oxyhemoglobin formed from reduced hemoglobin is plotted against oxygen tension. If there were no interaction, such as in the case of the monomeric myoglobin, a similar plot would yield a curve in the form of a rectangular hyperbola.

The increased acidity of oxyhemoglobin (Bohr effect, above) means that the pH of arterial blood is almost the same as that of venous blood. The greater acidity of this oxyhemoglobin compensates for the increase in carbonic acid found in venous blood.

The capacity of the blood for absorbing oxygen is called the *oxygen capacity* and it is proportional to the hemoglobin concentration. The oxygen capacity of 1 gram of hemoglobin is 1.31 cc., therefore, the oxygen capacity of 100 cc. of normal blood (15 grams hemoglobin) is 20 cc. (15×1.34).

DENATURATES OF HEMOGLOBIN

Some of the variations of the hemoglobin molecule which may be obtained are described below.

The terms *reduced hemoglobin* or *ferrohemoglobin*, are used for the molecule which has given up its oxygen.

Oxygenated hemoglobin or *oxyhemoglobin* is applied to the molecule which has oxygen molecules attached.

Methemoglobin, or *ferrihemoglobin* results when by the action of oxidizing agents the ferrous iron in the heme is changed to ferric iron. Normal blood contains about 0.1 per cent ferrihemoglobin, but in poisoning by drugs such as nitrites, chlorates, sulfanilamides etc. the percentage is increased. The larger quantity of the more darkly-colored ferrihemoglobin gives rise to a type of cyanosis to which the term *toxic* is applied. The discoloration of the skin becomes apparent when the ferrihemoglobin amounts to about 3 grams per 100 cc. of blood. Methylene blue, injected into the blood stream causes the formation of ferrohemoglobin.

Space and label methemoglobin

A *hemochromogen* of hemoglobin results if the heme with the ferrous iron is combined with a denatured globin.

Cathemoglobin is a compound of heme containing ferric iron with denatured globin.

HYDROGEN SULFIDE

Sulfhemoglobin is formed when ferrohemoglobin is treated with hydrogen sulfide under suitable conditions. It is a green compound and is formed when blood or hemoglobin undergoes putrefaction.

Except perhaps in extreme cases of intestinal putrefaction hydrogen sulfide is not absorbed in appreciable amount. But it appears that certain drugs, notably acetanilid and phenacetin (drugs employed for the relief of headache), sensitize hemoglobin so that it combines more readily with hydrogen sulfide. Small quantities of the gas absorbed from the alimentary canal may then cause sulfhemoglobin to reach a relatively high concentration in the circulation and give a bluish or mauve tint to the skin. This so-called *enterogenous cyanosis* occurs when the abnormal compound amounts to from 3 to 5 grams per 100 cc. of blood. The presence in the blood of sulfhemoglobin or of methemoglobin is detected by spectroscopic examination (Table 6.1).

CARBON DIOXIDE

Carbhemoglobin is formed from the union of carbon dioxide and hemoglobin. Apparently a carbamino compound is formed. Estimates of the amount of carbon dioxide which is carried in this way vary from 10 to 30 per cent of the total.

TABLE 6.1

Wave lengths (λ) at the points of maximum intensity of absorption bands of hemoglobin and its derivatives as well as some of the other heme compounds

Compound	Number of Bands	Station of Absorption Bands Wave Lengths in Angstrom Units			
Oxyhemoglobin	2	5760	5448	—	—
Reduced hemoglobin	1	5650	—	—	—
Carboxyhemoglobin	2	5709	5350	—	—
Methemoglobin	4	6300	5780	5400	5000
Sulfhemoglobin	3	6180	5780	5400	—
Hemochromogen	2	5585	5275	—	—

Protoporphyrin (in acid)	2	6000	5540	—	—
Urobilin	1	4900	—	—	—

CARBON MONOXIDE

Carbonmonoxyhemoglobin results from the union of carbon monoxide and hemoglobin. The gas unites with hemoglobin in the same proportion as does oxygen. It competes successfully with the latter for hemoglobin and displaces it volume for volume to form carbonmonoxyhemoglobin. Unlike oxygen, however, it forms with hemoglobin a stable compound which can be disrupted only with the greatest difficulty. The much greater avidity (between 200 and 250 times) which hemoglobin shows for CO renders the gas so highly dangerous when inhaled in any considerable quantity (see p. 523). Nitric oxide gas also has a strong affinity for hemoglobin and forms a stable compound with it. The fumes given off by high explosives during their combustion contain large amounts of nitric oxide and the commonest way in which this poisoning occurs is through persons entering a closed space after an explosion, before the gas has cleared away.

Types of Hemoglobins

There are small but significant variations in the amino acid composition of hemoglobins of different species. Further, there are different types of human hemoglobins. The various hemoglobins show different rates of denaturation, different electrophoretic mobilities, etc., in addition to those differences just mentioned.

The hemoglobins of adult and of fetal humans have been designated hemoglobin A and hemoglobin F respectively. Several other abnormal varieties have been found in recent years. In all of the cases studied so far, the differences are ascribable to inherited alterations in the globin portion. The heme portion remains unchanged.

Pigments Derived from Animal Porphyrins

Hematoporphyrin $C_{54}H_{54}O_8N_4(COOH)_4$ is an artificial derivative obtained by the action of strong mineral acids upon hemoglobin or upon hemin. It is closely related to protoporphyrin—the natural porphyrin of hemoglobin—but contains two more molecules of water in its vinyl groups.

Coproporphyrins and uroporphyrins. Coproporphyrins I and III can be obtained from the corresponding porphyrins (p. 53) by the replacement of two vinyl groups by propionyl groups or by decarboxylation of uroporphyrin. Uroporphyrins I and III are formed by carboxylation of the methyl groups of the corresponding coproporphyrins. Coproporphyrin I is present in small amounts in normal urine and in larger amounts in the feces. Relatively enormous amounts of both types of

coproporphyrin and of uroporphyrin are found in the urine and feces in conditions of disordered porphyrin metabolism (see below). Coproporphyrin (chiefly type III) is present normally in the bone marrow and the erythrocytes; it may be a precursor of protoporphyrin and a step in hemo-

Coproporphyrin I $C_{54}H_{54}O_8N_4(COOH)_4$ 

Uroporphyrin I

globin synthesis (ch. 8). Turacin mentioned on p. 54 is the copper salt of uroporphyrin III. Porphyrins, especially hematoporphyrin, uroporphyrin I and coproporphyrin I have the curious property, when injected into the blood stream or when produced in disease of sensitizing the skin to sun light. Of the naturally occurring porphyrins the light sensitizing action is most pronounced with uroporphyrin I.

By the action of mild reducing agents the vinyl groups of protoporphyrin are replaced by ethyl groups to form *mesoporphyrin*.

Bilirubin, $C_{55}H_{78}N_4O_6$ is an iron free and globin free derivative of hemoglobin. The ring struc-

Table of hemoglobin derivatives

ture of the porphyrin is broken at the alpha position, a straight chain compound resulting. This occurs before the iron and globin are split off so that no free protoporphyrin is produced normally in the circulation. Bilirubin is converted by reduction in the intestine to stercobilinogen, also called urobilinogen (p 642). Urobilin is formed by the oxidation of stercobilinogen, and is present in very small quantities in normal urine, but is not the pigment responsible for the color of urine.

Absorption spectra The various heme pigments and the compounds of hemoglobin when placed in the path of a beam of white light absorb waves of certain lengths but transmit the rest. That is, each possesses a characteristic absorption spectrum and it is by means of spectroscopy that they may be most readily detected. The different hemoglobins, reduced hemoglobin and oxyhemoglobin, CO and NO hemoglobins, hematomporphyrin, coproporphyrin, cytochrome, urobilin etc. have all their specific absorption bands. See table 6 1.

Porphyria Disorders of porphyrin metabolism in which abnormal porphyrins or large quantities of physiological porphyrins are formed and excreted are called porphyria. There are three types of this disease, which have been termed *congenital*, *acute* and *chronic*. Actually, all three are congenital and familial.

Congenital porphyria is characterized by light sensitivity, which may result in blistering and, not uncommonly, necrosis of the skin upon exposure to sunlight, and the excretion of large quantities of coproporphyrin and uroporphyrin, type I, and sometimes small quantities of protoporphyrin. The normal ratio of type I and type III porphyrins is disturbed, the former type being produced in excessive amounts. The urine is stained a port wine color and the pigment is deposited in teeth, bones and skin. Liver extract and ascorbic acid seem to exert a favorable influence upon the disease. In *acute porphyria*, large amounts of porphyrin type III (protoporphyrin) are excreted. Light sensitivity does not occur, but there are abdominal, nervous or mental symptoms, e.g., severe cramps and vomiting, progressive paralysis often of an ascending type, and various forms of psychosis. In the *chronic* form of the disease, coproporphyrin type III and small amounts of coproporphyrin type I are excreted in the urine and feces. There is mild light sensitivity.

Porphyria An increased excretion of porphyrins in the urine in other conditions than the porphyrias is termed porphyria. Increased excretion occurs in various *hepatic diseases*, type I and to a less extent type III being found in the urine and especially in the feces. Type I coproporphyrin is present in excess in the excreta of

patients suffering from several types of anemia—*pernicious anemia*, *hemolytic jaundice* and in *leukemia*. In the first of these it has been demonstrated in the megaloblasts, erythroblasts and reticulocytes. Increased excretion of coproporphyrin type III occurs in *aplastic anemia*, *Hodgkin's disease*, *polomyelitis*, *chronic alcoholism* and *lead poisoning*. In any condition associated with stimulation of the hemopoietic system porphyrin production is increased, and contrary to what might be expected it is type I rather than type III porphyrins which are produced and excreted in excess. The light sensitivity of *pellagra* may probably be explained by the excessive amounts of coproporphyrin (chiefly type I) which are formed and excreted in this disease, but it is not unlikely that the porphyria is merely secondary to hepatic involvement.

HEMOLYSIS AND SUSPENSION STABILITY OF THE BLOOD

Hemolysis or the Laking of Blood

Under normal circumstances the plasma contains no appreciable quantity of hemoglobin. If normal blood is centrifuged the corpuscles are driven to the bottom of the tube whereas the supernatant plasma is clear but faintly straw-colored. Under certain conditions, however, changes may occur in the red cell which will allow the hemoglobin to escape into the surrounding fluid, which then becomes discolored. This is called *hemolysis* or *laking*, and may be carried out in a test tube by means of various agencies both physical and chemical. Certain biological substances such as the toxins of bacteria and snake venoms are intensely hemolytic. On the other hand, substances belonging to the class of immune substances or antibodies, and known specifically as *hemolysins*, are formed in the blood. These have the power to hemolyze foreign red cells. After the action of certain hemolytic agents the dim colorless outline of the red cells—shadow cells or “ghosts”—may be seen; they represent the incompletely destroyed framework or stroma¹ (see frontispiece). Some of the means by which hemolysis may be induced will now be considered in greater detail.

Hypotonic solutions

The membranes of plant and animal cells are semipermeable (p 26). They allow the passage into the cell of water and various substances in solution, but offer a barrier to the entrance or egress of others. The red cell is no exception; it contains substances which cannot pass out, and is surrounded by a fluid (plasma) containing materials which cannot pass in. We have here then a minute and almost perfect osmometer

¹ When hemolysis is induced by certain reagents, e.g., linoleic acid, but the cell structure remains intact, the addition of electrolytes causes the reappearance of hemoglobin in the cells (“reversed hemolysis”). This phenomenon is due probably to shrinkage of the cells and the concentration of a residue of unliberated pigment and not to the return of hemoglobin to the cell.

(p 26), and indeed much of our knowledge of osmotic phenomena has been gained from the study of the behavior of plant and animal cells when placed in solutions of different concentrations. In normal blood the plasma and the corpuscles are in osmotic equilibrium, i.e., the fluids separated by the corpuscular membrane are isotonic. If, however, the dissolved substances in the plasma are diluted by the addition of distilled water, a flow of water into the corpuscles occurs. An osmotic pressure is developed within it which the cell membrane is unable to withstand. The cell swells and becomes globular, the membrane stretches and the hemoglobin is liberated.

The process is in reality rather more complicated than this. It is probable that the hemoglobin is not contained within the red cell merely as in a bladder, or even in a number of smaller compartments, but is closely bound in some way to the cell structure. One reason for this belief is that purely mechanical agencies will not liberate the pigment. The cell may be torn into the finest shreds yet each minute particle still retains its hold upon the hemoglobin. The pigment, however, is soon released when the surrounding fluid is made hypotonic. This suggests that the cell structure consists of semipermeable partitions of almost infinite fineness.

The normal red cell offers a certain resistance to the disintegrating effect of hypotonic solutions. A slight lowering of the osmotic pressure of the surrounding fluid will not produce hemolysis. The normal percentage of salts in human plasma is approximately 0.94. Normal cells may be placed in a 0.6 per cent saline solution without being hemolyzed. The cell increases in volume, but the hemoglobin does not escape. The first trace of hemolysis appears when the saline concentration is about 0.43 per cent and the cell volume increased to about 145 per cent. At 0.35 per cent the cells are fully “laked,” i.e., hemolysis is complete; the cell volume is around 165 per cent of normal just before this occurs. The resistance which erythrocytes offer to the hemolytic action of hy-

potonic solutions is used in this way as an index of the fragility of the red cells

In performing a fragility test a series of tubes is set up containing solutions of NaCl graded in strength from 0.9 to 0.20 per cent at intervals of 0.05 per cent above and below the range at which hemolysis is expected, and at intervals of 0.025 within that range. A sample of blood is introduced into the saline in each tube, and the one in which hemolysis commences and the one in which the process is complete are noted. A *mechanical fragility test* is sometimes employed, a sample of blood being placed in a flask with glass beads and rapidly rotated. The liberated hemoglobin is then measured. The mechanical fragility is increased in acholuric jaundice, certain other hemolytic anemias and in sickle cell anemia. The degree of hemolysis may be determined by centrifuging the diluted blood sample and estimating colorimetrically the quantity of hemoglobin in the supernatant fluid.

In pernicious anemia the red cells have been found to be actually less fragile than normal whereas in other conditions, e.g., some forms of purpura (p. 118) and acholuric jaundice (ch. 9), their fragility is increased.

Cells that show reduced resistance to hypotonic saline may show a normal resistance to other hemolytic agents, e.g., lysolecithin (p. 63) and *rice versa*. Erythrocytes of spherical form, such as those characteristic of acholuric jaundice, show a lowered osmotic resistance mainly because the cells cannot increase their volume by as great an increment as can normal cells without injury to the cell structure (see p. 10). The resistance to hemolysis by lysolecithin on the other hand is not influenced by the shape of the cells, the hemolytic process being chemical in nature.

The permeability of the membrane of the red cell is quite different from that of the capillary membrane which, as we have seen (ch. 3), allows the passage of all crystalloid substances and to some extent of plasma protein, and is also freely permeable to hemoglobin. The membrane of human erythrocytes, on the other hand, is impermeable under physiological conditions to hemoglobin, the plasma proteins, and to Ca^{++} , K^{+} , Mg^{++} and organic phosphate ions, but permits the passage of water, H^{+} , NH_4^{+} , and of Cl^{-} , HCO_3^{-} and PO_4^{-} . Potassium escapes freely from the cells under conditions which injure the cell membrane, the potassium loss is closely related to the escape of hemoglobin, i.e., to hemolysis. The human red cell membrane is not absolutely impermeable to the sodium ion for even under physiological condi-

tions and therefore in the absence of hemolysis minute amounts may pass from the plasma into the erythrocytes.* Since the red cell is impermeable to potassium whereas sodium can cross the membrane, the selective permeability of the latter cannot be explained simply upon the theory that the cell membrane is a sievelike structure whose "pores" are of such a size as to allow the smaller ions, but not the larger ones, to pass. The lipid soluble theory is also unsatisfactory, for the inorganic anions are lipid insoluble. The cell membrane is freely permeable to amino acids, urea and uric acid, so these substances under ordinary circumstances do not enter into the osmotic relationships between cells and plasma. Osmotic changes occur, however, when CO_2 enters the blood and diffuses into the cell (see p. 462).

The exchange of inorganic phosphate across the cell membrane is associated with the enzymatic synthesis and breakdown of organic phosphate esters within the erythrocyte. In the former process inorganic phosphate passes from the serum into the cell and in the reverse direction when organic phosphate compounds are broken down.

Chemical Substances

Ether, chloroform, benzene and alcohol act by dissolving the lipid constituents of the envelope and stroma of the cell. Other substances e.g., *bile salts, acids and alkalis and saponin* cause hemolysis but the manner in which they act is not altogether clear. Bile salts probably act by combining with the protein constituents, and saponin with the cholesterol. As a result of the chemical changes induced by either of these substances destruction of the cell stroma—*stromatolysis*—occurs. Acids probably act by penetrating the cell and increasing the osmotic concentration within. Swelling and liberation of the hemoglobin occurs in a manner analogous to that of hypotonic solutions. The stroma is not as a rule destroyed. Alkalis, particularly ammonia, are powerfully hemolytic, as is also ammonium chloride. The NH_3 enters the cell and through the increase in osmotic pressure causes swelling and liberation of the hemoglobin. Stromatolysis accompanies hemolysis by alkali.

Certain chemical poisons such as carbolic acid, nitrobenzene, pyrogallol, ricin, arsenical preparations used in the treatment of syphilis, and many other substances are capable of causing red cell destruction.

*The results of various investigators in the past have differed rather widely with respect to the permeability of the red cell to the sodium and potassium ions, but the experiments of Hurnick who employed radioactive isotopes of Na and K give strong support to the statement made here.

Substances of Bacterial Origin or Formed in the Animal Body

1 **SPECIFIC HEMOLYSINS** If blood is injected into the veins of an animal of another species, or as already mentioned (ch 5) into an individual of the same species but whose blood group is incompatible with the blood group to which the injected blood belongs, agglutination of the red cells of the donor occurs, and hemolysis follows as a secondary effect. But if a series of injections of erythrocytes is made over a period of days into the blood of another species the serum of the latter develops a substance which promptly destroys the foreign cells through a *primary* hemolytic effect quite independent of agglutination. This hemolytic reaction, which was first demonstrated by Bordet, is specific, that is to say, it is only the particular species of erythrocyte to which the animal has been sensitized by previous injections that is destroyed by the hemolytic substance. The latter on this account is known as a *specific hemolysin*. It belongs to the class of immune substances or antibodies. Bodies of similar nature cause the destruction of other foreign cells and are known as cytotoxins and bacteriotoxins. All are part of a general protective mechanism which the body is able to build up against the invasion of foreign cells. When referring to these and other immune reactions the substance which upon entering the body causes their development is referred to as the *antigen* (i.e., the foreign red cells in the case of hemolysins). The antibody itself (e.g., the hemolysin) is heat stable and is spoken of as the *amboceptor*. The latter (which is specific) requires for its action another body which is nonspecific, is present in all sera and is destroyed by heat. It is known as the *complement*. Three factors (*antigen, amboceptor and complement*) are therefore necessary for the hemolytic or bacteriolytic reaction. After the action of the hemolytic or bacteriolytic amboceptor has been annulled through destruction of the complement by heat, the reaction may be restored by the addition of any serum (i.e., by supplying fresh complement).

When serum which has developed a bacterial antibody is incubated with an emulsion of the particular bacteria which has served as antigen, a reaction occurs which "fixes" or binds the complement. The phenomenon is spoken of as *complement fixation*. These facts were applied by Wassermann to the diagnosis of syphilis, and by subsequent workers as a test for other diseases, e.g., tuberculosis. For example, the previously heated serum of a subject suspected to be suffering from syphilis is incubated with (a) an emulsion of syphilitic liver¹ tubercle or typhoid bacilli respec-

tively (the antigen) together with (b) complement furnished by normal guinea pig's serum. If the suspected serum contains a specific antibody (amboceptor) for the antigen employed, the former will bind the complement to the latter, i.e., fixation of complement will occur. The foregoing is an account of a bacteriolytic system. A hemolytic system is employed to render the reaction visible. Washed sheep's corpuscles are added to the former system, together with the previously heated serum of a rabbit which has been sensitized to the latter cells by repeated injections. This serum supplies the hemolytic amboceptor but its complement has been destroyed. If the test is positive no hemolysis of the corpuscles occurs, since the complement (nonspecific) of the patient's serum has been already fixed by the bacteriolytic amboceptor and the hemolysin of the rabbit serum is therefore unable to exert its usual effect.

2 **TOXIC SUBSTANCES OF BACTERIAL OR PARASITIC ORIGIN** The toxins of bacteria responsible for many diseases, e.g. streptococcus, staphylococcus, tetanus bacillus and the organism of scarlet fever may cause a destruction of red cells, it may also occur in extensive burns. The more virulent types of other infectious fevers (e.g., smallpox, diphtheria, are also sometimes accompanied by intense hemolysis. When the hemolysis is of moderate degree but occurs over longer periods the hemoglobin is converted into hile pigment. This, if formed in amounts greater than can be disposed of by the liver, undergoes partial reabsorption in the plasma which together with the solid tissues, especially of the skin and mucous membranes, becomes stained a yellowish tint—hemolytic jaundice (ch 5). In hemolytic states of long standing an iron containing derivative of hemoglobin termed *hemosiderin* is frequently deposited in large amounts in the tissues, particularly of the liver and spleen (p. 79).

3 **THE VENOMS OF CERTAIN POISONOUS SNAKES**, e.g., the cobra and the poisons of various stinging insects and spiders cause a destruction of the red cells to a greater or less degree. Snake venom (cobra) has been shown to act indirectly. It contains a principle which has power to remove unsaturated fatty acids from the lecithin molecule. The resulting product which is called *lysolecithin*, is intensely hemolytic. Since lecithin is present both in erythrocytes and plasma and indeed in all cells, the entrance of snake venom into the body causes the production of this intensely hemolytic substance. Kephalin is acted upon by snake venom in a like manner with the production of a lyso kephalin which has a similar hemolytic action.

4 **HEMOLYSINS FROM NORMAL TISSUES** A non specific hemolysin has been extracted by simple means from healthy tissues and identified as *cis vacuic acid*, it probably exists in the free state in the tissues. Other nonspecific hemolysins have

¹ As a matter of fact syphilitic liver has been found to be unnecessary, since lecithin and other materials for some unexplained reason will serve as antigens.

been isolated from various tissues after incubation at 37° and extraction with alcohol. These are thought to be present but bound to an inhibitory substance, and may be liberated in active form by disease or injury.

Hemoglobinuria

When the hemolysis reaches such a degree that the hemoglobin cannot be converted into bilirubin as rapidly as it is liberated, as in severe malaria (blackwater fever) *hemoglobinuria* occurs, that is, the pigment is passed in the urine, which is usually turned port wine color or a dark brown or even black, due to the action of the urinary acid in converting the pigment into acid hematin and methemoglobin. The concentration of hemoglobin must, as a rule, reach a level of about 0.13 gram per 100 cc. of blood before it appears in the urine. It should be remembered that hemoglobin once it has escaped from the erythrocytes is functionless. Not only is it unable to be retained within the capillaries on account of the relatively small size of its molecule but the environment of the plasma is unsuitable for its action.

The hemolysis in *blackwater fever* is not due to the destruction of erythrocytes by the malarial parasite, nor does the parasite affect the hemopoietic tissue in such a way that it produces cells which are unduly fragile. The cells are apparently not defective, but the work of Macgrath and his associates may provide an explanation of the high degree of hemolysis in this disease. They found that normal human tissues contain a hemolysin which is inhibited in its action by normal serum but not by the serum of a patient suffering from blackwater fever. It is suggested, therefore, that there is no special hemolytic agent in the blood in blackwater fever but rather an absence of a normal inhibitory substance.

Paroxysmal (cold) hemoglobinuria. This form of hemoglobinuria occurs most usually upon exposure to cold. There may be fever, headache, abdominal pain, vomiting and transient jaundice. It is sometimes associated with Raynaud's phenomenon in which condition spasmodic constrictions of the small vessels of the peripheral parts of the body occur, particularly after exposure to cold. The occasional association of the two conditions has suggested to some that they have a common cause, but direct evidence for this is lacking. It is an interesting observation that the blood of a subject of paroxysmal hemoglobinuria if cooled (to 5°C) outside the body and subsequently warmed under goes hemolysis (Donath phenomenon). There is apparently no defect, however, of the subject's corpuscles, they seem to be no less resistant than normal to hypotonic saline, the serum, on the other hand, has the power to hemolyze the cells of a normal person. The great majority of subjects are syphilitic. The hemoglobin, it seems, is liberated from the erythrocytes by the action of an

endogenous hemolysin which in the presence of complement becomes fixed to the red cells when the blood is chilled (cold phase). The presence of some thermolabile component of complement is required when the blood is again brought to ordinary body temperature (warm phase) to bring about hemolysis (see Siebens and associates). The phenomenon is quite distinct from cold autoagglutination (p. 49).

March hemoglobinuria. Hemolysis may occur and hemoglobin appear in the urine even in healthy persons after strenuous muscular effort. In certain persons this tendency is exaggerated and hemoglobinuria may follow relatively mild muscular exercise. It is seen not infrequently in soldiers after long marches. The free pigment in the blood and urine of such cases is oxyhemoglobin, not myoglobin as might be expected. The fragility of the red cells is not increased and neither hemolysins nor autoagglutinins which might account for the hemolysis have been discovered.

In the third type of paroxysmal hemoglobinuria—the *nocturnal hemoglobinuria of Marchiafava*—hemoglobin or hemosiderin (p. 79) is passed almost continuously in the urine but in greatest amounts at night. It is accompanied by a severe hemolytic anemia. The cause of the hemolysis is believed to be a peculiar susceptibility of the red cells to acid metabolites; their greater destruction at night being attributed to the accumulation of carbon dioxide during sleep. The abnormal cells are hemolyzed when incubated in serum made slightly acid (Ham), or in any normal serum but normal cells are not destroyed by the patient's serum. The fault in the patient's cells is thought to be some abnormality of the stroma protein.

The Suspension Stability of the Blood Erythrocyte Sedimentation Rate (E.S.R.)

The blood is a suspension of cells in a viscous fluid, the plasma. It is only the constant movement of the fluid that keeps the cells evenly distributed throughout. When the circulation comes to rest the cells at once commence to sink. Under ordinary circumstances the sedimentation of the cells in a sample of blood can progress to only a negligible extent, for it is soon circumvented by the clotting process which fixes them in a jellylike matrix. If for any reason, the blood is delayed from clotting, sedimentation may continue until an upper layer of clear plasma becomes separated from the cells which have descended through the fluid. When clotting then ensues the blood consists of two strata, a thin yellowish or buff-colored layer of clotted plasma laid upon a much deeper red stratum of cells. When blood had clotted in this way the upper layer was known to the older physiologists as the "buffy coat" (see also p. 109).

FIG 7.1 Showing the naked eye appearances of specimens of blood spread upon glass slides. The specimens, left to right, are from (a) healthy man (b) healthy woman, (c) healthy pregnant woman (d) man, appendicitis (e) man, pneumonia, (f) sepsis. Note the especially granular appearance of specimens e and f (after Fahraeus).

Ancient and medieval physicians carried out crude observations of the quantity of clear fluid which separated from blood upon standing as a means of diagnosis. In conformity with their humoral theories of disease, they believed it to be the "phlegm" which had separated from the other humors.

Biernaki (1891) was the first in modern times to draw attention to the increase in the rate of sedimentation of the blood in various pathological states. The subject has been studied in more recent times by Fahraeus and the *erythrocyte sedimentation rate* (ESR) has come to be recognized as a useful diagnostic procedure. The sedimentation rate is measured by the depth in millimeters of clear plasma which is formed at the top of a vertical column of blood at the end of one hour. For the determination of the ESR either Westergren's or Wintrobe's method is usually employed. In Westergren's method, the blood for examination (about 1.5 ml) is diluted 4 parts to 1 of a 3.8 per cent solution of sodium citrate.⁴ It is then drawn into a graduated glass tube about 300 mm long, and having a bore of 2.45 mm.⁵ The upper end of the tube which is fixed in a strictly perpendicular position is left open, whereas the lower end is closed, usually by a removable rubber cap held in position by a spring.

⁴ This is isotonic with plasma and has the same specific gravity.

⁵ Since the concentration of the blood in red cells influences the sinking rate, Walton recommends that their number be standardized to 5,000,000 per cu mm by the addition or removal of plasma if the subject's blood is below or above this level. In Wintrobe's method his hematocrit tube is employed, the packed cell volume (p. 18) being determined if desired after measuring the ESR. In the final calculation of the latter, a factor is used to correct for any existing anemia.

The determinations should be made at a temperature of 20°C.

The sedimentation rates expressed as the height of supernatant plasma, in mm per hour for normal blood of men, women and infants, are given in the following table.

	mm per hour
Men	1-3
Women	4-7
Newborn children	0-5

In normal pregnancy and in certain pathological states, the sinking rate of the red cells is found to be very markedly increased, in other words the suspension stability of the blood is reduced. The average figure during pregnancy is about 35 mm per hour. The rate is also increased during menstruation. The pathological states which show the most noteworthy increase in the rate are septicæmia, 100 mm per hour, and pulmonary tuberculosis, 65 mm. Anemia (sickle cell anemia and acholuric jaundice excepted), malignant tumors, inflammatory conditions of the female pelvic organs and many other conditions increase the rate moderately above the normal. Reduction in the sedimentation rate is rare, it occurs in allergic states, in peptone shock and in sickle cell anemia and acholuric jaundice.

TABLE 7.1

Showing the sedimentation rates of corpuscles from the same sample of blood suspended in different protein fractions of plasma (from Zozaya).

Protein Fraction	ESR
Fibrinogen	41-61 mm
Eaglobulin	42-64 mm
Pseudoglobulin	5-12 mm
Albumin	3-6 mm

The physical changes in the blood which might cause this unusually rapid rate of red cell settling are of considerable interest and were investigated thoroughly by Fahraeus. In considering the sedimentation rate of particles suspended in a fluid when they are of a size comparable with that of the red cells, four factors must be taken into account. These as applied to blood are

1 *Specific gravity* of the plasma as compared with that of the corpuscles. Corpuscles of high specific gravity would sink more quickly in normal plasma, and normal corpuscles more quickly in a plasma with a low specific gravity. In neither corpuscles nor plasma was any significant change of this nature found to explain an increase in the ESR.

2 *Lowered viscosity* of the plasma is another factor which could cause an increase in rate of sinking, but no such change could be detected.

3 *Increased size of the corpuscles* would increase their mass disproportionately to their surface and in consequence enhance their rate of sinking, but no significant alteration in size was found.

4 *Clumping* together of cells of normal size would have the same effect as an increase in size of the individual cells for just as lumps of clay sink rapidly in water, whereas clay in the form of fine particles remains suspended almost indefinitely, so aggregation of the corpuscles would cause their more rapid sedimentation.

This last factor is the chief cause of the lowered stability of the blood suspension in the pathological conditions cited above. The roughness and granular appearance of the blood, due to the corpuscular aggregation is evident to the naked eye when the blood is spread in a film upon a slide (fig. 71). Normal blood, in marked contrast, forms a smooth homogeneous film. Under the microscope the crowding together of the cells in large masses is quite obvious. An increase in the fibrinogen and euglobulin fractions of the plasma is held responsible for the effect. Dextran increases the sedimentation rate and is used to produce more rapid separation of plasma and formed elements. These substances act upon the corpuscles in some unknown way to make them adhere to one another and form clumps of agglutinated cells. It is probable that it is the relative proportions of the fibrinogen, globulin and albumin fractions of the plasma rather than their absolute concentrations which are of importance in determining the ESR. Thus a fall in the albumin concentration alone may have as great an accelerat-

ing effect as a rise in the other fractions. That the character of the plasma and not that of the cells is the principal determining factor is shown by the fact that if erythrocytes from blood with a high sedimentation rate (e.g., of pregnancy) are suspended in the plasma of blood having a low rate of sedimentation (e.g., of newborn) they settle at the slower rate, and conversely, erythrocytes with a normal sedimentation rate in their own plasma settle rapidly in plasma from blood with a high ESR. See table 71.

Though the protein constitution of the plasma is usually the most important single factor affecting the sedimentation rate, several other factors exert an influence. e.g., (a) the *shape* of the erythrocytes, any tendency toward a spherical form by reducing the proclivity of the cells to cling together (rouleaux formation) will retard sedimentation, (b) *temperature* a rise in temperature above 20°C, as a rule, accelerates the ESR, a fall retards it, (c) the *lecithin-cholesterol* ratio of the plasma, the rate is retarded by an increase in the lecithin concentration and accelerated by cholesterol, (d) *red cell concentration* a high erythrocyte count retards the ESR a low count accelerates it.

The nonspecificity of the test is evident: nevertheless determinations of the sedimentation rate are of considerable value, especially, (a) in gauging the degree of activity of tuberculous processes, (b) as an aid in the differential diagnosis of certain gynaecological lesions. Benign tumors of the pelvic organs cause no change in rate whereas as already mentioned, malignant growths inflammatory states and pregnancy cause a pronounced rise, (c) as an index of the extent and intensity in pyogenic infections, and (d) in estimating the activity of the inflammatory process in rheumatic fever.

THE SPLEEN; THE LIFE OF THE RED CELL; THE REGENERATION OF BLOOD; IRON METABOLISM

The Structure of the Spleen

The spleen is an important part of the reticulo-endothelial system. Its structure is such that blood is brought into intimate contact with phagocytic cells. Dotted throughout the spleen, like islands, and surrounded by the pulp are lighter areas of lymphoid tissue. These are the Malpighian corpuscles. The Malpighian corpuscle (fig 81) is pierced by a small artery. It is analogous to similar areas in lymph nodes, and serves the same function, namely the manufacture of lymphocytes. Blood enters the substance of the spleen by fine arterial vessels which pass through the Malpighian corpuscles and out into the splenic pulp. Here two different descriptions of its circulation have been given. Briefly, one of these indicates that the vessels open into and flood the splenic pulp, from which it passes back into the venous sinuses through numerous perforations in their walls. According to this view, the circulation through the splenic pulp is an open one. Others contend that the blood vessels are continuous throughout the splenic pulp and lead into the splenic sinuses. According to this view, the circulation through the splenic pulp is closed, the blood cells passing into the pulp or out from the pulp through openings in the vessel walls.¹

The Functions of the Spleen

The spleen has several important functions. The first three of these below are common to all parts of the reticuloendothelial system. (a) It has a part in the final disposal of red blood cells, (b) it phagocytoses bacteria and other particulate matter, (c) it produces antibodies, (d) it manufactures lymphocytes, (e) it has actions, possibly hormonal in nature, which influence the length of life of the erythrocytes and exert some influence

on hematopoiesis, (f) it influences the number of platelets and leucocytes, (g) it has an important reservoir function in many animals, though little in man.

1 *The role played by the spleen in the destruction of the blood cells.* In the pulp of the spleen are to be found relatively enormous mononuclear ameboid cells which have the power to engulf foreign particles of various sorts. They are known as *macrophages* and at times may be seen with fragments of erythrocytes or even whole corpuscles within their cytoplasm. These cells belong to the reticuloendothelial system (ch 11). In certain conditions in which a great destruction of red cells is a feature, immense numbers of these phagocytic cells may be seen loaded with erythrocyte fragments of various sizes. Sometimes merely a dust-like residue (*hemoconia*) containing hemoglobin is all that remains of the blood cell. The disposal of abnormal or overmature erythrocytes by the spleen may not be a phagocytic process entirely.

Attempts to demonstrate the red cell disposal function of the spleen by comparative estimates of the corpuscular contents of the arterial (incoming) and venous (outgoing) bloods have not, on the whole, been very successful. But Mann and his associates have been able, by spectroscopic examination of the arterial and venous bloods, to show a definite excess of bilirubin (iron free pigment) in the blood of the splenic vein over that of the splenic artery. The bilirubin in the venous blood of other organs was no greater in amount than that in the arterial blood. In diseases with marked red cell destruction, the spleen becomes impregnated with iron and with an iron-containing pigment, *hemosiderin*, derived from the hemoglobin of the disintegrated cells. Similar deposits occur in the liver and to a less extent in other tissues.

Although evidence derived from microscopical studies and from bilirubin estimations shows undoubtedly that red cell disintegration occurs in the spleen, it is believed that only fragmented,

¹ Weiss contends that the walls of the splenic sinusoids are made up of reticuloendothelial cells in flattened form. Some of these cells may become round and form "core" tissue, whereas others remain flat in the walls of the sinusoids.

dead, or effete and senile erythrocytes or those which are abnormal are disposed of in this way. The organ is believed not to attack healthy circulating cells. The reticuloendothelial cells of the spleen, in common with those elsewhere, conserve the iron from hemoglobin.

2 Other phagocytic activity The phagocytic activity of the reticuloendothelial cells of the spleen, which has been considered in relation to the removal of red blood cells, is also important in the defense against infection. Bacteria or other particulate matter being taken up by these cells. After splenectomy, animals become more susceptible to certain parasitic and bacterial infections. Although the spleen may hold only a small percentage of any particulate matter injected intravenously, nevertheless it also can be stimulated to form more reticuloendothelial cells and discharge them into the circulation. The phagocytic activity of the spleen, in common with other parts of the reticuloendothelial system, is influenced by various hormones. It can be strongly stimulated by estrogenic materials such as diethylstilbestrol and estradiol benzoate, and its phagocytic activity is greatly depressed by cortisone.

3 Antibody production This function of the spleen is important, especially when the antigen

is in particulate form, and its production of antibodies is relatively rapid. Somehow, the primitive reticular cells of the spleen are stimulated to divide and produce antibody-forming elements which subsequently mature into lymphocytes and plasma cells.

4 Lymphocyte production The spleen contains much lymphoid tissue and manufactures lymphocytes and other mononuclear cells.

5 The hemopoietic function of the spleen in the embryo In the embryo, the spleen, in common with the bone marrow and liver, is active in the production of erythrocytes and granulocytes as well as of lymphocytes. But erythropoiesis and granulopoiesis in the spleen normally cease at birth. Yet, many observations point to the spleen as exerting an influence upon the erythrocytes.

6 Suggested influences of the spleen on the structure and number of the blood cells Although, as mentioned before, the spleen destroys abnormal cells (e.g., the spherocytes of chronic congenital hemolytic anemia, the erythrocytes in sickle cell anemia) it does not normally destroy erythrocytes until after they have served their purpose. The levels of circulating erythrocytes, leukocytes, and platelets increase after splenectomy. The number of circulating reticulocytes is elevated also; they are thinner than normal and show nuclear changes. Because of the reticulocytosis after splenectomy, the suggestion has been made that a normal inhibition of the release of erythroid cells from the bone marrow diminishes after splenectomy, permitting an earlier release of these cells into the circulation. The increase in circulating leukocytes following splenectomy is thought also to be due to the removal of an inhibitory effect of the spleen on the production or release of leukocytes.

The spleen is concerned in some way with the life history of the platelets. In normal animals and in patients suffering from thrombocytopenic purpura, splenectomy increases the number of circulating platelets. This suggests some splenic influence on the production of platelets from megakaryocytes, since evidence for platelet destruction by the spleen is lacking.

7 Reservoir function of spleen Animal experiments in dogs, cats, and a number of other mammals have shown that the spleen has a large reservoir capacity. The splenic blood was found to be richer in red cells so that with splenic contraction, in the cat, there might be expelled into the circulation an amount of blood equal to one-sixth of the blood volume and red cells equal to one-fourth

of the body's total supply. In these animals, splenic contraction occurs with exercise, anoxia, hemorrhage, when the pressure in the carotid sinus is reduced, and when splenic nerves are stimulated or adrenaline injected. Although the reservoir function in animals may be of great importance, in man, under normal conditions, it is slight. The total volume of the spleen in man is not great and, at best, only a relatively small volume of blood could be released into the general circulation from it.

8 Other effects. A curious and unexplained action of the spleen has been discovered by Culik and Simpson, who found that toxic doses of the antihistoid compound, thio-thymine (2-thio-5-methyl uracil) causes the death of normal rabbits from pulmonary edema, but not of splenectomized animals. Moreover, if a splenectomized animal is injected with an aqueous-vent extract of hog or beef spleen, its susceptibility to the action of the drug in causing pulmonary edema is restored. Splenic extracts alone produce no such effect.

HYPERSPLENISM. Hypersplenism is a condition in which there is an excess of one of the normal functions of the spleen affecting the blood cells. It is a complication of splenomegaly. One or more of such blood states as thrombocytopenia, leucopenia, and anemia may be present. Various causal factors have been suggested: (a) antibody production; (b) excessive phagocytosis; (c) excessive production of an agent suppressing marrow activity.

IRRADIATION AND THE SPLEEN. Animals can be protected from usually lethal, although not massive doses of irradiation of the general body surface by shielding the spleen with lead, or by the intravenous injection of ground up spleen or bone marrow. In the latter instance the protective effect is obtained with that part of the material containing the cell nuclei. It has been suggested that relatively undifferentiated cells in the material injected or discharged by the shielded structures protect, in some way, the hematopoietic tissue exposed to the irradiation or restore it if it has been injured, as it is thought that the cells, although injured, still retain their potentiality to divide and mature.

Enlargement of the Spleen

Enlargement of the spleen is associated with a large number of pathological states; only a few will be mentioned.

In *thrombocytopenic purpura* the spleen is enlarged and its removal is followed by a rise in the

platelet count and amelioration of the symptoms. Also, substances such as antiplatelet serum or diphtheria toxin, which when injected cause platelet destruction, are rendered much less effective if the spleen has been removed. Splenectomy frequently brings about a cure in *hemolytic jaundice* (*acholuric jaundice*). The spleen may be considerably enlarged in *pernicious anemia* but splenectomy exerts no effect upon the course of the disease. In *splenic anemia* (congestive splenomegaly, Banti's disease) the spleen is tremendously enlarged and the liver becomes cirrhotic. There are portal hypertension and repeated hemorrhages. Splenectomy has been practiced in this disease with variable success. Relief of the portal hypertension and splenic congestion by anastomosis of the portal vein to the inferior vena cava is advocated by Whipple. Splenic enlargement is a feature of many other abnormal conditions such as malaria, Hodgkin's disease, leukemia, etc. but in these benefit does not follow its removal. The organ is also enlarged sometimes enormously in *polycythemia*, but splenectomy fails to cure the condition and indeed is attended by grave risks to life (Mojzishan).

Gaucher's disease is an interesting although rare condition which commencing usually in childhood is associated with a colossal enlargement of the spleen. The enlargement is due to hypertrophy and hyperplasia of reticuloendothelial elements. Masses of very large vesicular cells (Gaucher's cells) filled with a cerebroside called *cerasein* are seen in the lymphoid tissue and venous sinuses of the spleen. Hyperplasia of reticuloendothelial elements also occurs in other locations, e.g., bone marrow and liver. The disease is due apparently to some disorder of lipid metabolism. Splenectomy is the only effective treatment. *Niemann-Pick's disease* is a somewhat similar condition affecting the reticuloendothelial system and lipid metabolism. Characteristic cells known from their appearance as 'foam cells' are present in large numbers; they are loaded with sphingomyelin. Accumulations of this phospholipid are found also in the liver and brain. Subjects of this and the preceding disease are usually children of the Jewish race. *Von Jaksch's disease* occurs in infants and is characterized by splenomegaly, anemia and an increase in the number of white blood cells. Great enlargement of the spleen also occurs in *glycogen storage* (von Gierke's) disease. The chief characteristics are hypoglycemia with ketosis and a slight rise only in the blood sugar after an injection of adrenaline (ch. 58) and extensive deposits of glycogen particularly in the liver, associated usually with a deficiency in glucose 6 phosphatase.

From its position in the portal circulation the spleen is also very susceptible to enlargement, either as a result of mechanical obstruction to the

veins or to high venous pressure resulting from cardiac or hepatic disease

The Life of the Red Cell

From the amount of bile pigment which is excreted daily by the liver the conclusion must be drawn that a very large amount of hemoglobin (since this is the sole or at least the main source of bile pigment) is liberated from disintegrated red cells in 24 hours

There are three possible ways in which erythrocytes normally might be destroyed in the body (a) by the macrophages of the spleen, (b) by the action of a hemolytic substance in the blood, (c) through simple wear and tear and disintegration in the blood stream. There is no evidence that hemolysis occurs to any significant extent in normal blood and the phagocytic cells of the normal spleen seem quite inadequate to account for the wholesale destruction of cells which evidently must be going on continually in the body. The work of Rous indicates that the erythrocytes to a very large extent undergo disintegration in the blood stream as a result of the stresses and strains to which they are incessantly subjected during their passage through the vessels. When it is considered how delicate is the structure of the red cell and to what violent treatment it is exposed during its lifetime, this wastage is not surprising. The cells are flung from the heart into the arteries at high velocity. In their voyage around the circulation they are exposed to jostlings and innumerable collisions with one another and with the arterial walls. At times they are forced through channels which are too narrow to permit their passage without marked distortions of their shape, or they may be caught in a fork at the branching of a vessel and become "saddlebagged" over it. Their membranes are almost continually undergoing alterations in tension as a result of osmotic changes. At last, becoming older, they are unable to withstand these abuses and undergo fragmentation. Fragments of different shapes and varying in size from that of a half or a quarter of the whole cell to mere dustlike remnants containing hemoglobin (hemocoma) may be found in the circulating blood, in the spleen and to a limited extent occasionally in other tissues.

From determinations of bile pigment excretion it has been estimated that in health between 7,000,000 and 10,000,000 cells are destroyed in this way every second—and of course the same number must be formed afresh by the blood form-

ing tissue. The loss of hemoglobin is between 16 and 24 grams daily. The number of red cells and hemoglobin concentration in the circulation at any moment represents the balance struck between blood wastage and blood formation by the bone marrow.

Many attempts have been made to determine the life span of the erythrocyte. Several methods have been employed, e.g., stimulation of the discharge of reticulocytes from the marrow and determining the time of their maturation, measuring the bile pigment excretion. The simplest and most commonly employed method is some form of the *selective or differential agglutination technique*, introduced in 1918 by Ashby. This method consists in transfusing compatible red cells and later examining the recipient's blood from time to time for the presence of the foreign corpuscles which are counted in a hemocytometer. The foreign cells are distinguished from the transfused person's own cells by means of the serum of another belonging to a group with which the recipient's cells, but not the foreign cells, are incompatible* (p. 5). That is, the recipient's cells are agglutinated but not the foreign (donor's) cells. A plot of the number of surviving cells against time gives a straight line which meets the time axis at a point indicating the life span. To obtain accurate results it is necessary to agglutinate the recipient's cells completely, potent agglutinating sera must therefore be used.

Using this method it has been found that the life of the average red cell is about 120 days.

Landsteiner, Levine and James have employed the M and N groups in a similar way, injecting M cells into an N recipient, or vice versa, and using anti M or anti N serum to agglutinate the *transfused* cells, leaving the recipient's cells unagglutinated. A more recent method is that which employs the isotope of nitrogen (N^{15}) to tag the red cell in the bone marrow. This is done by feeding glycine into which the isotope has been incorporated, this amino acid is utilized in the synthesis of protoporphyrin. It is necessary to the method that the isotope should not leave the cell and be utilized again for the manufacture of hemoglobin, but should persist throughout the life of the cell. Since the uptake time is long the tagged cells are not all of the same age and hence with this pro-

* Thus if corpuscles of Group O are transfused into a person belonging to Group AB then, when the recipient's blood is mixed outside the body with Group B (anti A) or Group A (anti B) serum the recipient's corpuscles but not the foreign cells will be agglutinated.

cedure it is difficult to obtain a precise determination of the survival time. The life span of the red cell as determined in man by this method is 127 days. Whipple and Hawkins, by determinations of the bile pigment excretion, obtained a figure in dogs, of 120 days.

Survival of cells tagged with radioactive iron or radioactive chromium may also be followed. The values obtained for the life span are rather similar to those obtained by the differential agglutination procedure. Using differential agglutination, Mollison reported that normal erythrocytes infused into patients with hereditary spherocytosis survived normally, but erythrocytes from such patients had a short survival time in normal recipients. Ashby has found that in pernicious anemia the average life of transfused cells was 110 days, in aplastic anemia, 41 days, in malignant cases, 52 days, whereas in transfusions given post-operatively to ordinary surgical cases, uncomplicated by severe anemia or malignancy, the survival time of the transfused cells averaged 124 days.

The Regeneration of Blood

The red blood cells are formed in the red bone marrow (ch 11). Anoxia, no matter how produced, is a fundamental factor in stimulating erythrocyte production. This stimulating effect seems to be a consequence of an increase in the blood level of a hematopoietic factor of extramedullary origin which results from the anoxia. Anoxia is important also in bringing about the release of iron from its stores.

THE MATERIALS NECESSARY FOR ERYTHROCYTE FORMATION

1 *The red cell stroma.* It is doubtful whether the materials required for the construction of the framework of the cell, e.g., nucleoprotein, globulin, lecithin and cholesterol are ever lacking. The body possesses large supplies of these materials and an ordinary diet contains them in adequate amounts. In certain anemias, however, e.g., pernicious anemia and Cooley's anemia, the failure of the body to assemble these materials for the manufacture of cell stroma may possibly be a fundamental causative factor.

2 *Hemoglobin* is added to the red cell only after the cell's development has progressed to a certain stage (ch 11). Synthesis is believed to take place in the nucleus of the cells in the bone marrow. The complete history of hemoglobin in the body has yet to be written, but it is now established that

the body can synthesize pyrrol groups from simpler and readily available compounds, possibly, as suggested by Hans Fischer, from acetoacetic acid, glycine,² proline, oxyproline and tryptophane have been proposed by others as possible building stones. Given the pyrrol group, synthesis of protoporphyrin is readily effected (ch 6). An interesting experiment in this connection is described by Whipple and his associates. When hemoglobin was given intravenously to anemic dogs, the animals' hemoglobin was increased by an amount equal to that injected. At the same time the excretion of bile pigment was increased by a corresponding amount. This paradoxical result is interpreted in the following way. The pyrrol of the injected hemoglobin is excreted as bilirubin, whereas the globin part of the molecule is utilized for the production of new hemoglobin. The pyrrol groups of which must therefore be derived from some other source—food or body tissue—and synthesized to protoporphyrin. It has already been pointed out that heme (prophyrin + iron) is a universal material and is present in the great majority of food stuffs. So here it might be supposed, was a source of an almost unlimited supply of the necessary pigment element. Yet heme cannot be split by the digestive secretions and it is generally agreed that iron so combined cannot be utilized for hemoglobin synthesis. Globin, of course, is required to complete the hemoglobin molecule. Whipple and his associates have found that this protein is well utilized for hemoglobin synthesis, yielding from 30 to 40 grams of blood pigment for each 100 grams fed to anemic dogs. Hemoglobin or globin, or a digest of the latter when given intravenously to anemic animals forms hemoglobin almost gram for gram. They found that, as compared with the porphyrin part of the molecule, globin was of much greater importance for hemoglobin regeneration; this protein apparently is a limiting factor in hemoglobin synthesis. Upon a diet low in protein but adequate in iron, hemoglobin regeneration was minimal. The amino acids necessary for the construction of hemoglobin are present in milk, meat, and other sources of first class protein. Globin can also be synthesized to a limited extent apparently from endogenous sources. This function is probably situated in the liver. Certain amino acids, espe-

² The most convincing evidence that this amino acid is a precursor of pyrrol has been obtained by Shemin and Rittenberg who fed glycine to rats and to men, after incorporating isotopic nitrogen into its molecule, and found it in the newly formed protoporphyrin.

TABLE 8 1

Hemoglobin production influenced by diet

Diet Grams Daily	Hemoglobin Production (Two-Week Feed $\pm$ Period)
	grams
Bread 400	3
Milk 450, bread 400	3
Cream 100, bread 400	10
Butter 100, bread 350	15
Asparagus 200, bread 300	9
Spinach 200, bread 300	15
Raspberries 200, bread 300	5
Raisins 200 bread 300	25
Apricots 200, bread 300	48
Eggs 150 bread 300	45
Whole fish 250, bread 300	13
Beef muscle 250, bread 300	17
Pig muscle 250 bread 300	30
Chicken gizzard 250, bread 200	80
Kidney 250, bread 300	70
Chicken liver 250, bread 300	80
Beef liver 300 bread 300	80
Beef liver 450	95

cially proline and threonine, were found to increase hemoglobin regeneration after hemorrhage, which suggests that they are used for the synthesis of globin. Histidine which constitutes 8 per cent of the globin molecule is, contrary to expectation, less effective. It seems likely, that coproporphyrin is a precursor of protoporphyrin and thus constitutes a step in hemoglobin synthesis. The evidence for this is that (a) in pernicious anemia the protoporphyrin of the erythrocytes is closely correlated with the reticulocyte percentage, and (b) when the disease is in relapse the protoporphyrin is very low and coproporphyrin cannot be demonstrated, but after treatment with vitamin B₁₂ the coproporphyrin increases rapidly and in advance of the protoporphyrin.

Whipple, Hooper and Rabscheit carried out a series of experiments upon animals made anemic through repeated bleedings, and tested their power to regenerate hemoglobin when fed upon various diets. Meats were found to be the most potent for this purpose. Carbohydrates in the form of bread and sugar were found to be ineffective. In fact they had actually a definitely depressing effect upon the hemoglobin repair process, for animals regenerated their blood more rapidly when starved than when fed upon a bread and sugar diet. In explanation of this fact Whipple suggested that the starved animal drew upon

its tissues to supply the basic elements for hemoglobin synthesis, whereas carbohydrate food on account of its well known protein-sparing effect prevented the tissues from being utilized in this way. Infection or very severe liver damage markedly depresses hemoglobin regeneration in anemic dogs. The depressing effect upon regeneration of hemoglobin which is seen in the Eck fistula animals is apparently due to interference with liver function (defective protein synthesis) and to the reduction in iron absorption.

These workers found that, of all protein foods, liver was by far the most effective for blood regeneration. Next in order came kidney and chicken gizzard. Milk had little regenerating effect. Table 8 1 shows the comparative values of the various articles of diet. A bread mixture consisting of potato and wheat flour, bran, sugar and the necessary salts and vitamins was used as the basal diet. This was practically inert so far as the regeneration of hemoglobin was concerned. The article to be tested was added to this basal diet.

The animals (dogs) were rendered anemic by three or four successive bleedings until the hemoglobin had been reduced to 30 per cent of the normal. The item of food to be tested was then added to the basal diet and the animal bled from time to time in order to maintain the hemoglobin at the original level of 30 per cent. The amount of blood removed expressed in grams of hemoglobin gave a direct measure of the amount of pigment regenerated in a given time.

Iron Metabolism

Being an essential constituent of the hemoglobin molecule, this mineral must be available in adequate amounts in order that normal blood regeneration shall occur. Iron provides the keystone for hemoglobin construction, unless it is supplied in appropriate amounts the maturation of the red cells is retarded, and the numbers discharged from the bone marrow into the general circulation reduced.

ABSORPTION, STORAGE AND EXCRETION OF IRON

Iron is absorbed to some extent throughout the entire intestinal tract, but in by far the greatest amount from the upper part of the small intestine. The absorption is by way of the blood. There is no evidence for a significant uptake by lymphatics. After absorption the element is stored in the intestinal mucosa, the liver and to a less extent in the spleen and kidney. Liver iron is readily increased by iron feeding or injection. Under ordinary circumstances only minute quantities of iron

are detectable in the plasma, the normal amount being about 0.1 mg/100 ml, although the iron-binding capacity of plasma is about three times this value. The great proportion of the iron of the blood is present in the red cells. A smaller quantity is present in the muscle (myoglobin, cytochrome, etc.), the remainder is stored in liver, kidney, and various other tissues as *ferritin* and *hemosiderin*. Whole blood contains from 45 to 50 mg per cent and the total quantity in the adult human body is between 4 and 5 grams. See table 8.2. Iron is present in the blood mainly as (a) plasma iron, and (b) iron combined with hemoglobin, which accounts for from 92 to 98 per cent of the total. There is very little excretion of iron by the bowel or kidney under ordinary conditions. The daily loss in adults is about 1 mg. The view of McCance and Widdowson that normally the iron stores of the body are regulated not by excretion but through the control of absorption is now generally accepted. Iron is, therefore, very largely a "one way" element. That which is absorbed is held by the body with great avidity and the iron liberated from hemoglobin is used again for the manufacture of new hemoglobin; the pigment part of the molecule alone being excreted in the bile.

Several factors influence iron absorption. It will be affected by the acidity of the intestine and motility of the gut and by the presence of reducing agents such as ascorbic acid. The level of phosphate also has an important effect, its presence decreasing absorption and its absence increasing it. Indeed a low level of phosphate in the diet accompanied by a high intake of iron may lead to a very high absorption of iron. Interference with the external pancreatic secretion by duct ligation or ethionine damage also enhances iron absorption. Inorganic iron seems to be more readily absorbed than the iron found in various foods. The iron in milk, cereal and meat is absorbed relatively well. When given with phytic acid the absorption of iron is poor. It is now known that the truly organic iron of foods, namely that combined in heme, is not available since it is not released by peptic or tryptic digestion, whereas the inorganic iron which may represent 50 per cent or more of the total iron of the food is available. About 5 to 10% of the food iron is absorbed. Severe infection reduces iron absorption very markedly, sometimes to only one-tenth of the normal.

In iron deficiency anemia the absorption of iron is enhanced. This seems to be related to a reduction in the hemoglobin levels and an increase in

hematopoietic activity rather than to the state of the iron stores, though this point is still somewhat controversial.

A conception of the mechanism whereby the iron absorption occurs has been offered by Granick and his associates. Their results with radioactive iron indicate that ferrous iron passes from the intestinal lumen into the mucosal cells, and is here oxidized to the ferric form (FeOH). The ferric iron, as ferric hydroxide phosphate, combines with a protein known as *apoferritin* (mol wt around 460,000) the iron-phosphorus-protein complex *ferritin* being formed. Ferritin is thus a conjugated protein containing about 23 per cent of iron. The iron-phosphorus portion has the approximate formula $[(\text{FeOOH})(\text{FePO}_4)_2\text{H}_2]$.

At the vascular surface of the mucosal cell the iron of ferritin is reduced to the ferrous form, the conversion is facilitated by vitamin C. Immediately upon entering the blood stream it is oxidized and combined with the B_1 iron-binding globulin, named *transferrin* or *siderophilin*, of the plasma, in this complex form iron is carried. At the periphery of the circulation ferric ions diffuse across the capillary wall into the tissue fluids but iron enters the cells in the ferrous form. Probably under some circumstances, especially when the oxygen supply to the tissues is low, ferrous iron passes directly into the plasma without going through the ferritin stage. When saturated with ferritin the mucosal cells act as a sort of block. If, on the other hand, there should be a scarcity of iron in the intestinal lumen the iron thus stored in the epithelial cells is released into the circulation. Thus the ferritin mechanism tends to stabilize the level of plasma iron. However, the so-called mucosal block is by no means perfect, for iron,

TABLE 8.2

The distribution of iron in the body of a dog weighing 20 kilograms (Hahn)

	mg	per cent total body iron
Blood hemoglobin iron	900	57
Muscle hemoglobin iron	110	7
Total hemoglobin iron	1010	64
Parenchyma iron (muscle and other tissues)	240	16
Available visceral storage (liver, spleen and marrow)	225	15
Available iron of other tissues (estimated)	75±	5±
Total iron	1550	100

if in high concentration in the intestinal contents continues to be absorbed into the plasma. But the homeostasis of plasma iron is not dependent altogether upon the ferritin mechanism, for even while iron is passing in considerable amounts into the blood, its concentration in the plasma shows little or no rise. This is because it is taken up for the manufacture of hemoglobin by the red bone marrow, and when this has been satisfied, by the reticuloendothelial and parenchymal cells of other tissues where it is stored, especially in the liver and spleen, or utilized in the formation of muscle hemoglobin, respiratory enzymes and other complexes. These compounds, and to a much greater extent, the hemoglobin of effete erythrocytes is continually yielding iron to the plasma. The endogenous iron amounts to about 24 mg daily, and, except for the very small amount that is excreted in the urine, feces and bile, is available for re-use. The level of plasma iron represents the balance struck at any moment between the iron from such sources, together with that absorbed from the intestine, and the iron taken up by the bone marrow and other tissues. Excretion plays a negligible part in the stabilization of the plasma level of iron. Ordinarily, the greater part of the iron in the parenchymal cells is in the form of ferritin, but in the reticuloendothelial cells it is deposited mainly as hemosiderin. Generally speaking, when iron storage increases, the proportion deposited in the tissues as hemosiderin also increases.

An adequate supply of pyridoxin is essential for the normal absorption of iron from the intestine.

The main features of iron metabolism are summarized in the following scheme

Besides its well known function as an essential element in the hemoglobin molecule, and as a constituent of other respiratory pigments, iron appears to play a role in the nutrition of epithelial surfaces. Abnormal nail growth, glossitis, fissures around the corners of the mouth and localized thickening of the mucous lining of the esophagus leading to dysphagia occur in anemias due to iron deficiency, and are cured by iron administration.

It has been calculated by Moore that the adult male loses 0.5 to 1.5 mg of iron per day. This loss is increased by about 0.5 to 1 mg per day in the adult female before the menopause, and during pregnancy the iron requirements of the female are further increased by 1 to 2 mg per day. Children require 0.35 to 0.6 mg per day to build up their iron stores during growth. Since, normally, about 10 per cent of the dietary iron is absorbed, it will be evident that the daily requirement for the adult male, i.e., the amount required to replace the small amounts lost in the excreta and in discarded cells from the skin and gastrointestinal tract, is approximately 12 to 15 mg. It will also be clear that for growing children and for women before the menopause or during pregnancy the requirement for iron will be very considerably increased.

Iron is sometimes given parenterally but it should be remembered that plasma has a limited iron-binding capacity and that the free metal exerts a toxic effect. If this iron-binding capacity is not exceeded, injected ionized iron will combine with the metal-combining protein as does the iron absorbed from the gut. Injected colloidal iron will be taken up by reticuloendothelial cells and will be dealt with much like the iron from hemoglobin breakdown.

The Significance of Copper, Manganese and Cobalt

Copper is believed to act as a catalyst in some stage of hemoglobin synthesis. It does not itself enter into the structure of the hemoglobin molecule. Waddell, Elvehjem, Steenbock and Hart found that in young rats rendered anemic by being placed upon a diet of whole cow's milk, iron alone failed to promote hemoglobin regeneration.⁴ When the iron was supplemented by a very small quantity of copper, blood regeneration was induced. Manganese exerts a similar though less pronounced supplementary effect. The liver is the main storehouse for copper and minute amounts (0.1 to 0.5 mg.) are present normally in blood.

Though anemia due to copper deficiency is unknown in man, a severe and even fatal anemia due to the lack of this metal may occur in farm animals, e.g., the "falling sickness" of South African cattle.

Cobalt has a powerfully stimulating effect upon red cell production and in repeated doses may induce polycythemia. When rats were injected with cobaltous chloride their plasma rather quickly showed a high titer of a factor stimulating erythropoiesis. Cobalt is also an essential dietary constituent for the synthesis of hemoglobin. Experimental animals kept upon a diet adequate in all respects for normal erythropoiesis, except for the absence of cobalt, develop a severe anemia. Cattle and sheep grazing upon land lacking in this mineral become anemic and fail to respond to iron therapy, but are cured dramatically by the administration of traces of cobalt. Cobalt is a constituent of vitamin B₁₂.

Hemochromatosis

This is a disturbance in iron metabolism in which extensive deposits of a colloid iron-containing pigment called *hemosiderin* are found in the cells of the liver, spleen and other tissues. Hemosiderin contains up to 55 per cent of iron, but its exact chemical composition is unknown. The total iron content of the body is greatly increased, it may be 10 times the normal amount. A second yellow pigment known as *hemofuscin* is also sometimes present in the connective and muscular tissues. Other features of the condition are *bronzing of the skin*, *cirrhosis of the liver*, *sclerosis of the pancreas* with diabetes (bronzed diabetes), and some

times testicular atrophy. The disease may appear after repeated transfusions.

Hemochromatosis has been attributed to a high iron content of the diet combined with a deficiency of some essential constituent. A condition resembling hemochromatosis has been reported in Negroes of certain South African tribes who subsist mainly upon a diet of maize and ingest excessive amounts of iron derived from the pots in which the food is cooked. In rats and dogs on a somewhat similar diet, a high absorption of iron was obtained. The low phosphate level of the diet was thought to be a major factor. It is probable that other factors are involved however in hemochromatosis. A patient suffering from hemochromatosis absorbs 20 per cent of a dose of ferrous iron given orally, or more than 10 times the amount absorbed by a normal person. Yet the quantity found in the blood is less than that present in the blood of a normal person receiving such a dose.

Hemosiderosis is the term applied to the deposit of hemosiderin in the tissues which occurs as a result of the excessive breakdown of red cells in malaria and hemolytic types of anemia. It may be looked upon simply as an exaggeration of the normal process of iron deposition.

THE ANEMIAS

Classification

We have seen that in health the population of red cells and the concentration of hemoglobin in the blood are kept at normal levels by a nice balance between the new formation and the wastage of erythrocytes. Anemia results when the balance is tipped one way or the other, i.e., by a defect of blood formation or an increase in blood wastage. Basically, it is a condition in which the hemoglobin level of the blood is reduced below the normal limits. The anemias may be classified broadly into (A) those associated with blood loss or increased blood destruction and (B) those caused by defective blood formation.

A. Anemias caused by blood loss or increased blood destruction

I. Posthemorrhagic anemias

Hemorrhage

a. Acute

b. Chronic, as a result, for example of peptic ulcer, uterine bleeding, ankylostomiasis (hookworm disease), purpura, etc.

II. Hemolytic anemias

Red cell destruction, as a result of

a. Chemical hemolytic poisons, lead, arsenic, ureted hydrogen and certain coal tar derivatives

b. Certain specific infections, e.g., malaria, septicemia

c. Abnormal structure of the red cells which render them more susceptible to phagocytosis or to disintegration in the blood stream, e.g., chronic congenital hemolytic (Lederer's) anemia, and thalassemia (Cooley's anemia, Mediterranean anemia or erythroblastic anemia)

d. An endogenous hemolysin of unknown nature, e.g., chronic congenital hemolytic jaundice and the anemia associated with paroxysmal hemoglobinuria

e. Anti-Rh, and occasionally anti-A and anti-B agglutinins causing hemolytic disease of the newborn

In the hemolytic group the increased blood de-

struction is manifested by a rise in the concentration of bile pigment in the plasma which gives an indirect van den Bergh reaction, a greater excretion of bile pigment and porphyrin in the urine and feces, and the deposit of an iron-containing pigment in the liver and other tissues. There is frequently jaundice of a slight or moderate grade.

Sickle cell anemia is believed to be caused by blood destruction as a result of a congenital anomaly of the red cells. In this type, which occurs almost exclusively in Negroes, elongated crescent or sickle shaped hemoglobin erythrocytes some 15 μ or so in length are a characteristic feature. Such cells are found in the blood of a high percentage of Negroes (8 to 9 per cent) though only relatively few 1 in 40 of these develop anemia. There is also a proportion of Negroes and also a few whites whose red cells become sickle shaped under certain adverse conditions, especially as a result of reduction in the oxygen tension of the blood. This is spoken of as the sickle cell trait and is due to a single sickle cell allelomorphous gene (sickle cell anemia being caused by the presence of two genes). It has been shown by electrophoretic studies that the hemoglobin (probably the globin rather than the heme) of the erythrocytes in sickle cell anemia, in those showing sickle cells but no anemia or those in which sickling can be induced differs somewhat from normal hemoglobin. The abnormal hemoglobin constitutes 100 per cent of the blood pigment in sickle cell anemia 60 per cent when sickle cells are present but there is no anemia and 40 per cent in those in whom sickling can be induced by a low oxygen tension.

Chronic congenital hemolytic jaundice. Synonyms, acholuric jaundice, spherocytic anemia, hereditary spherocytosis, chronic familial jaundice, hemolytic splenomegaly. The chief features of this form of anemia are jaundice and a high incidence of pigment gall stones, spheroid erythrocytes (i.e., the diameter of the cells is reduced but their thickness is increased, their volume being approximately normal), reticulocytosis up to 60 per cent or more of the total red cell population, increased fragility of the cells and enlargement of the spleen. Splenectomy is usually followed by the disappearance of jaundice, a return of the red cell count to nor-

mal and a marked reduction in the reticulocytosis. The spherocytosis gradually disappears and with it usually though not invariably the increased fragility of the erythrocytes. These facts indicate that disordered function of the spleen is not the primary cause of the condition. The cause of the hemolysis is unknown though it may be due simply, as in certain other anemias, to the reaction of the macrophages of the spleen to the defective cells produced by an abnormally functioning bone marrow. Others believe that an endogenous hemolytic agent is responsible, a view which receives support from the experiments of Dameshek and Schwartz in which a hemolytic serum produced by the injection of guinea pig cells into rabbits was employed to produce anemia. The injection of this anti guinea pig hemolytic serum into guinea pigs caused a profound drop in the red cell count and the appearance of cells with spheroid shape, increased fragility and a reticulocytosis. These observers suggest that the greater fragility of the red cells is simply a function of their globular shape and that spherocytosis is a reaction of the bone marrow to excessive destruction of red cells caused by a circulating hemolytic agent. Others have shown that there are changes in the metabolism of the erythrocytes, there being a defect in glycolysis which may be a result of deficient phosphorylation. The administration of glucose diminishes the hemolysis in this condition.

Some divide the disease into two distinct forms—congenital and acquired. Justification for the division is provided by the fact that in the acquired form the patient's cells, after transfusion into a normal person, have a normal life span but normal cells transfused into the patient survive only for about one fourth of the normal time. This points to a hemolysis. In the congenital type the behavior of the cells is reversed, the patient's cells injected into a normal subject are removed rapidly but normal cells persist in the patient's circulation for the usual time. This suggests that in the congenital type the abnormality of the cells is due primarily to some defect of bone marrow function. These experiments were performed by Loutit and Molli son, who consider that in the congenital form the spherocytes are unduly susceptible to normal hemolytic processes, that a hemolysin acting under normal conditions may be lysolecithin, and that the slow movement of blood through the spleen favors the hemolytic action. This would explain the benefit which follows removal of the spleen, as well as why this operation does not always reduce the fragility of the cells.

Lederer's anemia is an acute hemolytic anemia. The leucocytes are increased in number and phagocytosis of red cells may be a pronounced feature. In *Thalassemia major*, or Cooley's anemia there is microcytosis and some of the red cells show concentric rings like a target ("target cells"). The

disease is congenital, being inherited as a Mendelian dominant. With some forms of the disease there may be also splenomegaly and bony changes. It is thought that the fundamental abnormality is a defect in the formation of hemoglobin.

B Anemias due to defective blood formation

I Nutritional anemias

a Iron deficiency—hypochromic, microcytic anemias. The deficiency may be due either to the excessive loss of iron from the body as in chronic hemorrhage or to an inadequate quantity of this element in the diet. The former is the usual cause in adult males, but in infants and adolescents, and in pregnancy or other conditions where the iron requirement is increased, the latter may be a factor. Under some circumstances too, a failure in the absorption of iron may be a cause of the intractability of anemia to iron administration by mouth.

b Protein deficiency, although in itself a less common cause of anemia, is not infrequently a contributory factor.

c Lack of folic acid. In man, lack of vitamin C is a possible factor also and in animals, deficiency of certain other vitamins—pyridoxin, riboflavin, nicotinic and pantothenic acids.

d The macrocytic anemias of sprue and pregnancy are usually classed with the nutritional anemias.

II Lack of or failure in the absorption or in the utilization of the specific antianemic factor (cyanocobalamin, vitamin B₁₂)—Addisonian pernicious anemia and certain related hyperchromic macrocytic anemias with a megaloblastic type of bone marrow. Bone marrow for microscopical examination is obtained by puncturing the sternum, iliac crest or a spinous process with a specially designed styletted needle and aspirating a small sample.

III Macrocytic anemias (hypo- or hyperchromic) with normoblastic or macroblastic bone marrow

IV Toxic agents which induce aplasia of the bone marrow or depress its function—aplastic anemias. Among such agents are quinine, gold salts, benzol, arsenamine, radium, X rays, and sometimes bacterial and syphilitic toxins. The red marrow is greatly reduced in amount, being replaced by fatty tissue. Blood formation is pro-

foundly depressed. Anemia of the aplastic type may also result from exhaustion of the bone marrow following a long period of overactivity induced by some other type of anemia, or may appear without a known cause (*idiopathic aplastic anemia*).

- V. *Infections*—the anemia accompanying infection is usually a mild, normocytic, normochromic type. As a rule, hemolysis is not a factor. The exact defect is not clear but there is a decreased production of hemoglobin associated with decreased absorption of iron, decreased β_2 metal-combining globulin of plasma and a decreased plasma iron level.

The cause of *splenic anemia* (Banti's) is unknown, it is therefore difficult to fit this type into any of the preceding categories. According to some there is increased blood destruction, but important factors appear to be depressed marrow function and the loss of blood resulting from repeated gastrointestinal hemorrhages. An anemia very closely resembling Addisonian or true pernicious anemia results from infestation with the fish tape worm, *Diphylllobothrium latum*. Some believe that an important factor in its causation is the competition of the parasite for vitamin B₁₂.

Blood indices. The following indices calculated from the hemoglobin concentration, red cell count and packed cell volume of a specimen of blood are employed to express the characters of the individual cells in the different types of anemia.

The color index. This is a numerical expression of the hemoglobin content of the individual red cells. It is obtained by dividing the hemoglobin value in grams per 100 cc. by the red cell count, both values being expressed as percentages of the normal. (The normal weight of hemoglobin per 100 cc. is taken as 14.5 grams and the red cell count as 5,000,000.) Thus, if the hemoglobin is 60 per cent of normal and the red cell count 50 per cent, then $60/50 = 1.2$ color index. But if the hemoglobin percentage is reduced to a greater degree than the red cell percentage the index will be less than unity. That is, each red cell contains less than its normal quota of hemoglobin. On the other hand, the hemoglobin concentration of the blood may be greatly reduced but if the reduction runs parallel with the reduction in red cell percentage the index will have the normal value of 1.0.

Mean corpuscular volume (M.C.V.) This expresses the volume of the individual red cell in μ^3 (1 ml. = $10^{12} \mu^3$). The mean corpuscular volume in μ^3 is obtained by dividing the volume of packed cells expressed in ml. per liter by the red cell count in millions per cu. mm. (e.g., $\frac{450}{5} = 90$).

Anemias may be classified according to the

M.C.V. as macrocytic (over 96), normocytic (86 to 96), and microcytic (under 86).

Mean corpuscular hemoglobin concentration is the hemoglobin in grams per 100 ml. of blood divided by the packed cell volume per 100 ml., expressed as a percentage (e.g., $\frac{15}{45} \times 100 = 33$ per cent).

This value is never greater than normal but may be normal (above 30 per cent, normochromic) or less than normal (below 30 per cent, hypochromic).

Mean corpuscular hemoglobin (M.C.H.) is the hemoglobin per red cell expressed in $\mu\mu\text{g}$ (10^{-12} g). This may be obtained by dividing the hemoglobin in grams per liter by the red blood cell count in millions per mm.³ (e.g., $\frac{150}{5} = 30 \mu\mu\text{g}$). The mean

corpuscular hemoglobin may vary with the concentration of hemoglobin within the cell and with the volume of the cell.

Attempts have been made to estimate the *total erythropoietic activity* of bone marrow from the erythroid myeloid ratio, plasma iron turnover and fecal urobilinogen, and the *effective erythropoiesis* (i.e., the proportion of cells produced by the bone marrow that are delivered into the circulation), by means of erythrocyte count, and by the uptake of radioactive iron by the red cells. It has been found that the effective erythropoiesis can be increased three times in acute anemia, and six times in chronic anemia.

Hypochromic Microcytic Anemias—Iron Deficiency

In this group the essential defect is one of hemoglobin formation. The hemoglobin percentage of the blood is reduced to a greater extent than the number of red cells. These, indeed, may show only a slight reduction. The color index and M.C.H. are considerably below the normal, which means that each red cell has received less than its normal quota of pigment. The erythrocytes are also smaller than normal, so the M.C.V. is also low. The low M.C.H. is in part the result of the smaller size of the red cell but also of a reduced concentration of pigment throughout the red cell's substance. Some of the corpuscles are so pale that they resemble "ghosts" or only the peripheral zone of the cell is colored (anisochromasia) (see figs 9.1 and 9.2, and frontispiece).

Iron deficiency is considered to be the essential cause of the anemias belonging to this class. The deficiency may result from increased iron requirements coupled with an inadequate amount of iron in the diet or from defective absorption of the metal from the food but the usual cause, in adult males, is blood loss.

FIG 91 Red cell diameter distribution curves in simple achlorhydric anemia and in pernicious anemia compared with the normal (after Haden, see also fig 92)

FIG 92 Red cell diameter thickness and volume in various clinical conditions compared with the normal (after Haden) D, diameter T, thickness V volume

Hypochromic anemia occurs most frequently in women of childbearing age when there is a dietary deficiency, especially of iron. The anemia is aggravated by the losses of iron incident to menstruation or repeated pregnancies. Davidson has recently emphasized the need for larger amounts of iron during this period in women. In the previous chapter, iron loss and iron requirements have been discussed.

ANEMIA OF INFANTS

The fetus accumulates a store of iron in the liver in the later months of gestation. This serves as a reserve that is drawn upon for the manufacture of hemoglobin in infancy. The high red cell concentration (p 12) with which the infant comes into the world also contributes to the iron reserves. In the normal infant the iron stores are

sufficient for the manufacture of hemoglobin for the first six months or so. Growth, however, makes heavy demands upon the iron supplies and after the first half year it is necessary to provide a diet which will contain adequate amounts of iron in order to guard against the development of anemia of the hypochromic type. Milk, it will be recalled, is very poor in both iron and copper. The iron content of milk is doubled by the pasteurization process and tripled in the drying or evaporation processes. The development of anemia in milk fed rats has been mentioned and the anemia of sucklings is a problem in the breeding of farm animals. If the iron stores are deficient at birth as in premature infants or as a result of maternal anemia, anemia may occur in the very young infant.

The hypochromic anemias respond in a spectacular fashion to the administration of inorganic iron (e.g., ferrous chloride, ferrous carbonate, etc.). The administration of copper is rarely necessary since this occurs in sufficient quantity in the diet and as an impurity in iron preparations.

A macrocytic anemia with a megaloblastic type of bone marrow also occurs in infants. It responds to vitamin B₁₂ and to folic acid. It is frequently accompanied by leukopenia and splenomegaly.

Pernicious Anemia (Addison's Anemia) and Related Macrocytic Anemias

Pernicious anemia is due essentially to a defect in the formation of the red blood cells.

CHIEF FEATURES of the blood picture are

1 *Great reduction* in the number of red cells and consequently in the hemoglobin percentage. The blood count in a very severe case may be less than 10 per cent of the normal.

2 The red cells are reduced in number below the normal to a greater extent than is the hemoglobin percentage. The MCV and MCH are therefore raised above normal. The high MCH is due to the greater size of the cells.

3 *Large cells*—the average diameter of the cells is increased to between 8 and 9 μ and exceptionally large cells called macrocytes are plentiful. The average volume of the individual red cells (figs 91 and 92) is about 135 μ^3 (normal about 90 μ^3). Normoblasts and earlier forms are present in the circulation and a characteristic large nucleated cell containing basophilic material in its cytoplasm and little or no hemoglobin is a feature of the blood picture. This cell, known as the megaloblast, differs chemically and morphologically from any normal cell of the erythrocyte series found either in bone marrow or blood. The reticulocytes are around 3 per cent.

Samples of bone marrow obtained by sternal puncture

A Normal

- 1 Erythrocytes
- 2 Erythroblasts
- 3 Early normoblast
- 4 Neutrophil leucocyte
- 5 Eosinophil leucocyte
- 6 Neutrophil metamyelocyte
- 7 Basophil metamyelocyte
- 8 Eosinophil metamyelocyte
- 9 Neutrophil myelocyte
- 10 Myeloblast
- 11 Hemocytoblast
- 12 Lymphocyte
- 13 Late normoblast
- 14 Megakaryocyte

B In pernicious anemia

- 1 Megaloblasts
- 2 Late normoblast
- 3 Giant neutrophil leucocyte
- 4 Erythroblast
- 5 Erythrocytes (macrocytes)
- 6 Megaloblast in mitosis

C In microcytic anemia due to iron deficiency

- 1 Early normoblast
- 2 Erythrocytes (microcytes)
- 3 Extruded nucleus from normoblast
- 4 Late normoblasts
- 5 Eosinophil leucocyte
- 6 Myelocyte
- 7 Neutrophil leucocyte

4 The total number of leukocytes is reduced but the lymphocytes are relatively increased

5 Great variation in the size of the cells—*anisocytosis*, the cells varying from those smaller than normal to the large cells mentioned above *Poikilocytes* are moderate in number

6 Increase in iron and bilirubin of the plasma, increased excretion of pigment (urobilin)—in direct van den Bergh

7 Blood volume reduced mainly as a result of the red cell diminution, the plasma volume being around the normal level

8 Fragility of the red cells usually slightly reduced

OTHER FEATURES

1 The red bone marrow is hyperplastic. It extends into the shafts of the bones displacing the yellow marrow and even the bony walls may be eroded. Upon microscopical examination the marrow shows megaloblasts and other immature forms in large numbers (see ch. 11 and Plate I)

2 Achlorhydria almost always exists

3 Sore shiny tongue, *glossitis*, atrophy of lingual papillae

4 Chronic combine degeneration of the cord

5 There is an atrophy of the mucosa of the fundus and body of the stomach

6 Urobilin appears in the urine in severe cases, and in all those in which plasma bilirubin is increased urobilinogen is in excess in the feces. In health from 1/140 to 1/340 of the total amount of hemoglobin in the blood is excreted daily as urobilinogen. In pernicious anemia 1/10 of the total hemoglobin may be excreted as urobilinogen. Hemosiderin deposits (p. 70) occur

7 The disease shows remissions and relapses. During the remissions, the blood picture approaches the normal and the percentage of reticulocytes increases—*reticulocyte crises*. During the relapses, the characteristic hematological features of the condition are exaggerated

The essential factor in the production of pernicious anemia is not believed to be increased blood destruction, but rather a defect in blood formation. Increased blood destruction undoubtedly occurs as evidenced by the rise in plasma bilirubin, but it is a secondary effect. The abnormal erythrocytes probably stimulate the phagocytic activities of the reticuloendothelial cells in the spleen, liver and elsewhere. Since the fragility of the red cells is reduced rather than increased it would not appear that they disintegrate more readily in the blood stream. The discovery of an antianemic principle in liver and subsequent researches arising from the employment of this principle in the treatment of pernicious anemia

have shed a flood of light upon the nature of the disease

LIVER, LIVER EXTRACT, GASTRIC TISSUE AND THE ANTIANEMIC FACTOR

In 1926 Minot and Murphy, inspired by the laboratory finding of Whipple and his associates, namely, that liver was the most effective article of diet for the treatment of anemia in dogs, tried the effect of adding liver to the diet of pernicious anemia patients. The spectacular success which followed this treatment is well known and today lightly cooked liver (from $\frac{1}{2}$ to 1 pound per day) but preferably an extract of liver, or the essential principle, vitamin B_{12} , is recognized as a specific for the disease. Kidney tissue was shown to have a similar though less pronounced curative effect. The hematopoietic substance present in the liver and in nonprotein extracts of liver tissue and which is effective in the treatment of pernicious anemia is known as vitamin B_{12} , or cyanocobalamin and formerly as the antianemic or hematonic principle. The action of vitamin B_{12} is several times more potent given parenterally than when given orally. It may be mentioned here that Wilkinson found that the antianemic principle was present in normal human liver and in the livers of pernicious anemia patients who had received specific treatment, but was absent from the livers of untreated subjects of the disease.

The Chemical Identification of the Antianemic Factor, B_{12}

In 1948 Rickes and his associates and Smith reported the isolation of red, needle-shaped crystals of a substance which was many times more potent than the most purified extracts of liver in the treatment of pernicious anemia, causing a reticulocyte response in pernicious anemia patients in a parenteral dose of 1 μ g, or even less. The red crystalline material, now generally referred to as vitamin B_{12} , has since been shown to be a cobalt complex, and is apparently the antianemic factor in pure or nearly pure form. It also contains phosphorus and nitrogen, but no sulfur. Its molecular weight is around 1350 and its formula is $C_{64}H_{90}O_{14}N_{14}PCo$. Its chemical designation is cyanocobalamin.

Several analogues of this compound have been obtained from bacterial cultures, from the gastrointestinal contents of animals and from feces, sewage, etc.

It may be mentioned that the cobalt ion by it

self elicits no hemopoietic response in pernicious anemia

Besides its importance in hemopoiesis and its action in promoting the growth of certain bacteria, vitamin B₁₂ is a growth factor for higher animals, including man. It also has an influence upon the metabolism of certain sulfur containing amino acids (e.g., conversion of homocystine to methionine). According to Niewig, vitamin B₁₂ is essential for the synthesis of ribonucleic acid, a constituent of the nuclei of all cells, this would account for the neurological defects in pernicious anemia, and for the abnormalities of certain epithelial surfaces, such as that of the tongue (so the production of glossitis), as well as for the failure in erythrocyte maturation.

Vitamin B₁₂ is by far the most potent hemopoietic principle known, being several thousand times more potent weight for weight than folic acid. B₁₂ is also effective in arresting the course of the neurological lesions of pernicious anemia.

The Production of the Antianemic Principle, Intrinsic and Extrinsic Factors

As already mentioned, irreversible gastric atrophy occurs and achlorhydria is virtually an invariable accompaniment of pernicious anemia. The significance of this fact was demonstrated in 1929 by Castle who found that the gastric contents of a normal person during the digestion of meat were curative when fed to a subject of pernicious anemia. Later Castle and his associates showed that pure gastric juice obtained from a normal person by the administration of histamine when incubated with beef steak produced the curative material. The active principle was not produced when beef was incubated with gastric juice of a patient with pernicious anemia. The production of the anti anemic principle is not due to the action of hydrochloric acid, pepsin, rennin or lipase but to the presence of an enzyme-like but unidentified substance which acts at a pH of 7 (the optimal pH for the action of pepsin is 1.6). Before this, Sturgis and Isaacs found that gastric tissue contained the material necessary for the formation of the antianemic factor, it being, like liver itself, effective in the treatment of pernicious anemia. Desiccated defatted hog stomach is, therefore, also employed as an alternative to liver or liver extract for oral administration. The gastric factor is less stable than the liver principle, being destroyed by temperatures above 45°C or by digestion with pepsin or trypsin. In the hog, the gastric factor is produced by the mucosa of

the pyloric and cardiac regions of the stomach and the commencement of the duodenum, i.e., regions which secrete an alkaline juice (pyloric, cardiac and Brunner's glands). In the human subject the factor, according to Fox and Castle, is formed in the fundus and body of the stomach, none is found in the pyloric region nor in the duodenal secretions.

Two factors, therefore, were recognized as being essential for normal erythropoiesis: one in the food, especially in such items of diet as are rich in the vitamin B complex, it was called the *extrinsic* factor and for years eluded the keenest research, but was finally identified as vitamin B₁₂, the other factor is secreted in the gastric juice and is known as the *intrinsic* factor.

A characteristic lesion is found in pernicious anemia which readily explains the achlorhydria and the lack of the intrinsic factor. The fundus and body of the stomach show atrophy of the mucosa and extreme thinning of all coats. The gastric glands are almost completely destroyed, the muscular coat is atrophic. The pyloric region which does not produce the intrinsic factor is normal. One would be led to expect that total gastrectomy in man would be followed by pernicious anemia. If the survival time following total gastrectomy is sufficient to permit exhaustion of the vitamin B₁₂ stores an anemia of the pernicious type develops.

The Extrinsic Factor, the Action of the Intrinsic Factor

The extrinsic factor (vitamin B₁₂) is present in liver, beef, rice polishings, yeast, and other substances rich in the vitamin B complex. It is also found in the intestinal contents of normal persons, as well as in the feces of patients with pernicious anemia. There is, therefore, no reason to believe that a dietary deficiency of this factor is the cause of the disease. The basic defect in pernicious anemia is the failure of the gastric mucosa to produce, at least in effective amounts, the intrinsic factor. It is now believed that this factor is essential for the adequate absorption of vitamin B₁₂. This may involve some combination with the vitamin or it may influence some specific process in the gut wall involved in the absorption of the vitamin. When the intrinsic factor is given, the fecal excretion of vitamin B₁₂ labelled with radioactive cobalt is reduced. There is also the possibility that the intrinsic factor by binding vitamin B₁₂ keeps it from being taken up by the intestinal bacteria, thus ensuring that it will be available for absorption. In the absence of the intrinsic factor there is 'starvation in the midst

of plenty" in so far as the extrinsic factor is concerned. For this reason B_{12} is effective given parenterally in pernicious anemia in a fraction of the dose that is required by mouth. However, if B_{12} is administered with normal gastric juice the size of the effective oral dose is much reduced. In concluding this section the following remarks of Castle may be quoted:

"The disease would not develop if the patient could effect daily the transfer of a millionth of a gram of vitamin B_{12} the distance of a small portion of a millimeter across the intestinal mucosa and into the blood stream. This he cannot do, principally as a result of failure of his stomach to secrete into its lumen some essential but still unknown substance. Yet the patient may each day absorb without much difficulty the products of the digestion of many grams of carbohydrate, fat and protein from foods that in addition may contain consequential amounts of vitamin B_{12} in terms of his trivial need."

Other Megaloblastic Anemias

Though pernicious anemia is the most common type of anemia showing a megaloblastic bone marrow, there are other forms with closely similar marrow and blood pictures but whose pathogenesis are not altogether clear. Such megaloblastic anemias occur in tropical sprue, pregnancy, carcinoma of the stomach, gastrocolic fistula in which short circuits the region of the small intestine from which B_{12} is absorbed, and infestation with the tapeworm, *Diphyllobothrium latum*. The anemia of sprue, in which the absorption of fat is defective, is due possibly to the interference with the absorption of vitamin B_{12} other than through a lack of the intrinsic factor, though in certain cases the latter is absent even though there is not achlorhydria. In the megaloblastic anemia of pregnancy the marrow and blood pictures are similar to those of pernicious anemia, but there is as a rule not true achlorhydria, nor degenerative changes in the spinal cord, recovery follows childbirth. Also many cases of this disease, like that described by Wills as occurring in the tropics, and called *tropical nutritional* (or *macrocytic*) *anemia*, are unresponsive to the administration of vitamin B_{12} , but respond readily to crude liver extracts or to folic acid. In carcinoma of the stomach there is achlorhydria and the anemia may be indistin-

guishable in every way from pernicious anemia, even to the neurological symptoms, it is probably produced in the same manner—lack of the intrinsic factor. In the anemia caused by *Diphyllobothrium latum*, there is no lack of the intrinsic factor, but the worm interferes in some way with the utilization of the vitamin. Possibly this is caused by the parasite producing a principle that inhibits the specific action of the intrinsic factor, or by its absorbing or utilizing the vitamin in its own metabolism. The investigations of von Bonsdorff indicate that the parasite must be situated high up in the small intestine in order to cause anemia. Finally, a rare type of megaloblastic anemia which fails to respond to the hematologic principle was described originally by Wilkinson and Israels. It is not due to the lack of the erythrocyte maturation factor (B_{12}), but to failure of the latter to be utilized by the bone marrow. It was, therefore, named *achrestic anemia*.

The Response to Liver or Gastric Tissue

The antanemic principle acts upon the bone marrow, restoring the blood forming processes to normal. It is believed that megaloblastosis is not the result of a simple arrest of the maturation of red blood cells, but that the megaloblasts result from a long resting phase between stages of mitoses. Hence factors retarding cell division can lead to the production of this type of cell. The slow cell production results from the deficient for-

FIG 93 Showing effect of specific liver therapy upon the reticulocytes, erythrocytes, hemoglobin and plasma bilirubin (after Dyke)

"Tropical nutritional anemia occurs most frequently and severely in pregnant women. An anemia with similar characters which is resistant to treatment with purified preparations of liver, but is amenable to crude liver extracts or folic acid can be produced in monkeys

mation of DNA (deoxyribonucleic acid) and RNA (ribonucleic acid) which is a consequence of a lack of vitamin B₁₂. The direct effect of B₁₂ upon erythropoiesis has been demonstrated in man, when the vitamin is injected into megaloblastic bone marrow, the abnormal erythropoiesis is corrected locally before a general effect occurs (i.e., on the marrow in other situations).

The first detectable effect of specific treatment in pernicious anemia is a rise in the reticulocytes. In untreated cases of pernicious anemia these constitute 2 per cent or less of the red cells. Within 2 to 5 days after vitamin B₁₂, a potent liver extract, or a preparation of gastric tissue has been administered, large numbers of reticulocytes appear. The increase reaches its maximum about the fifth day, when the percentage is from 10 to 40 per cent. From then on the reticulocyte population declines, and there is an increased number of mature erythrocytes. The lower the red cell count before treatment, the greater is the reticulocyte response to specific therapy.

The rise in the hemoglobin concentration of the blood lags behind the multiplication of the red cells. If the stimulus to erythropoiesis is intense, the hemoglobin cannot be manufactured in suffi-

Pteroylglutamic Acid. Synonyms: Folic Acid, Vitamin B₉, Liver *Lactobacillus casei* Factor, Norite-eluate Factor, Vitamin M, Wills Factor, Factor U.

In 1941 Mitchell and his associates obtained a substance with acidic properties from the green leaves of various plants, e.g., spinach, peas, clover, etc., and gave it the appropriate name of *folic acid*. What has since proved to be the same principle had previously, from microbiological studies, been found in concentrates of liver and yeast (*norite-eluate factor*). It stimulates the growth of certain microorganisms, e.g., *Lactobacillus casei*, *Streptococcus faecalis* R (or *S. lactis* R), and is essential for the existence of certain protozoa and insects. It is, therefore, also known as the *liver L. casei factor*, but is now more commonly referred to by its chemical name *pteroyl glutamic acid* (PGA). It is made up of a pteridyl ring joined through para-aminobenzoic acid to a molecule of glutamic acid. Para-aminobenzoic (PAB) acid appears to be a precursor from which pteroylglutamic acid is synthesized in nature. The chemical structure of pteroylglutamic acid is shown below.

Pteroylglutamic acid N [4 [(2-amino-4-hydroxy-6-pteridyl) methyl] amino] benzoyl glutamic acid

cient quantities to furnish each cell with its quota of pigment and the color index and MCH fall well below the normal value.

With the improvement in the blood picture the general symptoms of the disease abate, but the secretion of acid gastric juice is rarely if ever restored. Specific treatment therefore does not remove the primary cause of the disease, but must be persisted in for the rest of the patient's life. The maintenance dose is, of course, much less than that required originally for the restoration of the normal blood picture. The neurological symptoms may improve if vitamin B₁₂ is given early, and in a dosage considerably greater than that required for maintaining the normal blood picture. The degenerative changes in the cord are due to the lack of the hematinic principle, and are not simply secondary to and caused by the anemia.

Of fundamental importance in the physiology of pteroylglutamic acid is its indispensability for the synthesis of deoxyribonucleic acid, a constituent of the nuclei of all cells (ch. 47). Certain analogues of folic acid, such as *aminopterin* (4-aminopteroylglutamic acid, or 4-aminofolic acid), *amethopterin* (4-amino-10-methyl pteroylglutamic acid) *aminoan-fol* (4-aminopteroylispartic acid) antagonize this action of the vitamin. Pteroylglutamic acid is synthesized in the intestine of some mammals, especially of the rat, and the analogues are useful in producing folic acid deficiency for experimental purposes. They have also been used in the treatment of acute leukemia, especially in children, the number of leukemic cells is reduced, and temporary remissions of the disease induced. A permanent cure does not, however, result, and the administration of the compounds is attended by certain toxic symptoms, e.g., stomatitis, diarrhea, alopecia and deafness.

THE HEMOPOIETIC ACTION OF PTEROYLGLUTAMIC ACID

Several observations had pointed to the existence in liver or in crude liver preparations of a principle effective in certain macrocytic anemias which failed to respond to highly purified liver extracts. There also appeared reports of a beneficial action of preparations of brewer's yeast, which does not contain vitamin B₁₂, in macrocytic anemias and in the nutritional anemia of monkeys. Suspecting that the unknown hemopoietic substance in crude preparations of liver was folic acid, Spies and his associates administered it to pernicious anemia patients with remarkable success. Pteroylglutamic acid is also effective in other anemias characterized by a megaloblastic bone marrow, e.g. the anemias of sprue and pregnancy, but fails in the treatment of macrocytic and other types of anemia with a normoblastic or macrolastic bone marrow. It relieves the nutritional leukopenia of monkeys and stimulates the production of granulocytes and is therefore of value in the treatment of agranulocytosis (p. 96). It has no effect whatever in arresting the progress of the neurological lesions (chronic combined degeneration of the cord) in pernicious anemia. Indeed, the neurological signs appear to be aggravated by its administration. Its action in restoring the bone marrow to normal is identical with that of the vitamin B₁₂.

Pteroylglutamic acid was synthesized by Angier and associates in 1945. The synthetic compound is as therapeutically effective as the natural principle.

The chief sources of folic acid are liver, kidney and green vegetables; its concentration in plant foods appears to run parallel with their chlorophyll content.

THE POSSIBLE RELATIONSHIP OF THE ANTI- ANEMIC FACTOR OF LIVER AND PTEROYLGLUTAMIC ACID

The chemistry and actions of folic acid and of the antianemic factor of liver show that they are separate and distinct principles. Moreover, it soon became evident that the concentration of folic acid in highly purified and potent liver extracts is equivalent to only a small fraction of the amount required to elicit a reticulocyte response in pernicious anemia. Again, as mentioned above, pteroylglutamic acid is wholly ineffective in arresting the cord changes of pernicious anemia. The nonidentity of the two principles was finally settled by the isolation of crystalline B₁₂.

Both vitamin B₁₂ and folic acid seem to be essential in the synthesis of nucleoproteins. It is thought that folic acid is necessary for DNA formation, but that vitamin B₁₂ is essential for both DNA and RNA synthesis. Since both DNA and RNA are necessary for the maintenance of the structure and function of neurons, this may explain why B₁₂ is effective in improving the neurological condition in pernicious anemia and folic acid is not.

Citrovorum factor *folic acid* *leucovorin*. A derivative of pteroylglutamic acid which promoted the growth of the microorganism *Leuconostoc citrovorum* was isolated in 1948 by Sauberlich and Baumann from liver extracts and yeast. This substance, which is now known as the *citrovorum factor*, has an action similar to that of pteroylglutamic acid in pernicious anemia and other megaloblastic anemias; it also annuls the toxic effects of such folic acid antagonists as aminopterin and amethopterin. Substances with the same action and apparently identical with the *citrovorum factor* have been prepared artificially and named *folic acid* (Shive and associates) and *leucovorin* (Jukes and associates).

Other antianemic agents. The pyrimidine base *thymine* (5-methyluracil) and *xanthopterin* (uropterin) give a hemopoietic response, but one which is much inferior to that of pteroylglutamic acid. An amount of thymine several thousand times the weight of an effective dose of pteroylglutamic acid is required to produce a reticulocyte response in pernicious anemia (Spies and associates).

Macrocytic (Hypochromic or Hyperchromic) Anemias with Normoblastic Bone Marrow

Macrocytic anemias showing a resemblance to Addisonian anemia, in so far as the blood picture is concerned, occur in various diseases, e.g. carcinoma (other than gastric), syphilis, etc. But the bone marrow is of the normoblastic type. Since they are not due to deficiency of the antianemic principle, they do not respond to the administration of liver extract or of gastric juice. Nor do they respond to the administration of folic acid.

Idiopathic Aplastic Anemia

This is a comparatively rare type of anemia in which there is a rapidly progressive reduction in all the blood cells—erythrocytes, leukocytes and platelets. There is little or no evidence of blood regeneration; reticulocytes are very scarce and nucleated forms are usually absent. The red cell count may reach an extraordinarily low figure—213,000 per cu. mm. in a case reported by Ehrlich.

Granulocytes and platelets may entirely disappear. The marrow is hypoplastic or aplastic, there is a great reduction in its cellular elements and almost complete absence of hemopoietic activity. The lymphocytopenia which also occurs, but is less marked than the reduction in granulocytes, suggests that the entire hemopoietic system is affected. The causes of the bone marrow hypoplasia have been mentioned.

A number of cases have been reported (Thompson, Richter and Edsall, Anderson) in which the typical blood picture of splastic anemia was associated with a normal or even a hyperplastic marrow. In these, to which the term "pseudoplastic anemia" might be applied, there would appear to be some interference with the maturation and delivery of the cells into the blood stream rather than to absolute suppression of marrow function.

Conclusions

It is only upon pernicious anemia or macrocytic anemias of the pernicious anemia type with a megaloblastic bone marrow that vitamin B₁₂ or "folic acid" therapy has any specific effect. Other macrocytic types (with a normoblastic type of marrow), the microcytic anemias and aplastic anemias fail to respond to the administration of liver extract, gastric tissue or pteroylglutamic acid. It has been mentioned that certain megaloblastic anemias (e.g., that of pregnancy) are resistant to the action of vitamin B₁₂ but respond to folic acid. In posthemorrhagic anemia and certain other secondary anemias *whole liver* is of value, not from any specific action but simply because it furnishes iron and protein of high quality.

THE WHITE BLOOD CORPUSCLES OR LEUKOCYTES— THE PLATELETS

Classification and Morphology

The white blood cells differs from the erythrocyte in that it contains no hemoglobin and has a nucleus. The majority of the white cells are also considerably larger than the erythrocytes, measuring from 8 to 15 μ in diameter, the size depending upon the particular variety. They are much less numerous than the red cells, in the adult they number from 5000 to 9000 per cu mm of blood. In infancy they are twice as numerous and throughout childhood the count is higher than in the adult. When a film of adult blood is examined under the microscope the white cells appear very sparsely scattered here and there among the crowds of colored corpuscles which outnumber them more than 600 to 1.

On a basis of morphological differences the colorless corpuscles are divided first into two main groups (I) Cells with a single nucleus and a clear nongranular cytoplasm—the lymphocytes and the monocytes, (II) cells having a lobed or incompletely partitioned nucleus and a cytoplasm containing fine chromophil granules—the granulocytes. Each of these two main classes is divided further into subgroups on a basis of differences in structure or staining properties¹ (see frontis piece).

I THE NONGRANULAR LEUKOCYTES— AGRANULOCYTES

These are of three varieties (1) *Small lymphocyte*, (2) *large lymphocyte*, (3) *monocyte*. Although these forms show no granules in the protoplasm under the ordinary methods of staining granulation may be demonstrated after staining with azure blue. The lymphocytes contain a few coarse azurophil granules, those of the monocytes are fine and very numerous.

¹ The term leukocyte is employed by most authors to denote all the white cells, and this from the simple meaning of the word seems logical. Some, however, confine the term to the granulocytes. The first of these usages will be followed in this text.

1 **SMALL LYMPHOCYTES** These are slightly larger than the red cells—about 8 μ in diameter. The nucleus is relatively large, slightly indented and stains more deeply with basic dyes than the surrounding narrow rim of cytoplasm which separates it from the boundary of the cell. The small lymphocytes originate in lymphoid tissue and are found in large numbers in the lymph nodes and spleen. They constitute in the adult from 20 to 25 per cent of the total number of white cells in blood and are the commonest cells found in lymph. In childhood lymphoid tissue is much more abundant than in adult life and the lymphocytes are more numerous. They amount to from 50 per cent or more of the leukocytes in early childhood and to about 35 per cent at the age of 10 years.

2 **LARGE LYMPHOCYTES** These resemble the preceding in general appearance but are considerably larger, being 12 μ or more in diameter. The cytoplasm forms a wider zone about the nucleus which is oval or kidney shaped. These cells are found in insignificant numbers in adult blood but are more plentiful in the blood of young children. They are largely confined under physiological conditions to the lymphoid tissue, but even here they are greatly outnumbered by the small lymphocytes. They are considered by many as a younger form of the small lymphocyte.

3 **MONOCYTES** are from 10 to 15 μ in diameter. They possess a relatively larger amount of cytoplasm. The nucleus has a deep indentation on one side, which gives it a kidney or saddlebag shape. On the supposition that this cell represented a stage in the development of the polymorphonuclear leukocyte, it was called the 'transitional leukocyte' by Ehrlich. This view has since been shown to be wrong for the monocyte bears a relationship to the lymphocytes rather than to the polymorphonuclears. It has been mentioned that the monocyte contains like the lymphocytes, azurophil granules in the cytoplasm. The monocytes are actively motile and phagocytic, and are considered by most observers to be derived from fixed histiocytes (p. 102). Such an origin would

class them as circulating elements of the reticulo-endothelial system. According to Maximow, however, they arise from lymphocytes. They constitute from 5 to 7 per cent of the white cells.

Small numbers (0.2 per cent) of a slightly different type of monocyte are also found in blood. Its nucleus instead of being kidney shaped is round or oval. It was previously known as the large mononuclear leukocyte, but it is probably simply a younger form of the preceding variety.

II THE GRANULOCYTES

These are divided into three groups according to the staining reactions of their granules. One type—the *eosinophilic*—stains with acid dyes, e.g., eosin, another—the *basophilic*—stains with basic dyes, e.g., methylene blue, and the third type—the *neutrophilic*—with neutral dyes, i.e., mixtures of acid and basic dyes. These staining reactions apply to human leukocytes, but such distinctions cannot always be made in other animal species. The nucleus of a granulocyte is composed of two or more lobes connected together by strands of chromatin.

1. **Eosinophils** are not numerous, they amount to no more than 2 to 4 per cent of the total white cell count. The granules which are oval and much coarser than those in the other two varieties are stained a bright red with eosin. The cell is also slightly larger and the nucleus usually bilobed. In certain pathological conditions which will be mentioned later they may form a much larger percentage of the leukocyte population.

2. **Basophils** are present to the extent of only

0.15 per cent or less. Their granules stain deeply with methylene blue. Their significance is not known. They have been considered by some observers to be degenerated neutrophils, but there appears to be little doubt that they are a distinct type and like the other granulocytes are a product of the bone marrow. Support is lent to the latter view by the fact that they are increased in conditions associated with excessive marrow activity, e.g., chronic myelocytic leukemia and polycythemia vera. They are also increased in chronic inflammation of the accessory nasal sinuses.

3. **Neutrophils** are by far the most numerous, constituting from 65 to 70 per cent or more of the total number of white cells. Their granules are quite small and are stained a violet tint with neutral dyes. As will be seen presently the neutrophils are actively ameboid in character, i.e., they are capable of locomotion and ingest foreign particulate matter. They are about 10 or 12 μ in diameter. Their nuclei show a variable number of lobes depending upon the age of the cell.

The Arneth Count or Index

It was pointed out by Arneth that the number of lobes in any neutrophil depends upon the cell's age—the older cells having the larger number.¹ A five-lobed nucleus for instance indicates a stage in the life of a cell just preceding its final dissolution, an unlobed but deeply indented nucleus a very young cell. Five stages in the life history of this polymorphonuclear leukocyte are therefore distinguished corresponding to the number of lobes developed in the nucleus. A count of the nuclear lobes in the cells of a blood film will give the proportion of cells of different relative ages. In figure 101 stage I shows a nucleus with a single lobe. Constriction of the nucleus can be seen but the nuclear substance is continuous from one part to the other. In stage II the nucleus is partitioned into two parts which are connected only by chromatin threads. In the next stage 3 lobes are seen and so on to the last or senile stage in which the nucleus has five or more lobes. The cells of this stage are large, edematous and nonmotile, their granules stain poorly or not at all. In some conditions, e.g., acute septic infections and pernicious anemia, enormous neutrophils (up to 20 μ) with a great number of nuclei are seen. These are known as *macropolycytes*.

The Arneth index is determined by counting the number of nuclear lobes in each of 100 neutrophils. The cells in the different stages are expressed as

FIG 101 Arneth stages

¹ The extent of the previous activity of the cell rather than its age may be the important factor determining the number of nuclear lobes.

percentages of the total. The count under the ordinary conditions of health is as follows:

	Percentages of leukocytes
Stage I	5
Stage II	30
Stage III	45
Stage IV	18
Stage V	2

In certain diseases the youngest cells (stage I) are much more numerous and may constitute 50 per cent of the total. There may be an entire absence of cells in the later stages (IV and V). An increase in the percentage of cells of the earlier stages is spoken of as a 'shift to the left'. It is seen in conditions which stimulate the bone marrow to a greater production of white cells, e.g., pyogenic infections. It is also seen in tuberculosis and after exposure to the X rays and after the injection of thyroid extract. In children a shift to the left occurs much more readily than in adults. In pernicious anemia the percentages of the older cells increase—"shift to the right"—and in some cases, as mentioned above, macropolyocytes appear. Except in the case of the senile nonmotile cells a relationship between the phagocytic activity of a particular cell and its age has not been demonstrated.

The Schilling index employs a simpler classification of the neutrophils but includes marrow elements. Four stages are recognized (see table 10 1): (a) the myelocyte which shows a single spherical nucleus, (b) young metamyelocyte with a slight indentation of the nucleus, (c) older metamyelocytes with the process of lobulation definitely indicated, this is known as the band cell of Schilling or 'Staff' cell and corresponds to the first stage of Arneth, (d) older neutrophils i.e., the other stages of Arneth. Stages (a) and (b) are not found normally in the blood. They appear when a pronounced 'shift to the left' occurs (see frontispiece and ch 11).

The nonmotile cells of the last or fifth stage of Arneth appear, periodically in increased numbers—in "showers"—in the blood stream. They are replaced by young cells from the marrow. Like the red cell the dying neutrophils disintegrate in the circulation or are disposed of by the macrophages of the spleen or the tissues. The life span of the neutrophils has been variously estimated. By some it is believed to be no more than about 3 days and by others no more than a few hours. Ponder, however, puts it at 21 days. He induced a leukocytosis and shift to the left in the Arneth stages by the injection of thyroid extract and followed the blood picture until the poly-

TABLE 10 1

Showing Schilling index and differential count of mature cells. Figures indicate percentages.

Neutrophils				Eosinophils	Basophils	Lymphocytes	Monocytes
Myelocytes	Juvenile metamyelocytes	Older metamyelocytes	Nucleus lobular

nuclear count returned to normal. Since the rise in the count is due to discharge of young cells (Stage I) from the marrow, when the count again showed the normal percentage of cells of Stage V it was assumed that the discharged cells had reached the end of their life span. At any rate the average life of the neutrophils is apparently much shorter than that of the red cell (p 70).

The Functions of the Leukocytes

The neutrophilic polymorphonuclear leukocytes as well as the monocytes and other reticuloendothelial elements constitute probably the most important elements which the body possesses for its defense against invading microorganisms. Their power to attack bacteria depends upon their motility and a proclivity for the ingestion of solid particles. The latter action, which was first demonstrated by Vetchnikoff, is termed *phagocytosis* (phago—I eat). These two varieties of white blood cell are free lances among the body cells, they wander from place to place through the tissues and practically no part of the body is barred to them. They inaugurate a process (*pseudopodium*), improvised at the moment from their cell protoplasm, through one of the joints in the endothelium of the capillary wall. Then by causing the semifluid substance of the cell body to stream into the protoplasmic projection, they pass out of the blood vessels "at will." By this action of *diapedesis*,² as it is called, myriads of white corpuscles may pass out of the vessels in a remarkably short time. Reaching a point where the bacteria have entered the body they surround the threatened area and proceed to destroy the invaders. If for instance, an actively inflamed region should be examined under the microscope, masses of neutrophils would be seen, and many of these would be

²The term *diapedesis*, literally a 'leaping through' is sometimes applied to the passage of red cells through an unbroken capillary wall, but the term is scarcely appropriate for a passive process of this nature.

observed to hold bacteria imprisoned within their bodies. As many as 15 or 20 microorganisms may be seen at times within a single cell. It has been shown that the bacteria are ingested alive and remain so for a time within the leukocyte (fig. 102).

When a tissue such as the mesentery or web of a frog, in which the capillaries are clearly visible, is examined in the living state a short time after a culture of bacteria has been injected into it, the small vessels leading to the site of inoculation are found swarming with neutrophils. In the surrounding tissues the amoeboid cells are seen moving somewhat ponderously hither and thither to engulf the offending bacteria. When the latter are intensely virulent in nature this normal leukocyte reaction may be seriously depressed. The monocytes, though much less numerous, also join in the general attack and show their phagocytic propensities to a marked degree. After the first flooding of the tissues with neutrophils and monocytes numbers of the latter come to rest and together with other reticuloendothelial elements of the tissues undergo transformation and aid in isolating the infected area from the neighboring healthy tissues. Until this is accomplished the danger of the infection becoming more widespread always exists. In their struggle against bacteria equipped as these are with powerful toxins, many of the white cells are killed. These collect within the center of the inflamed area together with exuded plasma, liquefied tissue cells and a few red cells that have escaped through the injured walls of the capillaries. This material constitutes pus, and the so-called pus cells are dead leukocytes. The circumscribing wall and its semifluid contents constitute an abscess. By the action of the phagocytes, aided by a protein digesting ferment (protease) which they elaborate, the overlying structures whether connective tissue, mucosa or skin are in part removed piece

meal. In this way a communication with the exterior is effected and the contents of the cavity are discharged.

Not only bacteria but practically any foreign material, whether a rose thorn or a catgut suture, is attacked and removed if possible, or loosened by the neutrophils aided by the monocytes and other phagocytic cells of the tissues. The removal of dead tissue or of blood clot or the separation of necrotic from living structures is accomplished in the same way. Devitalized bone, although not removed in its entirety, unless it is of very small size is nevertheless eroded and separated from the living tissue by the leukocytes. The disappearance of effete organs such as the tail and gills of the metamorphosing tadpole or the creeping muscles of insect larvae as these develop to the mature form, is effected by similar phagocytic cells. The application of heat to a part also attracts leukocytes in large numbers to the capillaries from which they immediately commence to migrate.

The activity of the leukocytes is best studied by the method of Sandison and Clarke in which a transparent chamber is inserted into the tissues, e.g., the rabbit's ear. After a time fine vessels grow into the chamber through openings in its sides which may be examined under the microscope. Another very simple method is that of *supravital staining*. A thin film of a non-toxic (supravital) dye, e.g., neutral red, azure, or brilliant cresyl blue is laid upon a glass slide and allowed to dry, a film of blood is laid over this and covered with an ordinary cover glass which is then sealed with vaseline around the edges. The preparation is kept warm and examined under the microscope; the cells remaining alive and active. The neutrophils seen in such preparations are not uniformly spherical as in fixed smears, but are continually changing their shape. Pseudopodia are in constant movement and the granules can be seen streaming through the cytoplasm with each movement of the cell. The rate of progression of the neutrophil is from 30 to 35 μ per minute at body temperature (fig. 102).

Of the functions of the other varieties of granulocytes—the *eosinophils* and *basophils*—little is known. The eosinophils are not markedly motile and only slightly phagocytic.

The *lymphocytes*—although, generally speaking they are not phagocytic—appear to exert such an action upon certain pathogenic microorganisms, notably, pneumococci types III and IV. A great migration of lymphocytes characterizes certain chronic types of inflammation.

An important function of the lymphocytes is the manufacture of serum globulin, both β - and γ -fractions having been found in extracts of lymphocytes. Immune substances (antibodies) are rec-

FIG. 102 Drawing of a neutrophil at half minute intervals to show motility and phagocytosis of bacteria.

ognized as being associated with the γ -globulin fraction, so it was presumed that the lymphocytes occupied a key position in defense reactions of an immunological nature. The investigations of White and Dougherty have gone a long way to substantiate this idea. The lymphocytes and serum of mice which had been immunized to sheep erythrocytes contained an antibody which lysed these cells, but none was found in the lymphocytes or serum of nonimmunized mice. Furthermore, extracts of the lymphocytes of the immunized animals contained antibody in a concentration from six to eight times higher than that found in the serum. Antihemolysins to staphylococcus toxin have also been demonstrated in the lymphocytes of mice immunized to this toxin. The production of antibodies in the lymph nodes was first demonstrated by McMaster and Hudach in 1935, and Ehrlich found that a threefold increase in output of lymphocytes from the nodes accompanied the antibody production.

The manner in which the lymphocytes add globulin to the plasma appears to be by a process of cytoplasmic budding and ultimate dissolution in the lymphoid tissues and blood stream. Budding can be observed within a Sandison-Clarke chamber inserted into the tissues.

The supply of globulin to the blood is apparently under the control of the pituitary gland through the action of its adrenocorticotrophic hormone upon the adrenal cortex. The pituitary-adrenal influence was demonstrated by White and Dougherty in the following way. Rabbits were immunized to sheep corpuscles and after the specific antibody had appeared in the circulation, were left untreated for a period of three months, when all antibody had disappeared. They were then divided into four groups. One group was injected with the original antigen, no significant rise in antibody concentration of the blood of these animals occurred. Of the remaining three groups one was injected with steroid fractions of the adrenal cortex, another with the adrenocorticotrophic hormone of the pituitary (ACTH) and the third with an aqueous extract of adrenal cortex. The steroid hormones caused an increase in antibody concentration, nearly as great as that caused originally by immunization—a maximal dissolution of lymphocytes in the lymphoid tissues and a scarcity of lymphocytes in the circulation. The response to the pituitary principle was also pronounced, although not as great as that given by the steroids, whereas the aqueous extract caused a relatively small reaction. The adrenal cortical fractions which exert this effect are those with an

oxygen atom in the 11 position (see chapter 58). Corticosterone and 11-dehydro-17-hydroxy corticosterone are therefore effective in this respect but not desoxy corticosterone.

It has also been found that injections of adrenal cortical hormone, or of the pituitary principle, increase the bulk of lymphoid tissue as a result of edema, the edema fluid containing larger numbers of lymphocytes undergoing dissolution. Later, after the edema has subsided, the tissue shrinks until its weight is less than before the injections. Adrenalectomy is followed by an increase in the mass of lymphoid tissue.

The reduction in lymphocytes in response to adrenal cortical hormones and ACTH is of moderate degree. The eosinophils show a much more pronounced reduction in number following the administration of these principles. The eosinopenia occurs so consistently and is so delicate that it is employed as a means of assaying the potency of cortisone and ACTH. Adrenaline also causes eosinopenia, perhaps by stimulating ACTH production. Adrenalectomized animals show a lymphocytosis, and overgrowth of lymphoid tissue is not an uncommon feature of adrenal insufficiency (Addison's disease) in man.

The Fate of the Lymphocytes

This has been a puzzling question for a number of years, for it has long been known that immense numbers of these cells disappear from the circulation daily. According to one estimate, the entire population of lymphocytes in the circulation of the dog are replaced twice each day (Drinker and Yoffey), replacement five times daily is given for the cat (Sanders and associates). Some have thought that lymphocytes were transformed into other types of cell, others that they returned to the lymph nodes and were destroyed in the germinal centers. But the most widely accepted explanation of the wastage of lymphocytes has been that they are shed from the mucosa of the gastrointestinal tract, and no doubt large numbers are discharged from the body in this way. Nevertheless, little effect is exerted upon the disappearance of lymphocytes in rabbits by the removal of the entire gastrointestinal tract and the injection of some 300,000,000 leukocytes into such a preparation does not cause a rise in the leukocyte count. It appears now from the work of the authors mentioned above that the large daily turnover of these cells is to a great extent at least the result of their dissolution in the lymphoid tissues and blood, thus globulin is supplied to the plasma.

Variations in the Number of Leukocytes in the Blood Stream

LEUKOCYTOSIS

In the event of some damage to the tissues which calls forth a leukocytic response, not only is there a migration of leukocytes from the blood to the site of injury, but also a discharge of these cells from the marrow and an increase of their number in the general circulation. Instead of the normal count of 7000 or 8000 per cubic millimeter the colorless cells may number from 20,000 to 30,000 within a short time. *Leukocytosis* is the term used to designate an increase in the total number of white cells. All varieties of the white cells do not necessarily share in the increase. In one instance it may be the neutrophils, in another the lymphocytes or the eosinophils that are increased, and it is the presence in abnormal numbers of one or other of these which then gives the high total leukocyte count. It is often of great diagnostic value to know which type of cell is responsible for the leukocytosis, and in order to determine this a so-called *differential count* of the cells is made. That is, the numbers of the different types in a stained smear of blood are counted and their percentages of the total count determined. Also, changes in the proportions of the different white cell types may occur although their total number is normal. Such alterations can be revealed only by a differential count. The following example is given in illustration, the lymphocytes and monocytes are relatively increased, the neutrophils and eosinophils reduced.

Total white cells per cu. mm.	7500
Lymphocytes per cent	35
Monocytes per cent	8
Neutrophils per cent	56
Eosinophils per cent	0.7

Very commonly an increase in the neutrophils is entirely responsible for the leukocytosis. On this account the latter term is used frequently but somewhat loosely to imply an increase in the count caused by the neutrophilic elements alone. *Neutrophilia* is a more precise term that has come into use for the latter condition. *Lymphocytosis*, *monocytosis* and *eosinophilia* are the respective terms employed to designate increase in the other elements.

Acute infections by the pus-forming organisms—*staphylococcus*, *streptococcus*, etc., are the most potent causes of a neutrophilic increase. On this account the examination of the white cells

furnishes a valuable diagnostic sign for the detection of hidden inflammatory conditions, e.g., appendicitis, empyema, etc. A neutrophilic leukocytosis occurs also in pneumonia, whooping cough, scarlet fever and some other infectious fevers. The nuclear count shows an increase in the young stages at the expense of the older (cb 11).

Pteroylglutamic ("folie") acid is a dietary constituent required by many species for the production of granulocytes by the bone marrow, and for the maintenance of the normal population in the circulation. Absence of this vitamin from the diet of monkeys and chicks is followed by a profound leukopenia.

Chemotaxis, Chemical Factors in Inflammation

Chemotaxis is the term applied to the unknown 'force' which draws the white cells from the blood stream to the point of injury in the tissues. This property of responding by a locomotory movement to chemical substances is not peculiar to leukocytes but is possessed by many types of free living unicellular organisms. Chemotaxis may be positive (i.e., attractive) or negative (repellent) and although the former is most commonly observed in leukocytic behavior, certain chemicals produce the opposite effect.

It was formerly thought that the chemical properties of the bacterial toxin were responsible for this effect but it has since been shown that nucleic acid and its derivatives, guanine, adenine, adenosine, etc., or some other principle supplied by the tissues (see below) are the specific stimulants. Injections of these substances cause a rapid rise in the leukocyte count. Toxins or other injurious agents act probably indirectly by liberating nucleic acid from the tissue cells as well as from injured leukocytes themselves. It has been suggested that the actual force which attracts the cells from the vessels to the tissue focus may have changes in surface tension of the blood cell membrane as its basis for during the early stages of the inflammatory reaction the leukocytes in the small vessels near the injured site appear 'sticky'. They collect and cling to the walls of the vessels and are thus separated from the red cells which occupy the axis of the stream. An artificial cell model may be used to illustrate the surface tension theory. When a small globule of mercury is placed in a weak solution of nitric acid, the globule moves rapidly toward a crystal of potassium dichromate dropped near it upon the surface of the solution as a result of a chemical reaction leading to surface tension effects, or if the mercury is placed in a dilute dichromate solution, it will move away from a drop of nitric acid in its vicinity (negative chemotaxis). Experiments, however, upon unicel-

lar organisms such as the amoeba, to which the white cell bears a strong resemblance, have failed to show that the spontaneous movements are surface tension phenomena. It must be admitted that the problem of chemotaxis remains unsolved. Phagocytosis does not necessarily depend upon chemotaxis but may occur quite apart from it, as when chemically inert material, e.g., particles of carbon or silica are engulfed by leukocytes coming into contact with them at random. On the other hand, a positive chemotactic effect may not be followed by phagocytosis, for neutrophils may be attracted by some dead or foreign material and move toward it with the apparent "intention" of devouring it, but not do so.

Menken has obtained a nitrogenous, crystalline principle from inflammatory exudates which increases capillary permeability, allowing the free escape of plasma protein, and induces the migration of leukocytes through the capillary wall. This substance, named *leukotaxine*, appears to be a simple polypeptide and is related neither to histamine nor to nucleic acid. It has also been found by others in the *succus entericus* of the rabbit. It seems to be the factor responsible for the swarm of leukocytes which in infective and inflammatory states are attracted from the circulation into the tissues of the affected part. Four other substances have been recovered by Menken from inflammatory exudates, these are called the *leukocytosis promoting factor* (L.P.F.), *necrosis*, *pyrexin* and the *leukopenic factor*.

The *leukocytosis promoting factor* causes the discharge of immature leukocytes from the bone marrow and hyperplasia of granulocytes and megakaryocytes within the latter. It is a pseudoglobulin, or closely associated with this fraction of the exudate, and is presumably responsible for the leukocytosis which is so often a feature of the blood in infective states. Although increased manufacture of granulocytes is induced by L.P.F., the rapid increase in leukocytes suggests that preformed cells are discharged into the circulation, and there is evidence that in the early stages of leukocytosis capillary sinuses of the marrow, harboring masses of leukocytes, are suddenly opened up and their cellular contents discharged. This suggests a vasomotor reaction, which is substantiated by the fact that even saline (1 cc.) injected intravenously into a rabbit causes about 300,000,000 mature neutrophils to enter the general blood stream within 1 hour.

Necrosis, which is associated with the euglobulin fraction of inflammatory exudates, is the substance which causes tissue injury, lymphatic ob-

struction and necrosis in inflammation. The lymphatic blockage, according to Menken, is salutary since it tends to limit the spread of the infection. Injection of this substance intravenously into animals causes widespread injury, e.g., hemorrhages into the gastrointestinal tract, focal necrosis of the liver and leukocytic infiltration of the kidneys. Necrosis is thermolabile and nonpyrogenic.

Pyrexin is a thermostable fraction associated also with the euglobulin. It appears to be a glycoprotein. It induces fever.

The *leukopenic factor* causes leukopenia as a result of the trapping of leukocytes in the lungs, spleen and liver. This factor causes urtica and vomiting when injected intravenously. It is closely associated with pyrexin and, although it can be separated by incomplete hydrolysis from the pyrogenic factor, it has not been shown with certainty that the two factors are separate and distinct.

Inasmuch as the leukocytes, especially the neutrophils, are essential elements in the defensive mechanisms of the body against infective microorganisms, their attraction to an infected part must be looked upon as a physiological and salutary response. It should, therefore, not be discouraged in any way by agents, e.g., many antiseptics, which, although themselves inimical to bacterial growth, defeat their own purpose by destroying the leukocytes, or reducing their activity. Such agents may even act to repel the neutrophils from the injured region. Sulfanilamide, on the contrary, is claimed to actually stimulate leukocyte activity either directly or by rendering the invading microorganisms less resistant, or more "appetizing," to the phagocytes. Some interesting observations have been made by Mal lery and McCutcheon on the movements of leukocytes in attack, which give a meaning to the well worn phrase "lowered resistance." The neutrophils in samples of blood from patients acutely ill and from those convalescent from various diseases were observed, and their rates of approach to a minute clump of bacteria measured and compared with the rates of approach of the observer's cells under identical conditions. In the acutely ill patients the rate of approach was 97μ per minute, as compared with the normal of 161μ per minute. No significant difference was observed between the phagocytes of the convalescent patients and those of the observer.

Physiological leukocytoses. It had formerly been taught that an increase in the neutrophils

occurred during digestion—*digestive leukocytosis*—but it seems that this was a misconception. These cells show spontaneous rhythmical variations in their numbers, the total white cell count reaching its maximum of about 7000 to 8000 in the afternoon, and its minimum, 5000 to 6000, in the early morning. These variations occur quite independently of meals. Leukocytosis also occurs during pregnancy, parturition and menstruation, in muscular exercise and after adrenalin administration, or in states such as fear, pain, anoxia etc., which cause the liberation of adrenaline from the adrenal gland. In infants and young children the leukocyte count is considerably higher than in adults, the count is also less constant in infancy, varying without apparent cause by 2000 or more per cu mm.

Eosinophilia or increase in the number of circulating eosinophils, occurs in several conditions, notably allergic states, e.g., asthma and anaphylactic shock, and in infections by various animal parasites, e.g., *hookworm (ankylostoma duodenal) disease*, in which the eosinophils may be 30 per cent of the total white cell count, and *trichinosis*. In the latter infection there is a general leukocytosis with the eosinophils running as high as 50 per cent of the total. Infections with hydatids, ascariis and other worms also cause eosinophilia to a greater or lesser degree. The significance of this association of eosinophilia with parasitic infection is unknown. These white cells are also increased in Leoffler's disease and in a number of skin diseases, the tissues in the neighborhood of the cutaneous lesions may be infiltrated with eosinophils. During the acute stage of pyogenic infections the eosinophils are usually reduced in number (eosinopenia), in the convalescent stage they are, as a rule, increased. The eosinopenia caused by ACTH and by adrenaline has been mentioned.

Lymphocytosis The neutrophils are not stimulated by tuberculous, malarial or syphilitic infection. In the active stage of such conditions either an absolute or relative increase in the number or circulating lymphocytes is the rule. In other chronic inflammatory states and in infections with the colon or diphtheria bacillus also it is the lymphocytes rather than the neutrophils that are increased in number. They indicate in general an inflammatory condition that is undergoing repair, is being held in check or at the most is making slow progress. Lymphocytosis therefore occurs as an aftermath of acute infections. The neutrophils on the other hand represent the 'shock troops' and their presence indicates that a more active campaign is being waged. In young children a relative lymphocytosis is the rule.

Monocytosis An increase in the monocytes is seen much less frequently than that of the other leukocytic types. Apart from monocytic leukemia

and glandular fever (see below), the chief conditions in which they appear in greater numbers than normal are tuberculosis, malaria, syphilis, brucellosis and bacterial endocarditis. According to Cunningham, a decline in the lymphocyte count with an increase in the monocytes in pulmonary tuberculosis is an indication that the tuberculosis process is being arrested.

Pathological Increases in the Leukocyte Population; Leukemia, Glandular Fever

The leukocytic increases discussed in the foregoing sections, even those associated with abnormal states, are moderate in degree, and are due to reactions which in themselves are of a "purposeful" character and on the whole physiological. But in the leukemias we find an altogether uncontrolled and often relatively enormous increase (up to 1,000,000 per cu mm) in the number of leukocytes, and a distorted mode of white cell production with the appearance of immature forms in the circulation.

The disease occurs spontaneously in the fowl (*chicken leukosis*) and in many mammalian species and can be transmitted by the transfusion of viable leukemic cells of one animal into the circulation of a normal animal. The transfused cells multiply in the blood of the host. That leukemia can be transferred in a similar way from man to animals has not been proved. The disease in fowl can also be transmitted by cell free blood passed through a Birkefeld filter, and is therefore believed to be due to a virus, probably a proteinlike substance. This substance does not pass from an affected to a normal bird—under natural conditions. The disease in man or in other mammals has not, as yet, been related to a virus. Whatever may instigate the abnormal blood state, its influence is impressed upon the earliest progenitors of the white cells in the bone marrow or lymphoid tissue, which results in the production of abnormally formed and malignant blood cells. This same morbid state may produce tumor masses (lymphosarcoma or myelosarcoma), clearly indicating its malignant nature.

In experimental leukemia in mice, which is closely similar or identical with the human disease, genetic factors are prominent. The influence of heredity is often evident also in human leukemia. By inbreeding mice which are susceptible to the spontaneous development of leukemia, strains have been produced in which from 80 to 90 per cent of the animals show the disease at the age of from 6 to 9 months. Little is known of the

other factors which may be concerned, whether hormonal, humoral, metabolic or nutritional (e.g., vitamin or mineral deficiency). Miller and Turner and Weismann and his colleagues have found that the urine of patients with leukemia contains principles which stimulate leukopoiesis in guinea pigs and produce a blood picture in these animals resembling that of human leukemia. The actions of these substances suggest that they are specific stimulators of leukocyte production. It is postulated that they are normal principles (one of which induces hyperplasia of lymphocytes, the other of granulocytes), but produced in excess in leukemia. The lymphocyte-stimulating principle appears to be a hydroxy-acid, whereas that which causes granulocyte hyperplasia is believed to be a noncarboxylic acid. A second myeloid-stimulating substance, obtained from the urine of patients with myeloid leukemia, has the character of a protein or of a glycoprotein.

It has been suggested by Miller and Turner that these two principles normally act reciprocally to control leukopoiesis and maintain a nice balance between the production of myeloid and lymphoid elements. The myeloid stimulating substance induces proliferation of myeloid elements, inhibition of lymphocytic hyperplasia and maturation of lymphocytes, whereas the lymphoid material acts to stimulate the proliferation of lymphocytes, to inhibit myeloid proliferation and to induce myeloid maturation.

The incidence of the disease in mice is greater in females than in males, which has suggested an influence of the sex hormones and the administration of estrogen or androgen has been found to increase or reduce, respectively, the susceptibility of these animals to the experimental transmission of the disease. 11-Dehydro-17 hydroxy corticosterone for a time reduces the number of leukocytes in the leukemia of mice and causes the shrinkage of lymphosarcomatous tissue, little lasting effect upon the course of the disease has been observed. Adrenalectomy has a pronounced effect in increasing the susceptibility of mice to the experimental disease.

The thymus appears also to have a definite effect upon the incidence of spontaneous leukemia in mice, removal of this structure causing a very marked reduction. The nature of the relationship is unknown.

The leukemias are usually classified on the basis of the cell type—lymphoid or myeloid (e.g., granulocytic)—involved in the malignant hyperplasia. Thus, *lymphatic* (*lymphoblastic* or *lymphocytic*)

leukemia and *myeloid* (*myelocytic* or *myeloblastic leukemia*, respectively), are usual designations. Either of these may be classed as *acute* or *chronic*. This latter division is based not so much upon the clinical course of the disease as upon the degree of immaturity of the cells in the blood and bone marrow, the acute form, as compared with the chronic, being characterized by cells in the earliest stage of development. In *acute myeloid* (*myeloblastic*) leukemia the type-cell is the *myeloblast*. The *myeloblast* is an entirely abnormal cell and not simply an immature leukocyte as seen normally in the bone marrow. It is a large cell about 20 μ in diameter with a single round or oval nucleus which nearly fills the cell. The chromatin is distributed evenly throughout the nucleus with little condensation into masses. The nucleus contains from four to five nucleoli. The cytoplasm is strongly basophilic, shows no granulation and is thin and irregular at the cell boundary. In suitable preparations a slow snail like movement of these cells can be demonstrated by slow cinematography. Undifferentiated myelocytes are also found in the blood. In the chronic form of *myeloid leukemia* (*myelocytic leukemia*) myeloblasts are infrequent and the myelocytes more plentiful.

In *acute lymphatic* (*lymphoblastic*) leukemia, the characteristic cell is the *lymphoblast*. This cell closely resembles, but can be distinguished from the myeloblast by the coarser chromatin structure in its nucleus, by possessing only one or two nucleoli and by showing a characteristic movement described by Wintrobe as "stately" and apparently purposeful. In the chronic form of *lymphatic* (*lymphocytic*) leukemia, the leukocytosis is due to small lymphocytes, which make up over 90 per cent of the total number of white cells, and may be 250,000 per cu. mm. Few immature cells are seen.

Leukemias in which the type cell is the monocyte, basophil, or even the megakaryocyte also occur rarely.

The somewhat redundant or contradictory terms *leukemic leukemia*, *subleukemic leukemia* and *aleukemic leukemia* are used, respectively, to designate the abundance, scarcity or absence of leukocytes in the blood. The first mentioned term is applied to those leukemias in which the blood picture is dominated by leukocytes. In subacute leukemia, the white cell count is normal or near the normal and only an odd immature form can be found, and in the aleukemic type few or no abnormal cells are present, the total count is not increased and may be subnormal. But this is only

a phase of the disease, a rise in the leukocyte count eventually occurs, the leukemia being usually of the lymphatic type

In the treatment of the leukemias, the destructive action of the X-rays upon lymphoid tissue and bone marrow is widely employed. The life of sufferers from the chronic form is thereby prolonged, but neither X-ray nor any other agent is of any avail in the acute forms. Internal radiation with radioactive phosphorus (P^{32}) is also used in the chronic form and acts like X-rays, but has a more selective action. Within recent years several chemical agents have been advocated for the treatment of chronic leukemias, e.g., urethane (ethyl carbamate), especially in the chronic myeloid type, nitrogen mustards, 4-amino-methyl pteroylglutamic acid (aminopterin) or other folic acid antagonist.

In *Hodgkin's disease*, which is allied to the leukemias, there is general enlargement of the lymphoid tissue and usually a moderate leukocytosis (15,000 to 25,000 per cu mm), in which neutrophils predominate and lymphocytes are reduced.

The monocytes and lymphocytes are increased, in the condition originally named *glandular fever* by Pfeiffer (1889) and *infectious mononucleosis* by Sprunt and Evans (1920). There is enlargement of the cervical lymph glands, spleen, and liver, and a leukocytosis, usually not exceeding 20,000, of which the mononuclear leukocytes (monocytes and leukocytes) constitute from 60 to 90 per cent or more. A characteristic serological feature of this disease is the usual, although not invariable, finding of a high titer of agglutinins against sheep corpuscles (heterophil antibodies), as first shown by Paul and Brunnell.

LEUKOPENIA

Leukopenia means a reduction in the number of circulating leukocytes. It is seen in certain diseases, notably typhoid fever, and may be induced experimentally by injections of the toxin of the typhoid bacillus—or emulsions of the dead organisms, and also by the injection of Menken's leukopenic factor (p. 93), the action of the adrenal cortical hormones and ACTH in producing a reduction in lymphocytes (*lymphopenia*) has been mentioned (p. 91). Leukopenia is also a feature of 'folic acid' deficiency in some species, e.g., monkey and chick. In some cases in which the white cells are reduced in number in the blood, the reduction is due to their attraction to some solid organ such as the lung or spleen. This has been

shown by taking blood counts from various regions. In other words leukopenia may be due to a redistribution of leukocytes in the body, rather than to an actual reduction in their number. A temporary fall in the leukocyte count may precede a leukocytosis. Certain poisons, e.g., benzol, cause leukopenia by depressing the activity of the bone marrow.

Granulocytopenia, *agranulocytosis*, etc. *Granulocytopenia* is the term applied to an abnormally low leukocyte count due to the reduction in granulocytes. The lymphocytes and monocytes are but slightly reduced or not at all, so that their proportion of the total count is increased. One or both of these types of agranular cells sometimes show an absolute increase. There may be complete absence of granulocytes when the term *agranulocytosis* is applicable. In most instances the absence of granulocytes is associated with a severe septic or necrotic condition of the throat. This condition, called *agranulocytic angina*, is fatal in the great majority of cases. The cause of these states is unknown but the fault is evidently one of the bone marrow, and is probably induced by some toxic agent. The marrow shows frequently an almost complete suppression of granulocyte formation but is normal so far as erythropoiesis is concerned. In animals reduction in the granulocytes is readily induced by the administration of benzol which acts specifically to depress marrow activity and there is a belief that in some cases agranulocytosis is induced by certain benzol derivatives employed for their antipyretic or analgesic properties. The arsenobenzenes, dimethylphenol and rarely sulfanilamide and sulfathiazols have been incriminated. Amidopyrine was the first drug shown to exert this effect but other drugs e.g. sulfonamides, arsenicals, certain derivatives of quinine and chloramphenicol sometimes cause the disease. In the treatment of these conditions pentose nucleotide has been employed with the object of stimulating the granulopoietic functions of the marrow, but pteroylglutamic acid ('folic acid') appears to be the most promising agent yet discovered for the treatment of granulocytopenia (see fig. 10-3).

In some cases of agranulocytosis the bone marrow shows an increase in the number of primitive cells of the granulocyte series (myelocytes and myeloblasts), and cells of these stages appear in the circulation. The maturation of granulocytes is apparently arrested at an early stage (ch. 11). From the analogy between this fault in granulopoiesis and the erythropoietic abnormality seen in pernicious anemia, the condition has been termed *pernicious leukopenia*, or the *maturation type* of the disease.

The Blood Platelets (Thrombocytes)

These are commonly stated to be simply fragments of protoplasm (i.e., non-nucleated) derived from the cytoplasm of the megakaryocytes (p 106). Their colorless cytoplasm contains two types of granules. Those of one type are arranged centrally in clumps or chains and stain supravitaly with neutral red or azure blue. Those of the other type are discrete, stain supravitaly with Janus green and are scattered throughout the body of the cell. The platelets have an average diameter about a third that of a red cell, namely, 2.5μ , and number from 200,000 to 400,000 per cu mm. The most usual figure found in health is around 250,000 per cu mm. These blood elements vary considerably in shape. Their best known function is concerned with the mechanism of blood clotting (ch 12). The disintegration of the platelets is said to occur more readily in blood drawn during the digestion of a meal of meat.

Variations in the number of platelets occur in the following conditions. They are increased after a meal of meat, after hemorrhage and in certain allergic conditions, in myeloid leukemia and in convalescence from infections.

They are diminished in purpura hemorrhagica, aplastic anemia, pernicious anemia, in anaphylaxis and in the acute stage of septic infections and as a result of irradiation.

The number of platelets per cubic millimeter may be determined by diluting a sample of blood with a fluid composed of sodium citrate 3.8 per cent, formalin 0.2 per cent and brilliant cresyl blue 0.1 per cent, and counting immediately. The proportion of platelets to red cells (normally about 1 to 20) is determined. If the number of red cells per cubic millimeter is known then the corresponding number of platelets is readily calculated. More commonly now a count of the platelets is made after diluting the blood with a solution which destroys the red cells. Probably the most accurate method is that described by Brecher and Cronkite who used ammonium oxalate as a diluting fluid and phase contrast microscopy for counting.

Besides their well known role in the coagulation of blood (ch 12) the platelets probably serve other functions. They have a pronounced tendency to agglutinate into masses and to form deposits upon any roughened surface or foreign material. Particles of India ink or microorganisms injected into the body become surrounded by a mass of agglutinated platelets. They may therefore aid in the body's defense against infective

FIG 10.3 Showing the effect of folic acid upon the granulocytes in agranulocytosis (After Black and Stanbury slightly modified)

agents. It is probable also that they serve to seal leaks in the capillaries by adhering to small defects which may occur from time to time in the delicate endothelial wall. They constitute the first defense against the loss of blood from larger vessels. Collecting around the margins of the vascular wound they help to close it, or at any rate serve to fasten the clot, which subsequently forms, to the vascular wall, through their action in inducing retraction and consolidation of the clot, they narrow the opening in the vessel and form a firm plug within its lumen. They liberate a vasoconstrictor principle which is identical with a substance extractable from serum (serotonin or 5-OH-tryptamine). Platelets possess substances which exert complex antigenic effects. They contain some materials which appear to be identical with the ABO blood antigens and others which are distinct and seemingly specific. According to Harrington antibodies for platelet antigens may be naturally-occurring or immune, complete or incomplete, agglutinins or lysins. Platelets prepared by differential centrifugation are relatively free from the other formed elements of the blood. These preparations may be effective in improving vascular tone and preventing loss of blood in severe thrombocytopenia. The length of life of

the platelets has been estimated at from 3 to 5 days

THE ORIGIN OF THE BLOOD CELLS—HEMATOPOIESIS

Introduction

There are two main schools of thought concerning the development of the blood cells in postnatal life (a) The *unitarian* or *monophyletic* school holds the view that all types of blood cells are derived from a common primitive free cell which they term the 'stem cell' or *hemocytoblast* (b) The *dualistic* school believes in the existence of two distinct types of stem cell, one in the bone marrow which gives rise to the myeloid elements—erythrocytes, granulocytes and megakaryocytes—and the other in lymphoid tissue which is responsible solely for the genesis of the lymphocyte. It is not possible to speak unreservedly for either theory, though the unitarian view seems to have the balance of evidence in its favor and will be followed in this text. Both schools are agreed, however, that in the early embryo the mesenchyme gives rise to a primitive free cell from which all the blood cells are derived. It is also generally conceded that certain cells (reticular cells) of the bone marrow and lymphoid tissues of the adult are the representatives of the mesenchyme cells of the embryo and to such cells all the blood cells trace their lineage.

The point at issue is, Do the bone marrow and lymphoid tissues give rise to two cell types, with their potentialities restricted, the one to the development of erythrocytes and granulocytes, the other to the development of lymphocytes? Or,

Do both types of tissue, myeloid and lymphoid, give rise to a primitive free cell—the stem cell or hemocytoblast—with potentialities for the production of all types of blood cells, but whose development along one or other line is determined simply by its immediate environment? The latter is the monophyletic view (Pappenheim, Maximal).

It is not maintained, however, that the individual blood cells arise, under ordinary circumstances, in direct line of development from the stem cells, that is each blood cell from a hemocytoblast. In health, the blood cells are produced through the multiplication of cells belonging to later stages of hemopoiesis (erythroblasts and

myelocytes, p. 106 and fig. 111). In other words a single stem cell is the ancestor of many millions of mature blood cells. This type of development, involving the proliferation of cells of later stages and the production of daughter cells of the same type which then undergo maturation, is called *homoplastic hemopoiesis*.

Under pathological conditions, on the other hand, the stem cells may undergo active proliferation, and produce, directly, immature blood cells (erythroblasts of various ages, myeloblasts and myelocytes). This is termed *heteroplastic hemopoiesis*.

Scheme I, and figures 111 and 112 will enable the reader to follow the description of the blood cell origins which will now be given.

Hematopoiesis (Blood Formation) at Different Embryonic Ages

IN THE EARLY EMBRYO

THE YOLK SAC The first signs of blood and blood vessels appear in the mesenchyme of the wall of the yolk sac i.e., outside the embryonic area proper. At a very early stage groups of mesenchyme cells in this situation—the *blood islands of Pander*—are first observed to arrange themselves into cords or columns which soon separate into a central and two outer layers.

The outer two enclosing layers form the walls of the primitive blood vessel—*primitive endothelium*. Of the central group some go to form the first blood cells, whereas the secretion or actual solution of others forms the plasma in which the cells are suspended. These free elements are known as the *primitive blood cells*. After this the mesenchyme loses its power to produce blood cells directly. A few primitive blood cells may arise from the primitive endothelium from time to time, but they are few in number and the process is believed to be relatively unimportant in most mammals, and does not persist for long. The further development of the primitive blood cells follows one or another of two courses (a) Some of the cells—*primary erythroblasts* and *erythrocytes*—acquire hemoglobin and serve as oxygen carriers. These are short lived and soon disappear forever (b) The rest remain colorless and apparently un-

FIG 11.1 Diagram showing maturation of the red cells. The view of Sabin, Doan and associates is indicated by the parenthesized terms (see footnote, p 105). As mentioned in the text the early and late erythroblasts of these observers are termed polychromatophil erythroblasts by Maximow. This term has been omitted from the diagram for the sake of simplicity (modified from Sabin).

FIG 11.2 Diagram showing maturation of the granulocytes. Parenthesized terms are those of Sabin, Doan and associates (modified from Sabin).

changed from their primitive state, they are very similar to, if not identical in appearance with, the large lymphocyte. These cells are found in adult bone marrow and lymphoid tissue, and in small numbers in circulating blood. They are termed by Maximow "hemocytoblasts" and upon them the monophyletic conception of blood formation in postembryonic life is based. They are the "stem cells" and are, according to the unitarians, potentially capable of producing any of the blood cells in the adult. Though these cells are identical, morphologically, with the primitive blood cells of which they are an older stage, apparently they are

functionally different, for they form secondary erythroblasts and erythrocytes (which the primitive cells do not) but never primary erythrocytes (Scheme 1). They also give rise to megakaryocytes. The latter are enormous cells (40μ) with multilobed nuclei. The primitive endothelium as well as the primitive blood cells gives rise to hemocytoblasts and also to a few histiocytes (p 102) which show phagocytic proclivities devouring degenerated red cells. In mammals few granulocytes are formed within the yolk vessels. They arise extravascularly from hemocytoblasts derived from the mesenchyme cells.

IN THE BODY OF THE EMBRYO. Although these stages of blood development are proceeding in the mesenchyme of the yolk sac, the heart and vessels are developing in the embryonic area. Soon the embryonic and extraembryonic systems of vessels form communications with one another and the primitive blood plasma, primary erythrocytes and hemocytoblasts flow into the body of the embryo. The mesenchyme cells of the general connective tissues of the embryo's body also form hemocytoblasts at this time. From these stem cells secondary erythrocytes and later, granulocytes and lymphocytes are produced. Blood formation throughout the general mesenchyme is, however, of short duration. Hemopoiesis soon becomes localized in the liver, spleen, bone marrow and lymph glands. Normally it is only in these situations that the mesenchyme cells exhibit their powers of producing hemocytoblasts, therefore, it is exclusively in these tissues that the hemopoietic function for a time is carried on.

IN LATE EMBRYONIC AND POSTNATAL LIFE

In the later part of prenatal life of most animals, the liver and spleen (except the lymphoid tissue of the latter) lose the power to produce stem cells and so no longer serve as blood-forming organs. The hemopoietic function from now on resides solely in the bone marrow and lymphoid tissues (p 104). The marrow is concerned with the production of red cells, granulocytes and platelets, the lymphoid tissue of lymph glands, of the Peyer's patches of the intestine, and of the spleen and thymus form lymphocytes. In certain animals, such as the opossum and frog, the formation of red cells (erythropoiesis) and of granulocytes (granulopoiesis) is continued throughout adult life by the spleen. In the bird, although the marrow is the chief organ for blood formation, the liver still retains in part its embryonic hemopoietic function.

In late embryonic and postnatal life the mesenchyme gives rise to three main types of cells

1 Those which retain their embryonic potencies throughout adult life, being capable of producing

SCHEME I DIAGRAM TO SHOW THE DEVELOPMENT OF THE BLOOD CELLS IN THE EARLY EMBRYO

hemocyto blasts (stem cells) and so of generating any or all of the blood cells. Some of these, called the *embryonic reticular cells*, are situated in the reticulum of the bone marrow and of the lymphoid tissue. Ordinarily these cells, as stated on page 107, are restricted in their hemopoietic activities, the great majority of the blood cells in conditions of health being formed by the divisions and redivisions of cells of their own kind (homoplastic hemopoiesis). Cells having similar potencies are also present in the general connective tissues, and in these situations are spoken of as *undifferentiated mesenchyme cells*. Under ordinary circumstances these latter cells do not give rise to stem cells. As the result of some abnormal stimulus, however, their dormant powers inherited from their mesenchyme ancestry may become aroused and they may then give rise to the various types of blood cells. For example, areas resembling marrow tissue may be produced by the experimental stimulation of these undifferentiated cells, the several types of blood cells are formed within such areas. Marx rendered the kidney of the rabbit necrotic by tying the renal vessels, and thereby induced in this situation hemopoietic activity resembling that which occurs in adult red marrow. Marrow like tissue producing erythrocytes and granulocytes may also arise as a result of an abnormal stimulus in the spleen, liver, adrenals, aorta, lymph nodes and other sites. In certain forms of anemia, especially of infants, the extramedullary formation of red cells sometimes occurs (in kidney, spleen, liver, etc.) and in leukemia granulocytes, which normally arise only in the bone marrow, are produced by the spleen.

2 The second type of cell has retained a certain

measure of its embryonic characteristics. These cells are endowed with the remarkable power of altering their form and functions under appropriate stimulation. They are found in the general connective tissues lying among the fibroblasts. They are allied to the connective tissues on the one hand and on the other to certain white cells (monocytes) of the blood and so form a connecting link between the tissues and the circulating cells.

The cells of this group constitute what has been termed as Aschoff the *reticuloendothelial system* (Scheme II).

3 In the general connective tissues the great majority of the original mesenchyme cells become transformed into the ordinary and completely differentiated connective tissue elements—the fibroblasts. These, once formed remain practically unchanged in structure and in function.

The Reticuloendothelial System

To the cells of this system the general term *histocyte* has been applied. The term simply means a tissue cell, and on this account is without descriptive value. But it would be difficult to coin a word that would embrace all the various cell types of this system, and yet would be sufficiently explicit to distinguish them from some of the blood cells. *Pyrrol* cells is a term that has been used in the past for a reason that will appear presently. The different types of histocytes possess one characteristic in common. They are phagocytic for foreign particles of all sorts, for this reason they were called *macrophages* by Metchnikoff to distinguish them from the much smaller

Reticuloendothelial cells or histiocytes—macrophages

I Fixed histiocytes

II Wandering histiocytes

SCHEME II

phagocytes of the blood—the neutrophils or *microphages*. In one particular, however, the histiocytes differ from all other cells of the body—neutrophils included. They are stained in the living state by weak solutions of certain colloidal dyes—pyrrol blue, trypan blue, lithium carmine, etc. The vital or supravital staining reaction is simply a process of ultramicroscopic phagocytosis. That is, the fine ultramicroscopic particles of the dye are taken up from the solution (which is too dilute to stain ordinary cells) and as a result of their accumulation into larger masses in the cytoplasm become visible under the microscope. It is by means of this reaction that the macrophages can be detected among the ordinary tissue cells from which it is sometimes difficult otherwise to distinguish them.

VARIETIES OF RETICULOENDOTHELIAL (R E) CELLS

The reticuloendothelial cells or histiocytes may be divided for the convenience of description into two groups—*fixed* and *wandering* (cf. scheme II).

FIG. 113. A, macrophage loaded with particles of India ink. B, macrophage showing processes. C, red cell (semidiagrammatic).

Fixed R E Cells

1 OF THE COMMON CONNECTIVE TISSUES (TIS-
SUE HISTIOCYTES) and of the loose tissue of the
serous membranes e.g. omentum, pleura, etc.
These are also sometimes referred to as resting
wandering cells. Their morphological character-
istics are various. Some are round or spindle
shaped, others are squamous, whereas many have
long mobile processes. They lie among the fibro-
blastic elements and often can be distinguished
from the latter only with difficulty except by
their special staining reactions. They may at any
time as a result of some stimulus, particularly one
of an inflammatory nature, become free and wan-
der through the tissues. After the stimulus has
been removed they may again come to rest.

2 OF THE RETICULUM of the spleen, lymph
glands, and bone marrow. These are large cells
joined to one another by means of long branching
processes. They lie among and are attached to
the fibers of the reticular stroma. They too, given
the necessary stimulus, may become detached and
actively motile.

3 FLAT ENDOTHELIAL-LIKE CELLS lining the
blood sinuses of the spleen, bone marrow, adrenal
cortex, and pituitary. This group also includes
those most interesting structures—the large flat
tened stellate cells in the blood sinuses of the liver
(Kupffer cells). The latter possess many branch-
ing processes and project into the capillary lumen.
In many instances they are almost free, being
moored to the capillary wall by a delicate strand
of protoplasm. At other times they may become
detached and are carried away in the blood stream
(fig. 113).

4 MICROGLIA of the central nervous system.

Wandering R E Cells or Free Histiocytes

1 OF THE SOLID TISSUES. From the foregoing it
is seen that many of the fixed histiocytes may
upon occasion become actively motile. Large cells

of this type are found in the general connective tissues in the omentum in the splenic pulp and in the lymph glands, bone marrow, etc (fig 11 1). The wandering cells may on the other hand come to rest and become fixed for the time. On account of the many different forms which these wandering macrophages may assume as a result of an inflammatory stimulus Maximow has named them *polyblasts*.

2 OF THE BLOOD (a) *Of extraneous origin* Under certain circumstances as a result of some intense pathological stimulus (e.g. leukemia bacterial endocarditis), the ordinary tissue macrophages already mentioned may be found in large numbers in the blood stream. They arise chiefly from the spleen and bone marrow and swarm into the venous system but rarely reach the arterial side for, on account of their huge size (30μ) they are strained out by the capillaries of the lung. Large numbers may be obtained from the right heart but few if any from the left.

(b) *Monocytes* (see p. 87) The origin of these normal elements of the blood has been the subject of considerable controversy. According to some they arise solely from histiocytes especially of the spleen and bone marrow and are therefore classed with the reticuloendothelial system. Lewis has shown that in hanging drop cultures macrophages may be transformed into monocytes or vice versa. Maximow on the contrary believes that the monocytes arise from lymphocytes stating that in certain situations e.g. in the spleen all transitional stages from lymphocyte to monocyte may be seen.

FUNCTIONS OF THE RETICULOENDOTHELIAL SYSTEM

The word 'endothelial' is not quite appropriate. The cells lining the blood sinuses are not true endothelial cells. The ordinary endothelial cell of the blood vessels is a highly differentiated cell like the fibroblast and has no characters in common with the so-called endothelial cells of the sinuses of the bone marrow, spleen, etc. These are called *littoral* (shore) cells by Maximow. They are relics of the primitive endothelium.

From the account of the histiocytes which has been given it is quite evident that phagocytosis is one of their chief functions. In this they constitute one of the most important and powerful means by which the defense of the body is sustained. Their action though similar to that of the neutrophilic leukocytes, is less mobile and more localized in character. They, with the aid of the lymphocytes, contribute toward the repair process which follows the acute phase of a tissue injury. The various types are for the most part

readily transformable one into another, the different forms which they assume being determined by local environmental conditions and the nature of the stimulus. Any of the stationary cells may change into wandering histiocytes (macrophages) or mobile cells may become fixed and either remain in the sessile state their special phagocytic properties or lose these entirely and become converted into the ordinary connective tissue elements—fibroblasts—or into epithelioid cells. The fibroblasts however, never undergo the reverse change and assume ameboid characters. Once formed they remain fixed. According to Maximow lymphocytes may give rise to macrophages. The latter however, never give rise to lymphocytes.

In chronic inflammation or in the repair stage of an acute process the histiocytes play an important rôle. Some (the so-called *dust cells* of the lung) are responsible for the removal of foreign particles which have been carried into the pulmonary alveoli by the inspired air. The ability of the Kupffer cells to take up ingested thorium dioxide (Thorotrast) which is opaque to the X rays is made use of to delineate the liver in the living subject. The spleen, placenta, ureter and kidney pelvis, the vessels of the extremities or of the brain and the cerebral ventricles can also be outlined radiographically by means of this agent. The administration of Thorotrast is not however, free from danger. It is radioactive, the alpha ray activity of 20 cc. of Thorotrast being equivalent to that of 1 μ g. of radium which is sufficient to produce pathological changes in susceptible persons. Thorium dioxide is eliminated from the body in insignificant amounts, almost all being permanently stored in the reticuloendothelial cells of the bone marrow, spleen and lungs as well as in the Kupffer cells, and even though no deleterious effects result from its radioactive properties it sets up a proliferation of connective tissue by acting as foreign material.

The epithelioid and giant cells of certain specific inflammatory processes e.g. tubercle which are derived from the histiocytes is but another instance of the latter's protean nature and it is owing to these activities that the tissues are rendered so remarkably adaptable and plastic in their reactions to altered conditions. The omentum for example has long enjoyed a reputation as a protective structure owing to its ability to form adhesions which serve to seal perforations of the gastrointestinal tract or to isolate infected regions within the abdominal cavity. The omental tissue is particularly richly supplied with both stationary and wandering histiocytes. It contains also even in health immense numbers of lymphocytes which in part are derived from division of their own kind locally, and in part, have come

from the blood stream. Normally the presence of these various cells in such numbers gives an appearance closely resembling a defense reaction—the physiological inflammation of Rossie. Histocytes and lymphocytes are continually being cast in showers into the peritoneal cavity at all times but to a much greater extent in irritative conditions. Monocytes have been studied in transparent chambers inserted into the tissue of the rabbit's ear. They have been observed to leave the circulation and to become motile and phagocytic and otherwise indistinguishable from tissue histocytes.

The formation of bile pigment (ch 39) and the final destruction of the blood cells (ch 8) in the spleen are other well established functions of the histocytes. The reticuloendothelial system is also believed to be concerned with antibody formation.

In certain pathological conditions, the *lipemia* of diabetes Gaucher's disease and Niemann Pick's disease (ch 8) the reticuloendothelial elements, especially of the spleen, are markedly increased in number and become loaded with lipid material.

The Blood-Forming Organs of Postnatal Life

Red cells, granulocytes and possibly platelets are formed in the bone marrow, and lymphocytes in the lymphoid tissue. The stroma or reticulum of these structures is the essential blood forming tissue. The latter consists of (a) a fine network of cylindrical or ribbonlike fibers which can be stained by silver preparations and (b) large cells—*reticular cells*—which are fused together by branching processes to form a loose network, the latter is intimately associated with the network of fibers which appear as reinforcing strands. The reticular cell (embryonic reticular cell, p 101) is the nearest approach in the adult body to the primitive mesenchyme cell. The blood forming capacity of the myeloid and lymphoid tissue depends upon the ability of these cells to form hemocytoblasts which in turn, according to the environment in which they are situated, are capable of developing into red cells, granulocytes or megakaryocytes on the one hand or lymphocytes on the other.

THE BONE MARROW

The red bone marrow is the hematopoietic tissue for erythrocytes and granulocytes in postnatal life. In the adult, this tissue is almost entirely confined to the flat bones such as, the sternum, ribs, diploe of the skull and the bodies of the vertebrae. There is little or none, usually, in the long bones, such as, the tibia and the bones of the

forearm, although small amounts may be found in the ends of the femur and humerus in young robust adults. The total volume of red bone marrow in the adult human body amounts to about 1400 cc. In infancy red marrow is present, not only in the ends of the long bones but it fills the cavity of the shaft which in adult life contains only a yellow fatty material, this is not hematopoietic. However, even in the adult the fatty marrow retains the essential reticular structure of hematopoietic tissue and is therefore capable under appropriate stimulation of blossoming into red marrow. So under certain conditions, for example in pernicious anemia and to a much less extent during residence at high altitudes or in any state associated with long-continued oxygen lack, the red marrow is increased in amount. It encroaches upon the medullary cavity of the shaft replacing to a greater or less degree the fatty tissue.¹ In aplastic anemia on the other hand the fatty marrow increases at the expense of the red marrow.

In old age the volume of the red marrow is much reduced and most of the flat bones contain minimal amounts.

Drinker has shown that the circulation of the marrow is closed, i.e., the blood and the reticular tissue are separated by a complete membrane. This is contrary to the older view that the blood came into direct contact with the marrow cells through gaps in the capillary walls. The vascular bed of the marrow is a meshwork of small blood sinuses (sinusoids) lined by flat endothelial like cells similar in character to those lining the sinuses of the spleen. Not all the sinusoids, however, are open at one time. It has been estimated by Drun that the marrow contains a great many more of these vessels than could possibly be accommodated within the resistant bony encasement, were they all in the dilated state. Some of the sinusoids are completely collapsed and impervious to the blood. Others are dilated but owing to the vessels that lead to and from them being constricted, they are isolated from the general circulation. Regions of low oxygen tension are in this way provided. It has already been pointed out (p 13) that a low oxygen tension serves as a stimulus to red cell formation.

¹ In some cases of rapidly developing anemia fat droplets may appear in the peripheral blood and after some cases of hemorrhage the fatty acids of the blood increase. These facts suggest a dispersal of the medullary fat in order to make room for an extension of the blood forming tissue—the red marrow.

The blood cells, if the observations of Maximow are accepted, are formed extravascularly and subsequently enter the blood stream.² Their pressure upon the endothelial wall causes its erosion or rupture and the cells invade *en masse* the lumen of the sinusoid where further growth and maturation of the cells follows. Finally, through the opening up at certain periods of the vessels leading from the hemopoietic region, the mature cells escape into the general circulation. The sudden showers of young cells that occur in pernicious anemia (blood crises) may be explained by a process of this nature. That the delivery of red cells into the circulation is normally intermittent is also suggested by the fact that the red cell count is not constant but shows a diurnal rhythm, the highest counts occurring in the morning hours. There may be a difference of 300,000 cells or so between the maximal and minimal daily levels of the red cell count. Normally no cells enter the general blood stream until maturation is nearly complete. Drinker, for instance, was unable to cause the passage of immature forms into the blood by prolonged perfusion of the marrow or by muscular exercise. The perfusion fluid evidently was unable to open a way into these isolated pools and wash out the immature forms. From what we know of the capillary circulation in other situations this is not unexpected (ch 15, 25 and 26).

Since the introduction of the technique of bone marrow puncture and of culture methods our knowledge of the cellular structure of human marrow under normal and pathological conditions has been greatly advanced. The total number of nucleated cells per cubic millimeter in the bone marrow is around 75,000. Cells of the granulocyte series make up about 25 per cent and those of the erythrocyte series from 50 to 60 per cent. The remainder are megakaryocytes and unidentified cells (see Plate I).

THE MATURATION OF THE BLOOD CELLS

Erythrocytes—Erythropoiesis

The red cells pass through several stages before they attain full maturity. In the examination of a simplified (hypoplastic) marrow, such as may be induced in the pigeon by underfeeding or in mammals after poisoning with benzol, most of the stages can be followed (cf fig 11-2 and frontispiece). The reticular cell, as we have seen, gives

² Sabin, Dean and others contend that only the granulocytes have an extravascular origin, the erythrocytes being derived not from reticular cells but from the endothelial elements (litteral cells of Maximow) of the marrow capillaries.

rise to the *hemocytoblast*. The latter divides into two daughter cells which stain deeply with basic dyes. These are called *basophilic erythroblasts* by Maximow; they contain no hemoglobin. The next stage which may be distinguished is, following Maximow's terminology, the *polychromatophil erythroblast*. The earliest cells of this stage are large, with a large, round and often vesicular nucleus, their cytoplasm is rich in basophilic material but also contains traces of hemoglobin. The hemoglobin concentration increases in amount as development advances, the more mature cells being well supplied with pigment. Hemoglobin is acidophilic, so the cells of the erythroblast stage, since they have retained a relatively large amount of basophilic substance, stain with both acid and basic dyes. This property of dual staining, known as *polychromasia*, diminishes again as the cells mature beyond the erythroblastic stage and gradually lose their basophilic material.

Several authors (Sabin, Dean and associates) distinguish three types of cells during this stage of development—the *megaloblast* and the *early* and *late erythroblasts*. The megaloblast of these authors corresponds to the youngest of the polychromatophil erythroblasts mentioned above, i.e. a large nucleated cell which, owing to its relatively large proportion of basophilic material, shows only a very slight tendency to polychromasia. Maximow avoids the term megaloblast, advising that it be reserved for the large cell of pernicious anemia to which it was originally applied. He and other hematologists claim that the latter cell, although resembling the primitive cell of normal marrow, is not identical with it (see p. 104).

The older erythroblasts give rise to *normoblasts*. The normoblast, as the name itself implies, resembles the mature erythrocyte in size and hemoglobin content but still retains its nucleus which, however, shows condensation of its chromatin material (*pyknosis*) and stains more deeply. In the final stage of the maturation process, the nucleus is extruded from the cell and the now nearly mature erythrocyte is discharged from the marrow into the general circulation. It betrays its youth only by a fine basophilic reticulation of its cytoplasm and is therefore called the *reticulocyte* (p. 13). It is probably not until the reticulocytes have reached a certain concentration in the marrow that they become discharged into the general blood stream.

In healthy marrow the multiplication of the red cells which occurs to replace those lost from the circulation through wear and tear is effected al-

most entirely by the division and redivision of later forms i.e. of normoblasts and older erythroblasts (homoplastic development) and to a negligible extent through the multiplication and subsequent maturation of the more primitive forms. The youngest erythroblasts (basophilic and polychromatophilic erythroblasts) for example in normal marrow are absent or amount to no more than 0.01 to 0.04 per cent of the total nucleated cells of the erythrocyte series according to Sabin; the older erythroblasts make up about 30 per cent and the normoblasts 70 per cent or so. In pernicious anemia on the other hand large numbers of very primitive cells including the characteristic megaloblast are present. In this disease erythropoiesis is abnormal in that the cells produced are not only of a more primitive type but are different from ones ever seen at any stage of normal erythropoiesis. It is not then merely a matter of reversion to a primitive but otherwise normal mode of red cell development. The benefits of liver therapy apparently depend upon the power of the hepatic principle to restore the normal mode of red cell development.

Granulocytes—Granulopoiesis

The earliest stage in the differentiation of the granulocytes from the primitive reticular cell of the marrow is that of the so-called *myeloblast*. It is generally agreed that the origin of the granulocytes is extravascular and that they pass into the marrow vessels only after they acquire motility. Maximon considers the myeloblast to be nothing more or less than the polyvalent hemocytoblast or stem cell identical with the large lymphocyte; the minute differences in structure between it and the latter being due, it is thought, to the environment in which it is placed i.e. the bone marrow. Here it gives rise to the three types of granulocyte. The myeloblast is given added interest since

a cell similar to but not identical with it is predominant in the blood and marrow of certain forms of *leukemia* (p. 94) when it may constitute 90 per cent of the white cells. It forms only a very small percentage of the cells of normal marrow.

After the stage of the myeloblast a few specific granules begin to appear in the cytoplasm which at the same time becomes less basophilic in character. At present are a few azurophilic granules. In the subsequent history of the cell up to its discharge into the circulation four stages based upon the development of specific granulation and the reduction in basophilic material are recognized. The cells of the first three of these stages are termed *myelocytes* A, B and C respectively. The cells of the fourth stage are called *metamyelocytes*. In the youngest stage (A) the granules as mentioned above are very few and are in greater numbers in myelocyte B and in maximum quantity in myelocyte C. The nucleus in these stages is oval or spherical and shows no attempt at lobulation. The metamyelocyte is characterized by slight indentation of the nucleus and the first evidence of typical smudge movement. Finally the nucleus becomes deeply indented or constricted at one or more points and is discharged into the circulation as a young leukocyte (neutrophil, eosinophil or basophil). This is the first stage of Arnet's mentioned on page 88. It is also referred to by Schilling as the older metamyelocyte or the band cell. As shown in figure 11.4 three levels of development are distinguished. Level I extends from the reticular cell to and includes the myeloblast. Level II embraces the myelocyte and the metamyelocyte cells at this level multiply actively and have the power of growth. Level III includes those forms present in normal blood (Arnet's stages) the cells have lost the power to divide and grow.

As in the case of erythropoiesis the earliest stages of white cell development—myeloblastic and early myelocytic—are little in evidence in normal bone marrow. The leukocytes are supplied to the blood through the division and redivision of the later forms of white cell elements—i.e. the myelocytes. A census taken of the colorless elements of the marrow in normal rabbits gives an average of about 1 per cent myeloblasts, 90 per cent myelocytes C and metamyelocytes.

*The cell myelocyte A resembles closely its progenitor the myeloblast and represents a transition stage between the latter cell and the older myelocyte. It is often referred to as the promyelocyte. Some use this latter term to include also myelocyte B.

FIG. 11.4. Liver from an animal after the intravenous injection of India ink. A, Kupfer cells loaded with ink particles. L, liver cells.

of which the great majority are neutrophilic, and about 4 per cent young leukocytes. Younger myelocytes make up the balance. The number of leukocytic elements is three times greater than the number of red cell elements—erythroblasts and normoblasts. The ratio of granulocytes to red cells in blood, on the other hand, is 1 to 600. The difference in the cell mitosis in marrow and in blood is ascribed to the greater mortality of the leukocytes and the consequent necessity for a greater hemopoietic activity in order to replace them.

In myeloid leukemia the process of granulopoiesis is pushed back to a more embryonic type and immature forms appear in the blood. The marrow picture indicates a great activity of the early myelocytic and myeloblastic stages. The marrow of the fetus and to a less degree that of the newborn show also a relatively large proportion of immature cells.

Lymphoid Tissue and the Formation of Lymphocytes

The central areas of the follicles in lymphoid tissue (lymph glands, spleen, etc.) stain more lightly with the ordinary stains than the peripheral zones. These lighter areas, about 1 mm in diameter and pierced near the center by a small arteriole, are generally known as the "germ centers." In the embryo and in newborn animals the earliest stage in the development of the lymphocytes is represented in lymphoid tissue as well as in the bone marrow by a large lymphocyte or hemocytoblast. It is analogous and practically identical in structure with the myeloblast. It is called the *lymphoblast*. In postnatal life, lymphocytes arise only from lymphoid tissue. The ancestral cell or hemocytoblast stems from the undifferentiated primitive reticular cell of the lymphoid stroma similar to that in the marrow from which the myeloblast and, according to Maximow, the erythroblast arise but, as in the case of the myeloid cells, the lymphocytes normally arise from the division of cells of later stages.

The total mass of lymphoid tissue amounts to between 1 and 3 per cent of the body weight, and its output of cells is relatively enormous. Yoffey estimated the daily production at 35,000,000,000, the tremendous wastage has already been mentioned (p. 70).

An interesting experiment of Maximow's supports the view that the large lymphocyte or hemocytoblast is the common precursor of the granulocyte and lymphocyte and that the course of development which the stem cell shall follow is

determined by its immediate environment. Lymphoid tissue was cultured in an environment prepared to simulate that of the bone marrow by the use of a preparation of blood plasma and marrow extract. Proliferation of the large lymphocytes and their differentiation into myelocytes were clearly observed.

Distinguishing Features of the Different Stages of the Leukocyte Series

Oxidase GRANULES

The mature granulocytes, the myelocytes and myeloblasts (except the very youngest) and the primitive monocytes contain fine, reddish brown granules (*oxidase granules*) which become evident when the cells are stained in the following way (Washburn technique). The cells are first treated with a solution consisting of benzidine, 0.3 gram in 99 cc of alcohol and 1 cc of a saturated solution of sodium nitroprusside. Ten drops of this solution are applied to a dried blood film and allowed to stand for 4½ minutes. Five drops of a solution of hydrogen peroxide in 25 cc of water are then added. After standing for another 4½ minutes the film is washed and dried and stained with Lieshman's stain. Cells of the lymphoid series do not contain oxidase granules.

MOTILITY AND PHAGOCYTOSIS

When stained supravitality the primitive monocyte is phagocytic and actively motile, whereas myeloblasts and lymphoblasts are usually stated to be nonmotile. In hanging drop preparations, however, Rich states that both of the last mentioned cells also show definite motility and that the mode of locomotion of each type is characteristic. *The myeloblasts and the younger myelocytes* exhibit a wormlike motion, whereas the lymphoblast protrudes a long tongue of cytoplasm in a direction opposite to that in which it is moving, it thus assumes a shape resembling that of a hand mirror or a frying pan.

NUCLEAR STRUCTURE

The nucleus of the myeloblast shows a delicate reticular structure and no definite nuclear membrane, the nucleoli are indefinitely marked off from the rest of the nuclear material. The nucleus of the lymphocyte on the contrary is well defined as are also the nucleoli, and the reticulum is coarser.

These distinguishing features of the various cell types are employed in diagnosing the different forms of leukemia.

The Platelets

These are generally stated to arise from giant cells of the marrow (40 μ or more in diameter)

known as megakaryocytes. The latter have an irregular, ring-shaped nucleus, and are capable of amoeboid movements. It was first suggested by Wright that fragments of their protoplasm became detached to form the blood platelets. Normally, the marrow contains only a few of these cells, but it has been stated that an increase or decrease in their number is followed by corresponding changes in the number of circulating platelets.⁴

The Origin of Monocytes (see p 103)

⁴Wright's view of the origin of the platelets from megakaryocytes, though very widely held, has not gone unquestioned. Various alternate theories have been advanced with respect to the origin of the platelets. Some believe that they are formed from the cytoplasm of leukocytes, and others that they are simply precipitates from the plasma. Howell and Donahue concluded from their experiments that the platelets are derived from megakaryocytes in the lungs. They based their view on the finding that both in cats and in man the platelet count was somewhat higher in arterial than in venous blood. The ratio of platelets to erythrocytes in arterial blood was 1:21.4, as compared with 1:23.8 in the blood of the corresponding vein, which implies that platelets are destroyed or removed from circulation in the capillaries and replenished in the lungs. Further evidence was derived from the observation that a smear of lung tissue showed large numbers of giant cells, whereas only a few were found in a similar specimen of bone marrow. It is probable, however, that the lung megakaryocytes do not originate in the lungs but have their source in the bone marrow and, owing to their large size, are merely trapped in the pulmonary capillaries. Several observers have expressed the belief that they are fragments of degenerated red cells. In support of this view Watson reports the observation that phenylhydrazine which damages the erythrocytes causes a sharp rise in the platelet count and a reduction in the number of red cells. This observer also found

that, when erythrocytes were suspended in a counting chamber, degeneration of the red cells occurred whereas bodies indistinguishable from platelets appeared. Furthermore, the platelet count, as shown by Bedson, is increased by splenectomy, or by "blocking" the reticuloendothelial macrophages (which, as we have seen, engulf red cell fragments) by injections of India ink. The term "blocking" refers to the overloading of the reticuloendothelial cells with the ink particles and the consequent suppression of their phagocytic properties.

THE COAGULATION (CLOTTING) OF BLOOD

General Description of Clot Formation

If blood is collected into a test tube it will be found at the end of 5 or 6 minutes that it has lost its fluidity and has set into a jelly. The tube may be inverted but the blood which is now said to have *clotted* or *coagulated* does not escape. If it were possible to magnify this clot many times and to look within it, one would see a mesh of very delicate fibrils among which were entangled as in a net the red and white cells and many fragmented platelets. The fibrils can be readily revealed when a thin section of the clot is examined under the high power of the microscope. They are composed of *fibrin* formed by the conversion of the fibrinogen of the plasma from a soluble (hydrocol) into an insoluble form (hydrogel). The fibrin forms ultramicroscopic crystal like needles which as they are deposited create tenuous interlacing filaments within the structure of the protein. The process by which this change of fibrinogen from a liquid to a more or less rigid structure (fibrin) is effected has been compared by Mommertz to the manner in which a matted feltlike mass is formed from elongated objects—as reeds floating in water become tangled and coherent. It will be recalled that fibrinogen itself is composed of long fiberlike molecules. The immobilization of the molecules in this manner is called *coacervation*¹ by de Jong.

If the clot is permitted to stand for an hour or so it will be found to have shrunk and in shrinking to have expressed from its interstices a clear faintly straw-colored fluid. This is the *serum*. The latter remains perfectly fluid and is quite incapable of clotting. The shrinking and condensation of the clot is due to the gradual shortening of the fibrin threads which enmesh the corpuscles. In this retraction of the clot or *syneresis* as it is

¹ De Jong defines this as the process occurring in a condensed colloidal system in which particles with positive and negative electric charges are mutually attracted. According to the view of Mommertz a profibrin is first produced and then through electrostatic attraction of its particles a meshlike interlacement occurs to produce fibrin.

termed the platelets play an essential role. Though numbers of platelets undergo disintegration when the blood is shed (see below) others become attached here and there in groups of knotlike clumps to the fibrin threads and in some unexplained way cause bending and shortening of the latter. Clots formed in blood deficient in platelets are soft and friable and do not retract in the normal way. It used to be thought that the intact platelets which were seen in sections of blood clots served as nuclei from which the fibrinogen to fibrin conversion started but it has been demonstrated by Tocantins that the platelets take up their positions after the fibrin has formed. The full retraction of the clot and the separation of the serum ordinarily takes a considerable time but separation can be brought about within a few minutes by rapid centrifuging.²

If the blood is centrifuged as soon as it is shed and the cells in this way are separated from the plasma a clot forms in the latter due as before to the formation of fibrin threads. After a time the colorless clot shrinks and as in the case of whole blood expresses the transparent serum. The clotting process is therefore essentially a phenomenon of the plasma. The straw-colored layer—the so-called buffy coat—which forms on the surface of blood which clots slowly and so allows a certain degree of sedimentation of the cellular elements to occur is clotted plasma.

The Clotting Mechanism

The clotting mechanism in the simplest possible terms is shown in the following scheme

* There is a direct relationship between the platelet count and the rapidity and degree of clot retraction and the resulting firmness of the clot. The effect of the platelets upon clot retraction is exerted only when they disintegrate. The concentration of thrombin which induces lysis of these elements therefore influences the retraction of the clot. The concentration in the blood of the other formed elements affects clot retraction in the opposite way. In anemia for example clot retraction is more pronounced than normally whereas in polycythemia the clot is soft and friable. Increase in the fibrinogen concentration acts in a manner similar to that caused by a high platelet count hastening the retraction of the clot.

Prothrombin + thromboplastin + calcium →
thrombin

thrombin + fibrinogen → fibrin (clot)

The four primary factors, *prothrombin*, *thromboplastin*, *calcium* and *fibrinogen*, have long been recognized as being fundamentally involved in the coagulation of the blood

Plasma also contains considerable amounts of antithromboplastin which is capable of preventing the formation of thromboplastin or inactivating it after it has been formed

Normally, the blood remains fluid in the vessels, not only because it is in motion, but also because thromboplastin is present in the circulation in only minute amounts, or in an inactive form, and because the platelets remain intact. Therefore, thrombin, the coagulating enzyme, is not formed. Moreover, an antithrombin is present in normal blood, which serves to guard against any thrombin which might arise in sufficient amount to cause intravascular clotting

No field in physiology is more complex or has been so confused by contradictory results, differences of interpretation and diversity of opinion as that of blood coagulation. Each fact discovered, instead of simplifying the subject, usually brings new problems in its train. The relatively simple mechanism expressed above must now be elaborated in the light of modern findings. This can best be done by considering that the reactions resulting in coagulation take place in three stages: (a) the formation of thromboplastin, (b) the conversion of prothrombin to thrombin and (c) the conversion of fibrinogen to fibrin (see fig. 12 1)

It is now known that platelets contain little or no thromboplastin, yet the platelets are necessary for the development of the thromboplastic activity of plasma. The formation of plasma thromboplastin can be considered as the first stage in blood coagulation. Although there is no unanimity of opinion regarding the order in which various plasma factors react to form thromboplastin, there is general agreement as to the importance of these factors. At least three hemorrhagic conditions have been observed in which the common defect is in the formation of plasma thromboplastin. Each appears to be due to the lack of (or inactivation of) specific proteins present only in minute amounts. Since any hypothesis of blood coagulation must take these facts into account, a suggested scheme for the events in the first stage of coagulation is shown in figure 12 1. Antihemophilic factor (AHF), plasma thromboplastin component (PTC) and possibly other proteins (Stuart

factor, Hageman factor) react with a lipid material (phosphatidyl ethanolamine or cephalin) from platelets to establish thromboplastic activity. The reaction is apparently initiated by contact with a 'wetttable surface' or injured area. This suggests that lysis of platelets may be the initiating factor. (MacFarlane believes that PTC and AHF join with calcium ions to form an intermediate product which then combines with platelets.)

AHF is present in normal fresh plasma but is lacking, or inactive, in serum or aged plasma. It is not readily adsorbed on the usual prothrombin adsorbing reagents. Lack of this factor results in a condition now known as *Hemophilia A*. PTC or Christmas factor is present in both normal plasma and serum and is readily adsorbed on prothrombin adsorbing reagents. Lack of this factor results in a condition known as *Hemophilia B*. Rosenthal and his colleagues have described a third type of hemophilia attributed to lack of a plasma factor which, although not adsorbed by the prothrombin adsorbing reagents, is found in normal serum. They have called this factor PTA. According to the work of Tocantins a thromboplastin inhibitor exists in plasma. He has isolated this material from both normal and hemophilic plasma. It probably inhibits the development of thromboplastin as well as inactivating thromboplastin after the latter has been formed. The thromboplastin which can be obtained from tissues appears to be incomplete and needs a factor from plasma to make it fully active.

The conversion of prothrombin to thrombin normally depends on the presence of thromboplastin and thus can be considered the second stage in blood clotting (fig. 12 1). The work of several laboratories has indicated the existence of certain plasma and serum factors which accelerate the conversion of prothrombin to thrombin. The plasma factor was discovered independently in widely separated laboratories and has been referred to by a variety of names (see table 12 1). It appears to be associated with the globulin fraction of plasma and is normally present only in trace amounts. It is labile and is not easily adsorbed on $Al(OH)_3$, $Ca_3(PO_4)_2$ or other prothrombin-adsorbing agents. One of the first patients found to be deficient in this factor was studied by Owren. He called the condition parahemophilia. Seegers and his colleagues found that the activity of plasma AC-globulin was greatly increased during coagulation, and that plasma AC-globulin fraction was made more potent by small amounts

FIG 12.1 Blood coagulation

of thrombin. This suggested an autocatalytic type of reaction and led to a great deal of investigation regarding clotting accelerators in serum. It is now generally accepted that serum contains an activating material that is not always present in plasma. The active material is readily adsorbed on prothrombin adsorbing reagents and is more stable than the plasma fraction. The term "factor VII" is most commonly used to designate the serum active factor but many other terms are used (see table 13.1). Clinical cases with factor

VII deficiency have been reported by Alexander and Owen. Seegers and his colleagues have shown that a derivative of purified prothrombin acts as an accelerator and have suggested that the serum factor is derived from prothrombin during the coagulation process. In support of this hypothesis it may be pointed out that during Dicumarol or Tromexan administration both prothrombin and factor VII levels in the blood are decreased, with factor VII being the first to be affected.

Once thrombin is formed it acts enzymatically

TABLE 12 1

Synonymous terms for clotting factors

Name Used Here	Synonymous Terms	Stage of Blood Coagulation
PTC (plasma thromboplastin component)	CF (Christmas factor), platelet co factor 2, autoprothrombin 2	First
AHF (antihemophilic factor)	AHG (antihemophilic globulin), thromboplastinogen	First
Ac globulin	Labile factor, factor V, proaccelerin	First and second
Factor VII	Stable factor, auto prothrombin I, pro convertin, SPCA, cothromboplastin	Second
Plasminogen Plasmin	Profibrinolysin Fibrinolysin	Third Third

to convert the soluble fibrinogen into insoluble fibrin which forms the framework of the clot. This reaction can be considered the *third* stage in coagulation and is illustrated in figure 12 1. Plasma, and to a lesser extent serum, contain a substance known as antithrombin, the physiological importance of which has not yet been determined. Its function may be to prevent the accumulation of thrombin to levels which would cause intravascular clotting. Attempts to correlate decrease in antithrombin with a tendency towards thrombosis have been unsuccessful. Antithrombin was originally believed to be an albumin but recent work indicates that it is associated with the α -globulin fraction.

DEFIBRINATED BLOOD FIBRINOLYSIS

Blood which has been extravasated into the pleural, peritoneal or other body cavity is usually found to be fluid, if any considerable time has elapsed since the hemorrhage occurred. Such blood is found to be incoagulable, for it has already clotted and then undergone a natural process of defibrination, the clots having been dissolved as a result of the digestion of the fibrin (fibrinolysis) by proteolytic enzymes. The fluidity of menstrual blood is caused in the same way. A fibrinolysin, although not present in normal blood under ordinary circumstances, appears in plasma after shaking with chloroform.

A great deal of work has been carried out in

recent years on the fibrinolytic activity of the blood, and much has been learned of the mechanisms involved. Fibrinolysis occurs in a number of pathological conditions. It has been found, for example, that blood clots removed from a body immediately after sudden death undergo rapid dissolution due to the development of fibrinolytic activity. Also, blood taken from patients immediately after surgical operations, or from those who have suffered severe burns or hemorrhage, contains fibrinolysin, sometimes in high concentration. Through the action of fibrinolysins the fibrinous exudate filling the alveoli of the consolidated lung in lobar pneumonia is dissolved preparatory to its absorption. The blood normally contains a proferment, which has been called profibrinolysin or plasminogen (i.e., fibrinolysin in an inactive form), which under certain circumstances may be converted to the active enzyme by a second principle derived from the tissues. This is known as fibrinokinase. Activation can also be brought about artificially, as mentioned above, by chloroform and also by certain strains of streptococci, which possess an activating enzyme, known as streptokinase. The latter substance together with streptodornase (desoxyribonuclease), an enzyme also produced by streptococci, and which hydrolyzes desoxyribonucleoprotein of cell nuclei, has been employed in surgery to liquefy thick pus, and thus to render it more amenable to drainage.

Heparin. The action of certain impure extracts of liver in inhibiting the coagulation of blood was discovered by McLean, a pupil of Howell, in 1916. Later, a series of studies was carried out by Howell and Holt upon extracts of liver from which they obtained a powerful anticoagulant. They gave it the appropriate name of *heparin*. Howell and Holt obtained their material from dog's liver, but it was later (in 1933 at the University of Toronto) prepared in larger quantities by Charles and Scott from beef liver. Lung, muscle and intestinal wall also contain heparin in relatively large amounts. Smaller quantities are contained in spleen, heart and thymus. It is present in negligible quantities, if at all, in normal blood. Heparin is active both *in vivo* and *in vitro*, when it is injected into the living animal the blood remains incoagulable for several hours. A unit of heparin is defined as the quantity of material which will prevent for 24 hours the clotting of 1 cc. of cats' blood when kept in the cold. A very potent crystalline preparation has been obtained from beef liver by

Charles and Scott This contains nearly 100 units per milligram

The anticoagulant action of heparin is complex and depends upon at least three effects which it exerts upon the clotting mechanism (a) In association with a plasma fraction, heparin cofactor, it inhibits the action of thrombin in converting fibrinogen to fibrin (b) Heparin is also an anti-prothrombin, i.e., it prevents the activation of prothrombin to thrombin This property has been questioned until recently, but the experiments of Ferguson and of Quick have firmly established this action of heparin (c) Through its effects (a) and (b) in inhibiting the formation and action of thrombin, heparin reduces or prevents the agglutination and lysis of platelets

Jorpes found that, like certain other anticoagulants, such as azo dyes and germanin, the heparin molecule contains sulfuric acid groups, in virtue of which it acts as a relatively strong acid It belongs to the same chemical group as that to which mucotin and chondroitin sulfuric acids belong It is a complex carbohydrate containing esters of mucotin sulfuric acid and yields glucuronic acid, glucosamine and sulfuric acid groups upon hydrolysis Anticoagulants have been prepared by Chargaff and Olson by the introduction of sulfuric acid groups into such polysaccharides as cellulose, glycogen and starch and into the cerebroside, cerebrin and keratin

Since heparin is absent from the circulation, or present only in minute amounts, it cannot be responsible for maintaining the fluidity of the blood in the living body The most probable reasons that the blood does not clot intravascularly have been stated on page 110

From the evidence procured by Wilander, heparin appears to be a product of the "mast cells" of Ehrlich (i.e., mobile cells in the tissues containing fine basophil granules) which may be seen in clusters around the minute vessels of those tissues which give a high yield of heparin Mellanby suggests that the significance of heparin in tissues is that it serves as a local anticoagulant, preventing the clotting of blood circulating in the small vessels The fine granules to be seen in these cells show the metachromatic staining reaction, turning violet when treated with toluidine blue or azure A Heparin itself gives this reaction and the granules are therefore believed to be the anticoagulant in the form of minute droplets

Chargaff and Olson found that protamine (salmine) annuls the action of heparin both *in vitro* and *in vivo* Protamine, a simple protein with

basic properties (see also p 771) combines with heparin, the resulting compound being quite free from anticoagulant action Thus it is possible to determine the quantity of heparin in a sample of blood by ascertaining the quantity of protamine required to give the shortest coagulation time By this means the great lengthening of the coagulation time in anaphylaxis (up to 2 days or more) and peptose shock has been shown by Waters, Markowitz and Jaques to be due to the high concentration of heparin in the circulation (*heparinemia*, p 112 and p 118) Heparin is most effective when administered intravenously, much larger doses being required when it is given by subcutaneous injections Besides its action in prolonging the coagulation time, heparin, as shown by Murray, Jaques and Best, hinders the agglutination and deposition of platelets and thus discourages thrombus formation Heparin has been recognized for a number of years as a valuable anticoagulant for use in physiological experiments, but it is only comparatively recently that purified preparations suitable for clinical use have become available Its most important field of usefulness is in blood transfusions, in operations upon the blood vessels and to check the extension of coronary, and certain other types of thrombosis Its employment as a preventive against postoperative and other thrombotic states which carry the threat of fatal pulmonary embolism (p 120) has been advocated by several investigators (Howell, Mason, Hedenius, and Murray and associates) Widstrom and Wilander have suggested its use to prevent the formation of fibrinous adhesions in pleurisy, in heparinized rabbits the inflammatory exudate caused by the injection of iodine into the pleural cavity is incoagulable The systematic use of heparin and, later, of other anticoagulants for the prevention of the spread of coronary thrombi was initiated by Irving Wright and his colleagues

THE PROPERTIES OF PROTHROMBIN AND THROMBIN AND OF THROMBOPLASTIN

Prothrombin and thrombin, according to Seegers, are carbohydrate-containing proteins This investigator has prepared from beef plasma highly potent preparations of these agents At a pH of 7.0 prothrombin and thrombin are highly soluble in water or physiological saline, it being possible to prepare a 60 per cent solution of either material Prothrombin is insoluble at a pH of 4.9 and thrombin at about 4.3 Both substances are completely and permanently inactivated by acid

(pH 3.5) and by alkali (pH 11.0) They are destroyed by heating to 60°C for 30 minutes. The estimated concentration of prothrombin in blood is around 25 mg per 100 cc. Prothrombin is formed in the liver and its production depends on an adequate amount of vitamin K.

A linear relationship (inverse law) can be shown to exist between the relative concentration of thrombin in the plasma and the reciprocal of the coagulation time, i.e., the higher the thrombin concentration, the shorter the time required for a clot to appear.

Thromboplastin is present in all tissues—lung, placenta, and brain being especially rich sources. Although it is the general custom to speak of thromboplastin as a single principle, the term refers to an "activity" rather than a precise factor. Thromboplastin concerned with normal coagulation is formed by an interaction between the products of lysis of platelets and plasma proteins as has already been described.

Evidence now available indicates that tissue thromboplastin is not "complete," since incubation with plasma or serum will augment its activity.

THE MEANS USED TO PREVENT OR RETARD COAGULATION—ANTICOAGULANTS

COLD. Since the clotting mechanism consists of a series of chemical and enzymatic reactions, it is to be expected that coagulation will be retarded by lowering the temperature. Keeping blood at a temperature of from 5 to 10°C postpones coagulation but does not absolutely prevent its occurrence. Cold, e.g., ice, etc., applied to the surface of the body as a means of arresting hemorrhage has, however, no effect in retarding the coagulation process. Actually a hemostatic action is exerted in such instances as a result of the vasoconstriction reflexly induced.

AVOIDANCE OF CONTACT OF THE BLOOD WITH FOREIGN MATERIALS OR INJURED TISSUES. Drawing the blood directly from an artery or vein (in order to prevent contact with the tissues—a source of thromboplastin), and collecting it into a receptacle whose walls have been made smooth and *unwettable* by a coating of paraffin, or preferably of *silicone*, will slow greatly the coagulation process. Silicone is the most effective substance known for this purpose, it acts like the vascular endothelium in inhibiting the break down of platelets (Jaques and associates) and the formation of thromboplastin activity. Plasma, after collection in silicone lined apparatus and centrifuged at high speed in order to remove the platelets as completely as possible, will remain fluid for 3 or 4 days even at room temperature. Avian

blood collected in this way will remain unclotted almost indefinitely. The importance of a smooth surface in maintaining the fluidity of blood is also shown clearly in the classical experiment of the "living test tube." If a section of the jugular vein of an animal, e.g., the horse, be isolated between ligatures and carefully removed with its contained blood, this will not clot for a long period, not until changes occur in the lining of the vessel wall and the necessary thromboplastin is thereby provided.

On the other hand, if the blood flows over a rough surface, coagulation is hastened. The blood coming from a ragged wound which involves a greater destruction of tissue, is also likely to clot more quickly than if it issues from a blood vessel that has been cleanly incised as by a scalpel or a razor. The contact of a sponge or a powdered substance to the wound by increasing the extent of surface exposed also hastens the formation of the clot.

DECALCIFICATION. The addition of oxalate (sodium, potassium or ammonium) or a fluoride to blood to the extent of 0.1 per cent or more, completely destroys its power to clot spontaneously. In the former instance the calcium is precipitated as calcium oxalate. Oxalated blood recovers its ability to clot if shaken with chloroform but the fibrin which forms redissolves after the blood has stood for a time. Fluoride does not precipitate the calcium but forms a weakly dissociated calcium compound. Sodium citrate also prevents coagulation. In this instance a double salt—calcium sodium citrate—is formed which again is only slightly dissociated. If calcium in the ionic form e.g., the chloride, be added to the oxalated, fluoride or citrated plasma (recalcification), the power of the blood to clot is regained. Also the addition of thrombin or of thromboplastin to the decalcified blood causes it to clot.

NEUTRAL SALTS. Magnesium sulfate solution in a strength of 27 per cent mixed in the proportion of 1 to 4 of blood postpones coagulation for some time but does not prevent it indefinitely. Sodium sulphate in half saturated solution added to an equal quantity of blood has a similar effect, as has also a 10 per cent solution of sodium chloride in the same proportion. The manner in which these substances act is not clear. They do not decalcify the blood. That the activity of some or other elements necessary for the clotting process is merely suspended and that none is destroyed is shown by the fact that mere dilution of the "salted" blood is followed by clotting. Some think that these substances may act by preserving the platelets and corpuscles from disintegration and so hindering the liberation of thromboplastin. Zinc sulphate in 0.5 per cent solution prevents coagulation by precipitation of the fibrinogen. Sodium thiosulfate and germanin are anticoagulant, this

action depending apparently upon their sulfur content

AZO DYES, such as Chicago blue 6 B, Trypan red, Trypan blue, Chlorazol fast pink, B K S etc., are powerfully anticoagulant. Chicago blue, the anticoagulant property of which was discovered by Rous and his associates in 1930, is more potent either *in vivo* or *in vitro* than the earlier preparations of heparin. One milligram of purified Chicago blue will prevent for 60 hours the coagulation of 1 cc of rabbit's blood kept on ice.

CERTAIN SUBSTANCES OF A BIOLOGICAL NATURE

(a) *Hirudin*, a substance secreted by the buccal glands of the leech and extracted commercially, has a very powerful anticoagulant effect. It is a typical antithrombin, i.e., it inactivates thrombin. *Hirudin* has been used extensively in the past to prevent coagulation during physiological experiments. (b) *Snake venoms*. The poisons of some snakes, particularly of the cobra, are powerfully anticoagulant. One hundredth part of a milligram per kilogram of body weight will, according to Howell, entirely prevent coagulation. Its anticoagulant effect is thought to be due to some chemical change which is produced in the thromboplastin. The anticoagulant effect of cobra venom is probably intimately associated with its hemolytic action (p. 63). Some other snake venoms, however, have just the reverse effect and cause intravascular clotting. (c) *Heparin*. (d) *Peptone solution* when injected prevents coagulation. According to Howell it acts by stimulating the liberation of heparin from the liver. Confirmatory evidence for this explanation has been furnished by others (Quick, and Waters and associates). Peptones also have an anticoagulant action when added to shed blood. The anticoagulant effect under these circumstances is ascribed by Mills and by Pickering to the increased resistance of the platelets to disintegration induced by the peptone solution. (e) In *anaphylactic shock* the blood remains incoagulable indefinitely (up to 2 days at least). Waters, Markowitz and Jaques have shown that this is due to the liberation of heparin from the liver. Anaphylaxis produced in hepatectomized dogs is not accompanied by a prolonged coagulation time. (f) *Cysteine*. (g) *Dicumarol* 3,3'-methylene bis (4-hydroxycoumarin), present in spoiled sweet clover hay, see p. 117. Schofield in Canada and Roderick in N. Dakota showed that hemorrhagic disease of farm animals could be cured by replacing spoiled sweet clover in the diet with fresh fodder. The latter observer also showed that the reduced coagulability of the blood was due to diminution in prothrombin. Link demonstrated that the toxic principle was the substance now generally known as Dicumarol, a derivative of coumarin, ($C_9H_6O_2$) the odorous principle in new mown clover hay. Dicumarol does not act

in vitro as an anticoagulant nor in the body except after it has been partially metabolized. When Dicumarol is administered intravenously, only traces can be detected in the circulation after from 20 to 24 hours, yet it is not excreted in the urine or feces. Most of the drug has disappeared before any appreciable reduction in the concentration of prothrombin in the blood has occurred.

It has long been known that the administration of salicylates, e.g., acetylsalicylic acid (aspirin) and sodium salicylate, is often followed by spontaneous bleeding, which has been shown to be associated with hyperprothrombinemia. Salicylates also cause a diminution in the number of platelets. The anticoagulant action of salicylates is antagonized by vitamin K.

SUBSTANCES WHICH HASTEN THE CLOTTING PROCESS (HEMOSTATICS)

It has been widely accepted that adrenaline hastens coagulation but such an effect has not been proved. The effects of thrombin and thromboplastin have been discussed. Tissue extracts especially those of lung and thymus which are rich in thromboplastin are powerfully coagulant, as are also the venoms of some species of snakes. The coagulant property of such venoms depends upon their containing a proteolytic enzyme which converts prothrombin to thrombin, the conversion occurs in the absence of ionized calcium.

Thrombin sprayed upon the bleeding surface in conjunction with fibrinogen to form a covering film or foam of fibrin, is an effective means of arresting bleeding, especially from numerous small vessels. Among other hemostatic agents used to hasten the clotting process are sodium alginate derived from seaweed, and a gauze made of oxidized cellulose, which swells when soaked with blood. When sodium alginate comes into contact with the blood and serum of the wound it is converted to calcium alginate, which clots to form a tenacious layer.

Tests Employed in the Investigation of Defects in the Clotting Mechanism

Coagulation time. This is the time which the blood takes to clot after it has been shed. Obviously, any condition which decreases the coagulability of the blood lengthens the coagulation time and *vice versa*.

A number of methods have been devised to determine the precise moment when clotting occurs. The clotting time as determined by different methods varies considerably since the index or criterion of coagulation is not the same in all, and the conditions to which the blood is subjected are also different. On this account the values are not absolute and the results obtained by different

methods cannot be compared strictly with one another

A simple but rough method when a considerable quantity can be secured is to collect the blood into a small test tube and take as the coagulation time, the period elapsing from the moment the blood was shed to when it congeals, as indicated by tilting the tube from time to time. This procedure is employed in the Howell and the Lee White methods. In the latter, 1 cc of blood is collected in a thoroughly cleaned Wasserman tube about 8 mm in diameter. The coagulation time of normal human blood as determined by this method is from 6 to 15 minutes.

An alternative method and one which requires only a drop of blood is the following. The blood is drawn into a capillary glass tube about 4 or 5 inches long. A section of the tube is broken off from time to time. The time elapsing from the moment when the wound was made to that when fine threads of fibrin appear between the ends of the broken sections of the tube is taken as the coagulation time. The normal coagulation time by this method is about 5 minutes. There are many other methods for determining the coagulation time, e.g., Brodie & Gibbs', Cannon and Mendenhall's etc. but all have their defects and the foregoing is probably just as accurate as more elaborate procedures.

Prothrombin time, determination of the prothrombin concentration. Quick's method is as follows. Nine volumes (about 2 cc) of blood obtained from a vein in a silicone coated syringe are decalcified by the addition of 1 volume of 0.1 mol solution of sodium oxalate. After centrifuging 0.1 cc of the oxalated plasma is mixed with 0.1 cc of thromboplastic material (prepared from fresh rabbit's brain) and recalcified with 0.1 cc of 0.025 mol solution of calcium chloride. The time from the addition of the calcium until the first fine mesh of fibrin filaments appears is recorded by a stop watch. The test is carried out in a water bath at 37.5°C. The prothrombin concentration in per cent of the normal is calculated as follows:

$$\text{Prothrombin concentration} = \frac{K}{ct - a}$$

(per cent of normal)

ct = clotting time, K , a constant = 303, a , a second constant = 8.7. Thus if the clotting time is 21 seconds the prothrombin concentration is $303/(21 - 8.7) = 25$ per cent of normal (approx.)

Clot retraction time. This is measured by collecting a few cubic centimeters of blood in a test tube. After clotting has occurred the clot is separated from the walls of the tube by means of a fine wire and the tube placed in an incubator set at a temperature of 37°C. The clot of blood, normally,

retracts to a firm mass, the serum separating out without a couple of hours. In certain types of purpura (thrombocytopenic) the clot remains bulky, soft and friable. In hemophilia, on the contrary, when clotting does occur, the clot usually retracts normally.

The bleeding time. The determination of the bleeding time simply consists in pricking the skin and noting the time the drop of blood takes to clot sufficiently in order to close the puncture in the skin and stop the bleeding. The precise moment when bleeding ceases is determined by touching the blood from the tiny wound every few seconds with a piece of filter paper. The moment when the latter ceases to be stained is taken as the end point. The normal bleeding time is about 2½ minutes.² One might suppose that the bleeding time would be a better gauge of the body's ability to protect itself against hemorrhage than the coagulation time, but the fact that it is normal, as a rule, in hemophilia (see below) shows that this is not so. The ability to seal a wound in a minute vessel is dependent more upon vascular factors, contraction of the vessel wall and "glueing" together of endothelial surfaces, than upon the clotting of the blood. Actually, there is little relationship between the bleeding time and the coagulation time. The former is prolonged in conditions associated with low platelet counts. It is shortened by the local application or intravenous injection of platelet extracts, by the application of solutions with a low pH (around 5), or by the injection of posterior pituitary extracts.

THROMBOPLASTIN GENERATION TEST

Immediately before the test is started 0.1 ml of platelet-poor, citrated plasma is pipetted into each of several small tubes of uniform diameter which are placed in a water bath at 37°C. In a further tube in the water bath at 37°C is placed 0.3 ml of alumina plasma diluted 1 to 5, 0.3 ml of platelet suspension, or phosphatidyl ethanolamine, and 0.3 ml of serum diluted 1 to 10. To this is added 0.3 ml of M-40 CaCl₂. At intervals of 1 minute 0.1 ml of the mixture is withdrawn into a graduated Pasteur pipette and discharged simultaneously with 0.1 ml of M-40 CaCl₂ into one of the tubes containing 0.1 ml of substrate.

² Ivy and his associates recommend first raising the venous pressure in the arm by constricting it above the point where the skin puncture is to be made. A constricting pressure of about 40 mm Hg is applied. Tocantins has devised an instrument which makes an incision of approximately uniform length and depth.

The clotting times of the substrate samples are recorded. These clotting times give a measure of the rate of generation of thromboplastin in the incubation mixture.

Hemorrhagic Diseases

It is well to emphasize here that a low serum calcium is never a cause of hemorrhagic disease. In hypoparathyroidism, in which the serum calcium may be depressed to less than half the normal value, the coagulation time is not lengthened.

HYPOPROTHROMBINEMIA

Depression of the prothrombin level in the blood—*hypoprothrombinemia*—occurs under several conditions, such as vitamin K deficiency and severe liver damage. A bleeding tendency is not shown, however, according to Quick until the prothrombin concentration falls to about 20 per cent of the normal. Other observers, however, place the critical level somewhat higher.

Hemorrhagic disease of the newborn has been shown quite definitely to be the result of a low prothrombin concentration. At birth and up to 6 hours thereafter, the prothrombin level is not far below normal, but apparently the baby comes into the world with a small reserve. This tends to become quickly exhausted, so that the prothrombin concentration may reach a low level at the end of 24 hours. This physiological hypoprothrombinemia is due, mainly, to lack of vitamin K. When the infant commences to take food, bacteria are introduced into the intestinal tract which acting upon the contents of the intestine synthesize the antihemorrhagic vitamin (ch. 43) and the hypoprothrombinemia is corrected automatically. Should the hemorrhagic state actually develop it is quickly arrested by the administration of vitamin K. Large doses may be given to the mother in the later months of pregnancy as a preventive. *Hypoprothrombinemia* and a hemorrhagic tendency also occur in certain diseases, e.g., acute yellow atrophy, associated with severe liver damage, in certain intestinal diseases e.g., sprue and ulcerative colitis, and in the hemorrhagic disease of farm animals caused by eating spoiled sweet clover. In the animal disease the low prothrombin level is due to a toxic substance (*dicoumarol* p. 115). The mode of action of this compound is not explained by any damaging effect which it might have upon the liver for in therapeutic doses it appears to have no such action although in large doses it may have. In the latter instance its anticoagulant action is

then enhanced as a result of the interference with prothrombin manufacture by the liver. It appears to antagonize the action of vitamin K, being more effective when the concentration of this vitamin is low. It may, therefore, be classed with the anti-vitamins.

The bleeding tendency which for years has been recognized to be a feature of obstructive jaundice, or when bile is lost to the exterior through a biliary fistula has been shown to be the result of vitamin K lack. The deficiency is not due, however, to any dearth of the vitamin in the intestinal tract but simply to the absence of bile salts without which the vitamin cannot be absorbed into the blood stream (p. 914).

Hypoprothrombinemia may be caused by bacteriostatic agents e.g. sulfonamides active against the intestinal flora responsible for the synthesis of vitamin K.

HEMOPHILIA

The coagulation time but not the bleeding time as defined above is greatly prolonged in this condition. In some cases the blood after removal from the body may show no signs of clotting after an hour or so. On this account a fatal hemorrhage may follow a wound that would be trivial in a normal person. The extraction of a tooth a slight accident or a minor operation have resulted in death on many occasions. The subjects are known popularly as 'bleeders'. Hemophilia is transmitted as a sex-linked recessive character. The males are affected but do not transmit the disease; the females though they transmit the disease do not suffer themselves (law of Nasse (1820)). A father, then, who is a bleeder does not transmit the disease to his children in a manifest form. His sons are entirely free from any taint but his daughters inherit the disease in a masked or latent form and transmit it to their offspring. Of these the males show the disease and the daughters again are not bleeders but are carriers for the next generation. In other words the manifest disease skips a generation. Some of these bleeder families have been traced back for a hundred years or so and cover in some cases five generations and hundreds of individuals. The incidence of the disease in these is

*Not every person with a tendency to bleed can be classed as a hemophilic. True hemophilia answers to the following criteria: (a) history showing characteristic type of inheritance; (b) coagulation time of drawn blood but not the bleeding time is greatly delayed; (c) no reduction in platelets.

stances followed in general the plan outlined above. It is theoretically possible, should a "bleeder" and a "transmitter" marry, for the female as well as the male children to be "bleeders." Such a coincidence is so very rare, and the cases of true hemophilia in the female, therefore, so few, that it is usually stated that hemophilia is confined to the male sex.

The defect in the clotting mechanism of hemophiliacs is not definitely known, but a factor seems to be a lack of a sufficient amount of active plasma thromboplastin. The plasma thromboplastin may be actually deficient in amount, fail to undergo conversion from an inactive to an active (Quick) form, or is inactivated or antagonized in some way by inhibitory substances (Tocantins). Tissue thromboplastin or normal platelet-free plasma added to hemophilic blood restores the normal clotting time. Thus, there is no lack of prothrombin, nor is heparin responsible for the prolongation of the clotting time. The platelets in hemophilia are not reduced in number, but they are less fragile than normal. Yet, platelet stability is not the cause of the bleeding in hemophilia. The platelets, contrary to a previous belief, do not contain significant amounts of thromboplastin so that they do not, through their failure to disintegrate readily, withhold this principle from the plasma. Moreover, complete disintegration of the platelets in hemophilic blood by saponin (Pickering) does not correct the defect in the clotting mechanism, and Quick found that platelets from the blood of a hemophilic restored to normal the clotting time of blood which, due to a deficiency of platelets, clotted slowly.

It may seem surprising that the bleeding time is not prolonged in hemophilia, but it must be remembered that the wound which is made in determining the bleeding time is very small, and even though the clotting mechanism itself is defective, it is capable of being sealed by the contraction of the walls of the minute vessels, and the sticking together of the apposed endothelial surfaces. It is when larger vessels are opened that persistent hemorrhage occurs in hemophilia.

Logically, the measure to be used to arrest bleeding in hemophilia, and the one that has proved most effective, is to furnish the missing thromboplastic material either by transfusion of fresh blood, or plasma that has been stored at -20°C . Some success has been achieved recently by the use of fraction I prepared from fresh human plasma.

Two other rare hemorrhagic conditions are *heparinemia* and *afibrinogenemia*. Heparinemia, as

its name indicates, is the presence of heparin in the blood. The blood may be rendered quite incoagulable. The bleeding is unaffected by vitamin K administration, but may be checked by protamine or toluidine blue given intravenously. As already mentioned (p. 115), the experimental production of peptone or anaphylactic shock is associated with the discharge of heparin into the circulation. Oddly enough, tumors of mast cells which contain relatively enormous quantities of heparin do not affect the coagulability of the blood. A congenital absence or very low concentration of fibrinogen—*afibrinogenemia*—is a very rare anomaly of the blood-clotting mechanism.

Purpura. This term is applied to a variety of hemorrhagic states in which spontaneous bleeding occurs beneath the skin, from the mucous membranes or into joints. The subcutaneous hemorrhages appear as small or large purplish spots (*Petechiae* and *ecchymoses* respectively) which gradually pass through the color changes characteristic of a bruise. Since purpura is so varied in its characters and occurs in diseased states that are so widely different, it should be considered as a symptom of a disorder of the blood vascular system rather than as a disease in itself. It occurs in the malignant forms of many acute diseases—smallpox, scarlet fever, diphtheria, streptococcal infections, etc. Subcutaneous and submucous hemorrhages are also features of scurvy, leukemia, certain anemias and of the action of various toxic agents, e.g., snake venoms, drugs and chemicals. In some types of purpura (e.g., infectious and toxic forms) *deterioration of the capillary wall* probably plays the chief role—the red cells escaping into the subcutaneous tissues or from the mucous membranes through capillary defects. On the other hand a great *reduction in platelets* (thrombocytopenia) appears to be an important if not the essential defect in other types and a condition resembling purpura hemorrhagica (see below) has been induced in animals by the injection of an antibody developed for the destruction of platelets. Nevertheless, the experiments of Bedson suggest that reduction of platelets or even their entire absence is not capable alone of inducing purpura. Some injury to the capillary wall must exist as well. This observer also found that splenectomized guinea pigs were highly resistant to the action of the antiplatelet serum. A theory has been advanced which causally relates the capillary defects to the thrombocytopenia. It is probable that the platelets serve, normally, to protect the capillary wall and, by their deposition upon the endothelium, act as a seal against the

e-cape of red cells through weakened points which are constantly occurring from general wear and tear. The reduction in platelets may result from several causes. There may be increased destruction of these elements or the normal mechanism of their production may be interfered with, as in aplastic anemia and leukemia.

The coagulation time in purpura is usually within normal limits but the bleeding time is as a rule prolonged. The clot which forms in the blood after it has been shed is said to be softer than the normal and does not contract and express the serum in the usual way.

THE CAPILLARY RESISTANCE TEST

When cutaneous purpuric spots do not occur spontaneously they may be induced in susceptible persons (lateal purpura) by means of a tourniquet or blood pressure cuff applied to the upper arm so as to obstruct the venous return but not the blood flow in the artery. The obstruction is maintained for 5 minutes. In scurvy and other conditions associated with weakness of the capillary membrane the increased intracapillary pressure so induced results in the formation of small hemorrhagic points (petechiae) beneath the skin of the forearm. A more precise method consists of the application to the skin (usually of the forearm just below the antecubital fossa) of a small suction cup and determining the minimum negative pressure which, when applied for one minute is required to produce petechiae. In health this lies between -200 and -300 mm Hg. A minimum effective pressure less than -200 mm Hg is abnormal.

Purpura hemorrhagica or Werlhof's disease (thrombocytopenic purpura) is associated with a great reduction in the platelet count. They may be almost absent from the circulation. Splenectomy is followed by an increase in platelets and frequently effects a cure. Recently snake venom has been successfully employed in the treatment of this disease. The observations of Troland and Lee point to the spleen in this disease as the source of a toxic material having a destructive action upon platelets. An acetone extract of the spleens of patients suffering from thrombocytopenic purpura when injected into rabbits caused a progressive fall (from 640 000 to 20 000 in 24 hours) in the platelet count. They have given the name *thrombocytopen* to the unidentified active principle in the extracts. Extracts prepared in the same way from normal spleens were without effect upon the platelet count. An abnormal number of megakaryocytes in the bone marrow especially of younger forms has been reported in purpura hemorrhagica

and it is suggested that the failure of these to produce platelets is the fundamental fault.

In one form of purpura—*purpura fulminans*—the hemorrhages are exceptionally severe and the subcutaneous extravasations often extensive. Death may occur within a few days from loss of blood. In this state there is undoubtedly an affection of the capillary endothelium as well as reduction in the number of thrombocytes. Purpuric manifestations may occur with more or less severe symptoms of gastrointestinal irritation—*Henoch's purpura*—or in others bleeding into the joints (*Schonlein's disease*) is a prominent feature. In either of these forms the purpuric spots may occur in association with urticarial wheals or more generalized edematous swellings of the subcutaneous tissues. Capillary damage is probably either the essential or a contributory factor in these states.

Calcium is commonly employed in the treatment of the various types of purpura and appears to reduce the hemorrhagic tendency but the manner in which the effect is brought about is obscure. It is not through increasing the coagulability of the blood.

INTRAVASCULAR CLOTTING—THROMBOSIS

Coagulation within the vessels may be brought about experimentally. (a) By the injection of thrombin into the blood stream. Repeated injections of small amounts of thrombin cause the blood, after the first immediate increase of coagulability, to become for a few hours less coagulable than normal (negative phase). This is due apparently to some decrease in the fibrinogen level of the blood. No permanent reduction in coagulability can however be produced by repeated injections of thrombin over a period of several weeks. (b) By the rapid injection of a tissue extract (thromboplastin) particularly of the lung, thymus or lymph glands. The repeated injection of small amounts of tissue extract may have the reverse effect—decreased coagulability. This was shown by Mellanby and later by Mills and his associates to be the result of the gradual deposition of fibrin upon the vascular walls. The blood failed to clot simply because it had been depleted of fibrinogen. (c) By injury to the vessel wall either by chemical, mechanical or infective agencies, a roughened surface being thereby exposed to the blood stream. Thromboplastin is also liberated from the injured vascular wall.

The formation of a compact and solid mass of platelets, red cells, or blood clot or mixture of these materials in a vessel (vein or artery) which partially or completely occludes its lumen is spoken of as *thrombosis*. The plug itself is termed

a *thrombus*. A thrombus may be formed simply by the clotting of the blood in the usual way, as occurs in a grossly damaged vessel. On the other hand the cellular elements of the blood may form a solid mass within a vessel and block its lumen independently of the clotting process. This occurs sometimes in the smaller vessels when the red cells become agglutinated into large clumps (agglutinative thrombus) as after the transfusion of incompatible blood, or when the blood forms a sludge (p 11). Once the vessel has become plugged in this way a true clot forms eventually in the stagnant column of blood behind the block.

When a thrombus, or a portion of it, becomes detached and carried away in the blood stream to become impacted in a vessel at some remote point in the circulation, it is spoken of as an *embolus*. When arising from a venous thrombus the embolus is likely to lodge in a vessel of the lung. If formed in the left heart it may plug a cerebral artery. The main vessel leading to a circumscribed area may become obstructed and the anastomosing channels may be insufficient to maintain the nourishment of the tissue. The isolation of an area in this way by the obliteration of its artery is spoken of as *infarction*, and the necrotic area as an *infarct*.

CAUSES OF THROMBOSIS IN MAN

The causes of thrombosis in the human subject may be grouped under the following heads

INJURY TO THE VESSEL. Complete mechanical obstruction of the circulation as by a ligature or pressure upon a vessel from without does not alone cause thrombosis. The latter is usually associated with some injury to the inner coat of the vessel, unless this occurs the blood may remain fluid for a considerable time. A thrombus, often very small in size, may form later merely as the result of the slowing of the stream, the formation of eddies in the blind pocket and the deposition and lysis of platelets. Septic infection is one of the commonest causes of endothelial damage leading to thrombosis. Some degree of thrombosis is always associated with acute inflammatory processes of septic origin. The thrombosis may be strictly localized to the smaller vessels at the site of the infection, or may extend into larger venous trunks, and is then due to the spread of the infection along the vein walls (phlebitis). The thrombosis of the femoral vein during the puerperium or of a cerebral sinus following mastoid disease are typical examples of infective thrombosis.

AGGLUTINATION OF CORPUSCLES (agglutinative thrombus)

TOXIC THROMBOSIS. Certain chemical poisons,

e.g., arsenical compounds, mercury, potassium chlorate, etc., may cause intravascular clotting. Poisonous mushrooms, certain snake venoms, as well as toxins formed within the body, as in eclampsia, or extensive burns may induce thrombosis. The manner in which these various agencies act, whether by injury to the vessel wall, disintegration of blood elements or through their effects upon some phase of the clotting process is obscure.

SPONTANEOUS OR POSTOPERATIVE THROMBOSIS, PULMONARY EMBOLISM. Spontaneous thrombosis may occur under a variety of conditions and in practically any vein in the body. Thrombosis particularly of the veins of the lower limbs not infrequently follows operations upon the abdominal or pelvic organs. When it occurs under these circumstances it is always a cause of anxiety to the surgeon because of the danger of the clot becoming detached and carried to the lung where it may block a branch of the pulmonary artery (pulmonary embolus). Infection is frequently blamed for the thrombosis, but in most cases no evidence for this can be found. Also the point where the thrombus forms—usually in the deep veins of the lower limb such as the plantar or calf veins or the femoral vein—lies at a distance from the field of operation and is separated from it by a considerable extent of healthy tissue. This precludes direct spread either of infection or of thrombus formation from the site of the wounded tissue.

The principal factors concerned in spontaneous thrombosis especially following operation, will now be discussed.

1 *Endothelial damage.* Some injury or a slight alteration in the vascular lining which makes it 'wettable' probably initiates the process.

2 *Slowing of the blood stream* as a result of enfeebled heart action, prolonged confinement to bed, debilitating diseases associated with a low metabolic rate and hypotension, or immobility of the limbs, seems to be an important factor in causation. It encourages the deposition of platelets on the vascular wall and may be accompanied by 'sludging' of the blood (p 11).

3 *Deposition of platelets.* Aschoff some years ago made an experimental study of postoperative thrombosis and gave an interesting and logical explanation of the processes involved. He states that when the vein is completely obstructed as is usual, the thrombus has a white portion or head which is directed proximally (toward the heart) and a dark red portion or tail. If the flow of blood is not completely blocked the thrombus consists of the white portion alone. A minute examination reveals a framework of ribs or beams extending from the wall of the vein and traversing the entire substance of the white thrombus. The ribs are made up chiefly of massed platelets covered with a layer of leukocytes. There is little or no sign of fibrin or of red cells, this white plug is not a clot

in the ordinary sense. The longer red portion or tail of the thrombus extends distally for a variable distance along the vessel and is made up of all the elements of the blood in their normal proportions. Fibrin threads are plentiful. This portion is evidently formed by the coagulation of the blood *en masse*. The mode of deposition of the platelets is compared to the manner in which sand, although kept in suspension in a rapid stream, is deposited in a ribbed pattern upon the sea shore or at a river's mouth where the current is slowed. Although the flow of blood in the veins is continuous it is not absolutely even, eddies occur in the venous current and even slight muscular movement causes a certain irregular wavelike motion of the blood column which accounts for the deposition of the platelets, not in a continuous even layer but in ripples. Also, owing to their specific gravity the platelets leave the axis or core of the stream and, separating from the other blood elements, come to occupy the more slowly moving zone next to the vessel wall. Finally, it is the reduction of the velocity in this outer zone of the current to a certain critical level that causes the platelets to settle upon the vascular walls. The ribs or ridges increase in height by the aggregation of fresh platelet masses, and secondary ridges are later formed upon the primary ones until at last the fabric extends like a coral growth into the axis of the stream.

In view of later investigators' some change in the endothelial lining must occur to render it "wetable," (1) above, before platelets will adhere and undergo lysis.

In the auricles during auricular fibrillation, in the slowing of the stream caused by a local dilation of the blood channels, e.g., in an aneurysm or varicose vein, and wherever eddies are produced, a white thrombus either with or without a covering of clotted blood is likely to form as a result of platelet deposition.

The observations of Sandison are pertinent to the question of thrombus formation. Examining the blood flow through the capillaries of the rabbit's ear by the transparent chamber method, he observed thrombi in the process of formation. When the blood flow was retarded platelets were seen to cling to the wall of the capillary or venule. By the deposition of successive layers, a white thrombus was formed which as it grew extended a considerable way along the blood channels. A small proportion of leukocytes were included in the mass, but no erythrocytes.

4 *Blood changes.* The platelets are increased after operations, and these elements show a greater tendency than is normal to clump together. The greater stickiness is due, according to Wright, to newly formed cells discharged from the bone marrow. The fibrinogen also is increased and, as a result of this, the rate of sedimentation of the

corpuscles is hastened (ch. 7), clot retraction is usually more pronounced than normally.

The coagulation time is shortened for the first few days after operation but it is doubtful whether an altered relationship between the different factors concerned in the clotting mechanism itself is of prime importance in the production of postoperative thrombosis. At first sight the liberation of thromboplastin from the damaged tissues would seem to be a probable cause of the thrombosis. Yet if this were responsible one would expect that the thromboses would occur immediately following operation and not as is actually the case a week or ten days later. Moreover, thrombi composed of masses of platelets have been induced in animals whose blood had been rendered incoagulable, and postoperative thrombosis may occur in subjects whose blood shows a clotting time within the normal range.

Although some alteration in the vascular endothelium and slowing of the venous blood flow are probably the most important factors in the production of postoperative thrombosis, alterations in the blood itself which follow tissue injury, namely the increase in the number of platelets and the rise in fibrinogen concentration, no doubt encourage the formation of the white thrombus. Anhydremia by increasing the viscosity of the blood may also favor its occurrence.

THE RELATION OF BLOOD FAT TO CLOTTING AND ITS POSSIBLE ROLE IN ATHEROSCLEROSIS

During the past few years much evidence has been obtained which suggests that consumption of excessive amounts of fat may be an etiological factor in atherosclerosis and thrombosis. Results of studies of the effect of fat meals on clotting times in man have been contradictory. This is probably due to the variety of tests used by different investigators. In general there does appear to be a tendency towards a shortening of clotting time after the ingestion of fat. The change however is not a large one and is by no means universally accepted. In any event the part played by fats in blood coagulation may not be related to their rôle in the development of thrombosis or atherosclerosis.

Summary

The most probable sequence of events in the formation of a thrombus postoperatively is as follows: first, some abnormality occurs in the endothelial lining of a vessel and its unwettable property is lost. Platelets adhere and agglutinate at this point and a white thrombus forms. Platelet accumulation and the growth of such a white thrombus are favored by a sluggish blood

flow As the platelets disintegrate, the series of reactions leading to thrombin production and the formation of a fibrin net (with or without entrapped red cells) is initiated The platelet thrombus with the clot subsequently formed may adhere firmly to the vascular lining, in which event the thrombus remains fixed and, though it may occlude the vessel, there will be relatively little danger of its being swept away in the blood stream to block a distant vessel Quick attaches much importance to clot retraction as a factor to the further growth of the clot and the production of an embolus If clot retraction is pronounced, as in anemia or when the platelet count is high, thrombin is expressed from the interstices of the fibrin net and causes extension of the clot The latter, attached by its base to the endothelium, but with its other end floating in the circulation and pointing in the direction of the blood flow, is continually adding to its length by fresh accretions of clotted blood This elongated mass has a rather precarious hold and after a time, loosened by the force of the blood stream or perhaps by some sudden movement of the patient, is detached and carried away According to this conception, clot retraction which draws the thrombus from the vascular wall (except at its base to which for a time it is moored) favors its enlargement in the blood stream, and is an essential factor in its ultimate detachment as an embolus The abnormality in the vascular lining which starts the train of events leading to thrombosis cannot always, nor perhaps often, be demonstrated, even histologically, but from indirect evidence some such alteration is believed to be present almost invariably

The following are the chief measures which have been employed in attempts to prevent postoperative thrombosis

- 1 Early movement of the limbs, to favor the venous flow

- 2 Avoidance of any restriction to respiration—which is an important factor in aiding the venous return from the limbs

- 3 Thyroid extract administration, to raise the metabolism and increase the circulation rate

- 4 Plenty of fluids, to prevent dehydration, and a diet composed largely of carbohydrate since the platelet count and the fibrinogen are raised by a high protein diet

- 5 The treatment of any anemia which may exist

- 6 The use of anticoagulants such as heparin by continuous intravenous administration or of Dicumarol by mouth, which tend to prevent platelet agglutination

THE MECHANISMS REGULATING THE REACTION OF THE BODY FLUIDS

Physicochemical Principles

THE ELECTROLYTIC DISSOCIATION THEORY

When certain chemical substances, such as acetic acid, hydrochloric acid and many others, are dissolved in water a proportion of their molecules—the proportion varies with the particular substance—undergo dissociation into their constituent ions. The latter move through the solution in all directions, some collide with one another and recombine, whereas a corresponding number are produced by the dissociation of other molecules. By the junction of some ions and the separation of others, the balance between undissociated (unionized) and dissociated (ionized) molecules is kept constant. That is, equilibrium is established. Substances whose molecules are dissociated in this way are known as *electrolytes*. An ion is an electrically charged atom or group of atoms and is referred to as a *cation* or an *anion* respectively according to the nature of the charge—positive or negative—which it holds. Cations are denoted by a plus sign or simply by a dot placed above the atomic symbol. The negative ion (anion) is indicated by a minus sign or an oblique dash. Thus HCl dissociates into the ions H^+ and Cl^- , H_2O itself into H^+ and OH^- and H_2CO_3 into H^+ and HCO_3^- . When an electric current is passed through the solution each ion carries a charge of electricity to one electrode or another, the anions (negative ions) migrating to the positive electrode or anode and the cations (positive ions) to the cathode. The conduction of an electric current through the solution will therefore be influenced by the concentrations of ions in the solution (i.e., upon the degree of dissociation of the particular electrolyte). Solutions of such substances as sodium chloride are good conductors, whereas solutions of other substances such as cane sugar which undergo little or no dissociation are not much better conductors than pure water.

When (a) the degree of dissociation of an acid or other electrolyte and (b) the total concentration of the acid in the solution are known, then the concentrations of dissociated and undissociated molecules can be calculated. It is found that after

equilibrium has been established the product of the concentrations of ions divided by the concentration of the undissociated molecules gives, at a given temperature and for a given electrolyte, a constant value which is known as the *ionization* or *dissociation constant*. This represents the operation of the mass law¹ as applied to the dissociation of electrolytes. So if HA represents an acid which is dissociated into cations H^+ and anions A then K_a represents the dissociation constant of the acid. The brackets enclosing the letters represent molar concentrations. Thus

Dissociated

$$\frac{[H^+] \times [A]}{[HA]} = K_a \text{ (ionization constant)}$$

Undissociated

After equilibrium has been reached the velocity at which the molecules HA dissociate into H^+ and A^- is equal to that at which the latter combine to form HA. In this way an equilibrium between dissociated and undissociated molecules is maintained, thus, $HA \rightleftharpoons H^+ + A^-$. For weak electrolytes the degree of dissociation increases with dilution, so that at infinite dilution the dissociation is complete. The greater the degree of dissociation the higher will be the numerator of the equation, and the higher consequently will be the value of the dissociation constant.

HYDROGEN ION AND HYDROXYL ION CONCENTRATIONS

The Ionization of Acids

If a measured amount of a normal solution of acetic acid be titrated against a normal solution of sodium hydroxide a definite amount of the base will be required for neutralization. If the same quantity of a normal solution of HCl be taken and

¹ The mass law states that the velocity of a chemical reaction is proportional to the concentrations of the reacting substances. Although this law holds for dilute solutions of such weak electrolytes as are present in blood it is inaccurate in the case of strong electrolytes in concentrated solutions.

titrated as before, it will be found that precisely the same amount of base will be required for complete neutralization. From this it might be assumed that the two acids are equally strong. But it is known that at similar concentrations the acid properties of hydrochloric are incomparably greater than those of acetic acid. The former inverts cane sugar more powerfully, it tastes more acid, it has a greater destructive effect upon animal tissues, and it will displace acetic acid from its salts.

Hydrochloric acid is dissociated into hydrogen ions and chlorine ions. To the H ion it owes its acid properties, it is the hydrogen ion concentration and not the total number of hydrogen atoms in its molecule that is responsible for the acid characters of any acid. The greater the degree of dissociation of the acid, the greater is the number of H ions which it will yield in solution, i.e., the greater will be the H ion concentration and the greater consequently will be its acid nature. Thus HCl, although it contains only one atom of hydrogen in its molecule, undergoes almost complete dissociation and consequently is a much stronger acid than carbonic (H_2CO_3), whose molecule contains two hydrogen atoms but dissociates to a very small extent into H^+ and HCO_3^- ; carbonic acid dissociates in two stages. Phosphoric is another weak acid which contains three atoms of hydrogen. It dissociates, however, to a greater extent than carbonic acid and in three stages.

The greater the degree of dissociation of an acid the higher will be the value of its dissociation constant. The latter therefore is a true measure of acid properties. The dissociation constant of a very weak acid such as carbonic is only 0.0000003 (first stage), the first dissociation constant of phosphoric acid is 0.011.

The Ionization of Bases

The OH ion on the other hand gives to bases in aqueous solution their characteristic properties, and when a base and acid neutralize one another it is the union of the hydrogen ion of the acid with the hydroxyl ion of the base with the formation of a molecule of water that brings about neutralizations, thus

The ionization of a base may therefore be repre-

sented by an equation analogous to that given for an acid. Thus

If the hydrogen ions are in excess the solution is acid, if the hydroxyl ions are in greater concentration the solution is alkaline.

The Ionization of Water—the Reaction of a Solution Expressed in Terms of Hydrogen Ion Concentration

The dissociation of water may be represented by the equation

Pure water has a definite although very slight conductivity value. The concentration of the molecules that are dissociated into H^+ and OH^- as compared with those undissociated is almost infinitesimal, the concentration of the H^+ and OH^- is so small that their presence produces no measurable decrease in the concentration of the total water molecules. The equation then may be written simply—

K_w , the dissociation constant for water therefore represents the product of these ionic concentrations and amounts to no more than 0.00000000000001.

Expressed more briefly, though perhaps more cryptically, the value is 1×10^{-14} . The symbol -14 to the right of the figure 10 is termed the negative exponent or index, and means that in order to express the value in the form of a decimal fraction, as in the preceding paragraph, the figure 1 must be placed 14 places to the right of the decimal point. Expressed as a vulgar fraction 10^{-14} would be $\frac{1}{100000000000000}$.

Other examples of this system of notation are

We already know that the H^+ and OH^- must be present in equal concentration and that the dissociation constant 1×10^{-14} is the product of these concentrations, i.e., the square of either. Therefore the square root of 10×10^{-14} , i.e., $1 \times$

10^{-7} indicates the concentration either of the H^+ or of the OH^-

The actual weight of ionized water in 1000 cc (1 liter) of water is therefore

1×10^{-7} grams H ions (atomic weight of hydrogen = 1)

17×10^{-7} grams OH ions (atomic weight of oxygen = 16)

Total 18×10^{-7} grams ionized H_2O

A solution containing 1 gram of hydrogen ion per liter is known as one having a normal concentration of hydrogen ions. Seventeen grams of OH ions in the same quantity of fluid is known as a normal solution of hydroxyl ions. Water is therefore 10^{-7} normal in both H^+ and OH^- ions. Since both are in equal numbers per unit of fluid, water is neutral in reaction.

If hydrochloric acid is added to water it is dissociated to the extent of over 90 per cent into H^+ and Cl^- . The concentration of H^+ in the water will therefore be greatly increased by the addition of acid. But it has already been seen that the product of the concentration of H^+ and OH^- in water is constant (K_w). This statement applies not only to pure water but to all aqueous solutions. This is a fundamental fact and upon it the determinations of the hydrogen ion concentration and the notations used for its expression are based. When therefore the H^+ are increased the OH^- must undergo a reciprocal reduction. If, for instance, the H^+ concentration is increased above its value in pure water, that is from 1×10^{-7} to say 1×10^{-6} (0.0000001 N to 0.0000001 N), then the concentration of OH^- must undergo a reduction to 1×10^{-8} in order that the product of these two shall remain the same ($1 \times 10^{-6} \times 1 \times 10^{-8} = 1 \times 10^{-14}$). On the other hand if a base be added to water and the OH^- concentration increased from its value in pure water, i.e., from 1×10^{-7} to, let us say, 1×10^{-6} , the H^+ concentration must undergo a corresponding diminution from 1×10^{-7} to 1×10^{-8} (0.0000001 N to 0.0000001 N). Therefore all that is required in order to indicate the concentrations of both H^+ and OH^- ions is an expression which denotes the concentration of either one. The concentration of the H^+ has therefore been chosen to express the reaction of a solution. The term "hydrogen ion concentration" is abbreviated to the symbol cH . If the hydrogen ion concentration (cH) is greater than that of pure water the reaction is acid, if less than this value, the reaction is alkaline, and if precisely the same, the reaction is neutral. Thus

If cH equals that of pure water, i.e., 1×10^{-7} the reaction is neutral

If cH exceeds that of pure water, e.g., from 1×10^{-7} to 1×10^{-6} the reaction is acid

If cH is less than that of pure water, e.g., from 1×10^{-7} to 1×10^{-8} the reaction is alkaline

The values represent the H^+ concentrations in terms of a normal solution (i.e., one containing 1 gram of ionized hydrogen per liter). No matter how concentrated in a solution the H^+ may be, some OH^- are always present, and vice versa, with maximum alkalinity a small number of H^+ are always present.

The Symbol pH

The value of the hydrogen ion concentration as indicated above was found inconvenient. When the cH was 1×10^{-6} , 1×10^{-8} etc., the first factor could, for the sake of simplicity, be omitted. The expression then became $cH 10^{-6}$, etc. But when the first factor was other than unity, e.g., as in 5×10^{-6} or 1.3×10^{-7} or 4×10^{-8} , this obviously could not be done. The writing of such expressions became cumbersome and the hydrogen ion concentrations which they represented were difficult to keep in mind.

Sorensen in 1909 introduced a system of notation by which the negative exponent of the common logarithm (i.e., to the base 10) of the decimal fraction expressing the H ion concentration is employed as a positive number. For example the H ion concentration of serum is 0.00000004 normal. The cH might be expressed either as 4×10^{-8} N, or as $1 \times 10^{-7.4}$ N. The latter expression is simplified by omitting the 10 and replacing the minus sign of the negative exponent by the symbol pH (hydrogen ion exponent). The value 7.40 is derived as follows. The log of the figure in the cH expression above, i.e., 4 is 0.6021 (cf log tables). This log subtracted from the negative exponent, i.e., 8, gives the required figure 7.40. Similarly a solution 0.0000005 normal in H ions may be expressed either as $cH 5 \times 10^{-8}$ or as $cH 1 \times 10^{-7.3}$. The log of 5 is 0.6990, the pH is, therefore, $8 - 0.6990 = 7.3$.

It must be remembered that a rise or fall in the pH indicates a change in hydrogen ion concentration (cH or $[H^+]$) in the opposite direction. Thus a pH of 5.00 indicates a higher acidity than a pH of 6.00, and a pH of 9.00, a lower hydrogen ion concentration than a pH of 8. pH 7.00 of course indicates neutrality. Attention should be drawn to another point that is not quite so obvious, namely that a solution of a pH 5.00 is more acid not simply by a sixth than a solution of pH 6.00,

TABLE 13 1

HCl Added	$\frac{\text{H}_2\text{CO}_3}{\text{NaHCO}_3}$	pH	$[\text{OH}^-]$	Relative Acidity	Relative Alkalinity
grams					
0	2 27.11 0	0 000000057 N	0 000000176 N	0 57	1 76
10	2 27.11 5	0 000000059	0 000000170	0 50	1 70
50	2 27.10 0	0 000000068	0 000000142	0 68	1 47
100	2 27. 8 2	0 000000083	0 000000120	0 83	1 20
150	2 27. 6 3	0 000000108	0 000000093	1 08	0 93
200	2 27: 4 4	0 000000151	0 000000065	1 51	0 65
250	2 27: 2 6	0 00000026	0 000000039	2 6	0 39
300	2 27 0 68	0 0000010	0 00000010	10	0 10
310	2 27: 0 31	0 0000022	0 000000015	22	0 045
318	—	0 00026	0 0000000039	260	0 0039
320	—	0 00045	0 0000000022	450	0 0022
330	—	0 0027	0 00000000037	2700	0 00037

but is in fact ten times more acid. A pH of 3.00 represents an acidity 1000 times greater than a pH of 6.00. Similarly a solution of pH 11.00 is 1000 times more alkaline than one of pH 8.00. Recalling the decimal fraction that these figures represent will make this clear. Thus pH 5.00 = 0.00001 normal and pH 6.00 = 0.000001 normal.

BUFFERS

These are substances which when present in a solution maintain that solution at a relatively constant pH when an acid or alkali is added to it. That is, a buffer has the power to "soak up" or "tampon" the acid or base, it takes up the shock, so to speak, of the strong acid or base, hence the term buffer. A buffer or buffer system consists of two parts—a weak acid and one of the salts of that acid. Acetic acid and sodium acetate, carbonic acid and sodium bicarbonate, phosphoric acid and sodium phosphate, are a few examples of such buffer pairs. Solutions of buffers are used in physiological experiments when for any reason it is desired to maintain the fluid medium at a constant hydrogen ion concentration, as for example in the study of the action of ferments.

The hydrogen ion concentration of a buffer solution is proportional to the ratio of the concentration of the free acid to the concentration of acid bound to base. The ratio of the buffer pair may be expressed as follows:

Concentration of free acid

$$\frac{[\text{HA}]}{[\text{BA}]}$$

Concentration of bound acid

The hydrogen ion concentration of the solution is equal to the product of the dissociation constant

of the acid (K) and the ratio of the buffer pair. Thus

$$\text{Hydrogen ion concentration } [\text{H}] = K \frac{[\text{HA}]}{[\text{BA}]}$$

In order to express the H ion concentration in terms of pH, the value for K is converted by means of logarithms to the corresponding pK figure. The equation then becomes

$$\text{pH} = \text{pK} + \log \frac{[\text{BA}]}{[\text{HA}]}$$

This is known as the Henderson-Hasselbalch equation (see also pp. 135 and 466).

The effect of a buffer in preventing changes in reaction of a solution when acid is added may be illustrated by an example given by L. J. Henderson (table 13 1).

One hundred liters of a 1 per cent solution of sodium bicarbonate is made up and kept in contact with an unlimited atmosphere containing 0.1 per cent of carbon dioxide. Time is allowed for the solution to absorb CO_2 and for equilibrium to be established between the pressure of gas in the atmosphere and that in the fluid. The temperature is kept constant at 17°C . The solution to start with is slightly alkaline. Hydrochloric acid is added in successive amounts up to 330 grams. It may be seen from the accompanying table that the reaction of the solution is little altered after as much as 150 grams of HCl have been added. Even after the addition of 250 grams the H-ion concentration is no more than 2.6 times that of a neutral solution. It is not until the bicarbonate has been completely used up that the acid exerts

any great effect. The ratio $\frac{\text{H}\cdot\text{CO}_3}{\text{NaHCO}_3}$ remains al-

most unchanged until some 50 grams of HCl have been added

The reaction may be expressed as follows

In this reaction three things have occurred

1 The very strong acid, hydrochloric, has disappeared, the very weak acid, carbonic, having taken its place

2 The weak carbonic acid is volatile and is quickly diffused into the atmosphere. Thus continues until equilibrium between the pressure of gas in the atmosphere and that in the solution has been re-established

3 The bicarbonate has served as a reserve of base which has soaked up or buffered the added acid. The bicarbonate has of course been reduced and (finally) completely used up in the process

THE DONNAN THEORY OF MEMBRANE EQUILIBRIUM

The Donnan effect is a state of ionic equilibrium set up between two sides of a membrane by the presence in a solution of electrolytes of an ion (such as protein) to which the membrane is impermeable. It is explained best by an illustrative example. Let two electrolytes, Na^+Cl^- and Na^+P^- , be separated by a membrane which is permeable to the ions Na^+ and Cl^- but impermeable to P^- . Thus,

When equilibrium has become established the product of the concentrations of the *diffusible* ions (Na^+ and Cl^-) on one side of the membrane equals the product of the concentration of these ions on the other side

$$\frac{[\text{Na}^+] \times [\text{Cl}^-]}{[\text{P}^-]} = [\text{Na}^+] \times [\text{Cl}^-]$$

Also on either side of the membrane the total concentration of anions (whether diffusible or nondiffusible) is equal to the concentration of cations each solution being electrically neutral

$$[\text{Na}^+] = [\text{Cl}^-]$$

Since the anion P^- is nondiffusible it follows that the diffusible ions Na^+ and Cl^- must be unequally distributed on the two sides of the membrane. In other words, the nondiffusible ion hinders (through electrostatic attraction) the free diffusion of the oppositely charged Na^+ ions. Therefore the concentration of the Cl^- ion is less and

that of the Na^+ ion is greater on the side occupied by the nondiffusible ion, thus

$$\begin{array}{c} | \\ [\text{Cl}^-] < [\text{Cl}^-] \\ | \\ [\text{Na}^+] > [\text{Na}^+] \\ | \\ [\text{P}^-] \end{array}$$

The ratio of the Na^+ concentrations on the two sides of the membrane (which may conveniently be styled *right* and *left*) is the same as, but reciprocal to, the ratio of the Cl^- concentrations. Thus

$$\frac{[\text{Na}^+ \text{ left}]}{[\text{Na}^+ \text{ right}]} = \frac{[\text{Cl}^- \text{ right}]}{[\text{Cl}^- \text{ left}]}$$

A difference in electric potential—*membrane potential*—is created between the solutions on the two sides of the membrane which is proportional to the logarithm of this ratio. When the ratio is 1:10 the potential difference at 19°C amounts to 58 mv. The ionic distribution may be represented thus

Numbers indicate concentrations in arbitrary units

The Donnan equilibrium is responsible for many physicochemical effects of the utmost physiological importance, e.g., a difference of pH on two sides of a cell membrane across which H^+ ions can diffuse, differences of electrical potential between two sides of a membrane and differences in osmotic pressure between the interior of a cell and the extracellular fluids (see also ch 3)

The Regulation of the Acid-Base Equilibrium of the Blood

Acids such as phosphoric, sulfuric and hydrochloric, carbonic and lactic as well as certain or-

ganic acids are continually being formed in the processes of metabolism. In disease, e.g., diabetes, acids such as β -hydroxybutyric and acetoacetic acids are produced in excess. Yet in health the reaction of the blood remains remarkably constant at about pH 7.4, and even in disease may show little or no variation from the normal, for the adjusting mechanisms called into play to neutralize and remove excess acid perform their duties with extraordinary efficiency.

The reaction of the blood is protected by three lines of defense: (a) the buffer systems of the blood, (b) excretion of carbon dioxide by the lung, and (c) excretion of fixed acid by the kidney. The intestinal mucosa also assists to some extent in the removal of acid, particularly of a part of the phosphoric. The role played by the kidneys in the regulation of the acid-base balance is considered in chapter 34.

THE BUFFER SYSTEMS OF THE BLOOD may now be enumerated:

I In the plasma (primary buffers)

- 1 Carbonic acid (free acid) and acid bound as sodium bicarbonate. Ratio 1 to 20

- 2 The acid and alkaline phosphates of sodium. Ratio 1 to 5

NaH_2PO_4 may be regarded as a weak acid and Na_2HPO_4 as the salt of the buffer pair.

- 3 Plasma proteins which at the reaction of the blood behave as acids and so combine with base

II In the corpuscles (secondary buffers). It is to be remembered that whole blood consists of two liquid phases separated from one another by the membrane of the corpuscles. Different materials in different concentrations exist within the red cell and in the plasma. The corpuscles as well as the plasma contain important buffers and an interchange of water, anions and H^+ occurs between the two across the membrane. The corpuscular membrane, on the other hand, is impermeable to K^+ and almost impermeable to Na^+ as well as to the colloidal anions, hemoglobin and plasma protein. The buffers of the red cells are

1 Oxyhemoglobin and reduced hemoglobin act each as a weak acid of a buffer pair of which the potassium salt of the pigment acts as the other half. Thus

and

- 2 The potassium salts of phosphoric acid

The reactions by which acids are buffered in the blood may now be considered in more detail. They may be grouped under the following heads:

1 Fixed acids formed during metabolism, e.g., lactic, sulfuric, phosphoric, etc., are buffered by the bicarbonate in a way analogous to that already described on pages 127-8. Taking lactic acid (HL) as a type the reaction may be expressed by the following equation:

The comparatively strong fixed acid is thus replaced by a neutral salt. Phosphates, sulfates, lactates, etc., are excreted in the urine, lactic acid is also removed to a large extent through its conversion to glycogen in the liver and muscles. Carbonic acid is removed through the diffusion of CO_2 into the alveolar air. The great value of bicarbonate in maintaining neutrality of the body fluids is not due so much to its true buffering action, i.e., to the replacement of a strong by a weak acid, but to the fact that the latter is volatile and can be eliminated by the lungs.

Some of the fixed acid also reacts with the alkaline phosphate with the production of a salt of the acid and a greater proportion of acid phosphate:

The ratio $\text{NaH}_2\text{PO}_4/\text{Na}_2\text{HPO}_4$ is readjusted by the excretion of the excess acid phosphate in the urine. The phosphate mechanism for removal of acid from the body is much less efficient, however, than in the bicarbonate system, for the reasons that (a) the excretion by the kidney is relatively

slow, and (b) base is lost from the body in combination with the acid. Plasma protein also yields base to neutralize fixed acids.

2 *Carbonic acid* which as a product of tissue activity is produced in much greater quantities (800 to 900 grams daily) than any other acid, it is buffered mainly by base released from hemoglobin. When carbon dioxide enters the blood the sodium bicarbonate of the plasma increases. The increase occurs to a much less extent if plasma separated from the red cells is exposed in the same way to a high tension of CO_2 . The rise in the sodium bicarbonate of whole blood is the result of interchanges between corpuscles and plasma.

It was thought at one time (Zunz) that the rise in plasma bicarbonate was due to the passage of base from the corpuscles into the plasma. It was shown by Gurber and by Hamburger, however, that the rise of bicarbonate was accompanied by a reduction in chloride. It was concluded that chloride derived from the NaCl of the plasma diffused into the red cell and the base (Na) thereby released combined with carbonic acid to form bicarbonate. This mechanism is referred to as the "*chloride shift*". The interchanges between the corpuscles and plasma are believed to occur as follows. As the blood passes from the arterial to the venous side CO_2 is absorbed and diffuses into the red cell. Herein, through the action of an enzyme—*carbonic anhydrase*—(ch 29), it is converted to carbonic acid (H_2CO_3). The oxyhemoglobin becomes at the same time reduced. Reduced hemoglobin is a much weaker acid than oxyhemoglobin and so gives up its alkali to the carbonic acid. Bicarbonate (HCO_3^-) and HHb are formed. The base which previously had been bound to the nondiffusible hemoglobin is now bound as bicarbonate. The concentration of bicarbonate ions (HCO_3^-) in the cells is thereby raised above that in the plasma and, as a result, this anion diffuses across the corpuscular membrane. Since the cations cannot diffuse, the ionic equilibrium between the plasma and the interior of the cell will tend to become disturbed. The equilibrium (p 468) is sustained by the diffusion of Cl ions from the plasma into the corpuscle where they combine with base. The HCO_3^- ions which leave the cells combine with the sodium released from chloride to form plasma bicarbonate (see fig 29.11).

The exchanges just described increase the concentration of osmotically active substances within

the cells, water therefore passes from plasma to corpuscle, which as a result increases in volume. Although described in steps, the reactions actually occur simultaneously. In the lungs reverse ionic interchanges occur between the cells and plasma. H_2CO_3 within the corpuscles is acted upon reversibly by carbonic anhydrase, CO_2 enters the plasma and diffuses into the alveolar air, oxygen is absorbed and diffuses into the cell. The oxyhemoglobin so formed, being a stronger acid, recaptures the base which it had lost. Cl ions leave the cells and recombine with plasma base, whereas HCO_3^- ions enter the cells and recombine with base released from chloride. Thus the plasma bicarbonate is reduced and the plasma chloride increased. Water leaves the cells for the plasma.

Carbonic acid is also buffered to a minor extent in the plasma through the protein and phosphate buffer systems. The plasma protein yields base and more free (acid) protein is produced. The alkaline phosphate is converted to the acid phosphate with a consequent fall in the $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$ ratio.

It is evident from the foregoing description of the interchanges between the corpuscles and the plasma that whole blood as compared with plasma possesses a much greater power to buffer CO_2 . For this reason plasma separated from the red cells without precautions to prevent the escape of CO_2 is called 'separated plasma' to distinguish it from plasma of whole blood, i.e., plasma in contact with the red cells. Only when precautions have been taken to prevent the escape of CO_2 during the separation of plasma from the cells will the separated plasma have the same reaction and amount of bicarbonate as existed when it was in the body. Only then will the equilibrium between cells and plasma be maintained unchanged. Such plasma is therefore referred to as "*true plasma*" (see also ch 29).

Alkali Reserve—Acidosis and Alkalosis THE ALKALI RESERVE

This term was brought into use by Van Slyke and Cullen to denote the amount of base in the blood which is available for the neutralization of fixed acids, e.g., lactic, hydrochloric, etc. When CO_2 enters the blood, base is liberated in the manner already described and bicarbonate, NaHCO_3 , is formed in the plasma. The plasma bicarbonate then is a measure of the base left over after all acids stronger than H_2CO_3 have been neutralized and indicates the reserve of alkali readily available for the neutralization of such acids. The

quantity of plasma bicarbonate therefore gives indirectly a measure of the extent of the production of fixed acids in the body. If acid production is increased the bicarbonate becomes reduced, its base being given up for the neutralization of the stronger acids. The term *alkali reserve*, it should be emphasized, refers only to base bound as bicarbonate and not to the total base of the blood. A large quantity of base, Na, K, Mg and Ca is already bound as salts of fixed acids, chiefly sodium chloride, which the weak acid H_2CO_3 is unable to displace (fig. 131). Though changes in the alkali reserve may result from alterations in the body's store of total base, they also occur quite independently of any such change, i.e., simply from variations in the distribution of base between carbonic acid and fixed acids.

It is also important to remember that the term *alkali reserve* refers to the *absolute* quantity of bound CO_2 in the plasma and has no reference to the ratio between this value and the quantity of the free CO_2 . Upon this ratio— $\text{H}_2\text{CO}_3/\text{NaHCO}_3$ —the pH of the plasma depends. The plasma bicarbonate may therefore be greatly depleted, yet if the free carbonic acid is reduced to a corresponding extent and the normal ratio of 1:20 thereby maintained, the hydrogen ion concentration will show no appreciable change. Large quantities of acid may be formed in the body yet such is the store of bicarbonate that these, as in the case of the example given on page 123, are taken care of and not until extreme depletion of the bicarbonate buffer occurs does any great change in blood reaction result.

Rapid adjustments of the ratio $\text{H}_2\text{CO}_3/\text{NaHCO}_3$ are brought about through the exquisite sensitivity of the respiratory mechanism to changes in pH, and to the chloride shift between plasma and red cells. The slightest reduction in plasma bicarbonate through its decomposition by acid is met by increased pulmonary ventilation and an equivalent reduction in the numerator of the above expression, i.e., by the elimination of CO_2 by the lungs. Low arterial and alveolar CO_2 tensions are therefore associated with a low alkali reserve.

On the other hand, when excess CO_2 is contained in the blood a compensatory increase in bicarbonate results (chloride shift). So high arterial and alveolar CO_2 tensions are associated with a high alkali reserve.

When excessive amounts of CO_2 are removed from the body (e.g., by forced breathing) a movement of chloride and bicarbonate ions occurs in

FIG. 131 Diagram illustrating normal acid-base balance (modified from Gamble, Ross and Tiedall)

the reverse direction, the plasma bicarbonate is reduced.

THE NORMAL ACID-BASE BALANCE AND ITS VARIATIONS

The pH of the arterial blood in health varies between 7.39 and 7.44. The normal value for the plasma bicarbonate of venous blood ranges between 53 and 75 volumes CO_2 per cent. The free CO_2 , being one-twentieth of this, amounts therefore to from about 2.5 to 3.5 volumes per cent.

In disease the pH of the blood, unless in the terminal stage, e.g., diabetic coma, never becomes actually acid, i.e., reaches a pH below 7.0, and as just stated, a reduction in the alkali reserve may occur with little or no change in blood reaction. The limits of pH compatible with life are probably not higher or lower respectively than 7.8 and 6.8. A pH of the latter value has been observed in a patient who was in a diabetic coma but who ultimately recovered under insulin treatment. The pH of venous blood during rest is lower by 0.02 than that of arterial blood. The red cells are more acid than the plasma by 0.03 to 0.14 pH.

ACIDOSIS AND ALKALOSIS—DEFINITIONS

Few terms in physiology have caused more confusion than these "Acidosis" has been used with

at least two different meanings. The term was originally introduced by Naunyn to denote the production in the body of the abnormal acid metabolites β hydroxybutyric and acetoacetic acids.

The term was used later by Van Slyke and Cullen to mean simply a decrease in the alkali reserve (plasma bicarbonate) below the normal level. This is the sense in which the term has been usually employed. Since the bicarbonate represents the base in the blood which is left over after the nonvolatile acids have been neutralized, a reduction in alkali reserve indicates frequently—although not necessarily—that an excess of fixed acids are being produced or retained in the body. We have seen how very efficient the compensatory mechanisms are in keeping the pH constant, and that an acidosis either in the sense of a reduction in alkali reserve or of an increased acid production may or may not be associated with a depression of the pH (reduced alkalinity). We also know that the term acidosis cannot mean any real acidity of the blood—a pH below 7.00—for this is incompatible with life, and only occurs when the alkali reserve is very greatly reduced and the bicarbonate buffer ratio cannot be maintained anywhere near the normal value. *Alkalosis* carries the corresponding meaning of an increased alkali

reserve. This may or may not be associated with a rise in blood pH (i.e. increased alkalinity).

Van Slyke in a later paper recognizes nine possible acid base states: one normal and eight abnormal (fig. 13.2). He avoids the terms acidosis and alkalosis, using the more precise designations: alkali deficit or CO_2 excess and alkali excess or CO_2 deficit respectively. In any one of these the ratio $\text{H}_2\text{CO}_3/\text{NaHCO}_3$ may be either increased or diminished with a consequent elevation or depression of pH; the acid base condition is then said to be *uncompensated*. On the other hand, when adjustments occur to maintain the ratio at the normal value, the condition is said to be *compensated*.

The nine acid base states are described as follows:

1. *Uncompensated alkali excess*. In this condition the $[\text{NaHCO}_3]$ is increased without a proportionate rise in $[\text{H}_2\text{CO}_3]$. The pH is raised (i.e. the alkalinity of the blood is increased). This may result from the ingestion of large quantities of alkali (sodium bicarbonate) or from the loss of HCl by vomiting as in pyloric obstruction (area 1 in figure 13.2).

2. *Uncompensated CO_2 deficit*. In this the $[\text{H}_2\text{CO}_3]$ is reduced below normal, the $[\text{NaHCO}_3]$ is also lowered, but not sufficiently to maintain $\text{H}_2\text{CO}_3/\text{NaHCO}_3$ ratio at its normal value. The pH

FIG. 13.2. Normal and abnormal variation of the $[\text{NaHCO}_3]$, $[\text{H}_2\text{CO}_3]$, CO_2 tensions and pH in oxygenated human whole blood drawn from resting subjects at sea level.

The curved lines are the CO_2 dissociation curves (ch. 29) of reduced (upper curve) and oxygenated blood (lower curve). The straight slanting lines indicate different $\text{NaHCO}_3/\text{H}_2\text{CO}_3$ ratios; the pH at each ratio having been calculated from the Henderson-Hasselbalch equation. The CO_2 present as bicarbonate at any point is obtained by subtracting from the total CO_2 the relatively small amount present as H_2CO_3 , indicated by the line near the bottom of the chart. The ratio, and so the pH, is the same at all points along a given line. Thus the intersection of the CO_2 dissociation curves by these so-called isohydronic lines marks off nine areas corresponding to the acid base states described above (after Van Slyke).

therefore is raised. A disturbance of this nature may result from forced breathing, or the hyper-ventilation induced by hot baths, high altitudes or shallow breathing (p. 523). It is sometimes also referred to as "gaseous alkalosis." Partial compensation occurs as evidenced by the reduced excretion of acid and ammonia in the urine and the increase in the urinary bicarbonate (areas 2 and 3).

5 *Compensated alkali excess* The $[\text{NaHCO}_3]$ is raised but a parallel rise occurs in $[\text{H}_2\text{CO}_3]$. The pH is therefore normal. A disturbance of this nature will result from conditions which cause (1) but of less severe degree (area 4).

4 *Compensated CO_2 excess* $[\text{H}_2\text{CO}_3]$ increased but accompanied by a proportional rise in $[\text{NaHCO}_3]$, pH is normal. This state occurs in conditions in which there is retention of CO_2 , e.g., emphysema (area 4).

5 *Normal acid base balance* $[\text{H}_2\text{CO}_3]$, $[\text{NaHCO}_3]$ and pH are normal (area 5).

6 *Compensated alkali deficit* $[\text{NaHCO}_3]$ is reduced and $[\text{H}_2\text{CO}_3]$ diminished proportionately. pH normal. The condition results from the abnormally low production of fixed acid as in diabetes, acid retention as in nephritis, or from the ingestion of mineral acids or acid producing salts (CaCl_2 , NH_4Cl). Thus and (9) are the acid base states to which the term "acidosis" has been usually applied. The compensatory adjustments are evident in the increased acid and ammonia excretion in the urine and the lowered CO_2 tension in the alveolar air. Alkali deficit may also result from the increased excretion of base as occurs in dehydrated states (ch. 3) and in animals following the production of a pancreatic fistula (area 6).

7 *Compensated CO_2 deficit* This is a reduction in $[\text{H}_2\text{CO}_3]$ and a parallel reduction in $[\text{NaHCO}_3]$. The pH is therefore normal. This state results from less severe grades of the conditions which cause (2) above. The excretion of NaHCO_3 by the kidney is much slower than the excretion of CO_2 by the lungs so a condition of CO_2 deficit, which is uncompensated to start with, later tends to become compensated (area 6).

8 *Uncompensated CO_2 excess* $[\text{H}_2\text{CO}_3]$ is increased but is not balanced by a proportional rise in $[\text{NaHCO}_3]$. The pH is lowered (i.e., blood is less alkaline). This is sometimes referred to as "gaseous acidosis." Such a state results from a hindrance to the excretion of CO_2 as may occur in pneumonia, obstruction to breathing or depression of the respiratory center by morphine. There is partial compensation, i.e., the bicarbonate is raised above the normal and there is an increased excretion of acid and ammonia by the kidneys (areas 7 and 8).

9 *Uncompensated alkali deficit* $[\text{NaHCO}_3]$ is reduced without there being a parallel reduction in $[\text{H}_2\text{CO}_3]$. The pH is lowered (i.e., the blood becomes less alkaline). Such an acid base state

occurs when large quantities of fixed acids— β hydroxybutyric and acetoacetic—are produced as in diabetic coma and in the terminal stages of nephritis when acid excretion is greatly impaired. The plasma bicarbonate is severely depleted, the CO_2 combining power of the plasma may be less than 20 volumes per cent (area 9).

It will be evident after a consideration of some of the foregoing acid base states that the terms "acidosis" and "alkalosis" if used to denote respectively a fall or a rise in plasma bicarbonate are misleading, since the blood may be no more acid or alkaline than normally. For example, in (2) above, the blowing off of CO_2 will result in a certain degree of compensatory reduction of NaHCO_3 . The reduction in the alkali reserve would therefore entitle it to be called acidosis though the blood was actually more alkaline than normally. In (5) on the other hand the blood is less alkaline than normally yet a certain degree of compensatory increase in the alkali reserve would have occurred. The term alkalosis would therefore apply, though its use would give an erroneous idea of the true state of the acid base balance. It is now more common practice to use the terms *respiratory alkalosis* when the pCO_2 is reduced by voluntary hyperventilation and *respiratory acidosis* when the pCO_2 is raised by an increase in the CO_2 tension of alveolar air. The term *metabolic alkalosis* is used to indicate an increase in CO_2 combining power as a result of metabolic reactions, and the term *metabolic acidosis* a decrease in CO_2 combining power. *Metabolic alkalosis* can be produced by the administration of sodium bicarbonate and *metabolic acidosis* by giving ammonium chloride.

MEASUREMENT OF THE HYDROGEN ION CONCENTRATION OF THE BLOOD

Electrometric Method

1 *By means of hydrogen electrodes* Two hydrogen electrodes are employed. The method is derived from the fact that in a suitable concentration cell a difference of potential between a metal electrode (e.g., mercury) and a solution of its ions (e.g., mercurous chloride) is set up which is proportional to the ion concentration. A hydrogen electrode, composed of spongy platinum saturated with hydrogen gas, is therefore used to determine the hydrogen ion concentration of a solution. The platinum is contained in a small tube and partially immersed in a normal solution of KCl. The tube above the solution is filled with hydrogen gas, which is adsorbed by the platinum. The

hydrogen electrode is balanced against a calomel electrode (metallic mercury in contact with a normal KCl solution saturated with HgCl_2), or against another hydrogen electrode dipping into a solution of known hydrogen ion concentration. When, as in the latter instance, the two hydrogen electrodes are connected, an electromotive force is developed, which varies with the difference in hydrogen ion concentration of the two solutions. This can be measured by a suitable instrument. Another electrometric method involves the use of quinhydrone—*quinhydrone electrode*. One platinum or gold electrode is placed in a solution of known hydrogen ion concentration, and the other dips into the unknown solution. A small quantity of quinhydrone is added to each solution. The quinhydrone undergoes oxidation to quinone or reduction to hydroquinone according to the hydrogen ion concentration of the solution. A potential difference is set up between the two electrodes and from its magnitude the H ion concentration is calculated.

2. *By means of the glass electrode*. Like the hydrogen electrode the potential of the glass electrode, in an electrical system similar to that just described for the latter, varies with changes in pH. It must be calibrated with solutions of known hydrogen ion concentration.

The glass electrode, as shown in figure 13-3, consists of a tube G of thin (0.001 mm), soft glass of special composition, closed at its lower end and sealed into tube A of ordinary glass. Filling the larger tube and surrounding the surface of special glass is a 0.1 N solution of HCl, into which dips a

silver-silver chloride electrode S. The solution, whose hydrogen ion concentration is to be determined, is introduced into the cup D, which fits the tube G. C is a calomel electrode and R a reservoir of saturated solution of KCl. Through the stopcock H contact is made with the glass tube containing the solution to be tested. The theory of the electrode is complicated and not fully understood. Electrolytic dissociation must occur within the special glass itself, since a minute electrical current can pass through it.

The glass electrode has largely superseded other types of electrode which have been used for the hydrogen ion determinations. It has the advantages of being less cumbersome, more durable, being unaffected by oxidizing agents and of requiring only a small amount of fluid for testing, for the tube D need contain only a drop or so.

Colorimetric Method

In the method of Levy, Rowntree and Marriott as modified by Dale and Evans, the blood is placed without loss of CO_2 in a collodion sac and dialyzed for 15 minutes against a solution of normal saline. A few drops of 0.02 per cent of the indicator neutral red are added to the dialysate. The latter is then placed in a comparator and its color matched with that of a phosphate mixture of known pH and containing neutral red in the same concentration as the blood dialysate. The reader is referred to Dale and Evans' article for the details of the method.

It might be thought that the H ion concentration would be reduced through the dilution of the dialyzed substance by the saline in the apparatus. But, since the pH of a buffered solution depends upon the ratio of free to bound acid and this of course will not be altered, so, moderate dilution does not effect the result. In the colorimetric method of Cullen, the pH is determined directly (i.e., without dialysis) upon plasma which is diluted 20 times. phenol red is used as indicator. In this method a correction must be made for dilution and also for protein content.

From the $\text{H}_2\text{CO}_3/\text{NaHCO}_3$ Ratio

The total CO_2 in a sample of plasma is obtained as described on page 465. The free CO_2 , i.e., the CO_2 in simple solution, is obtained by calculation from the partial pressure of CO_2 with which the sample was equilibrated. The calculation is made as follows. The figure for the partial pressure of CO_2 is multiplied by the absorption coefficient of CO_2 in plasma, which at 33°C is 0.510 (p. 465). If, then, the partial pressure of CO_2 is 40 mm Hg (as in normal arterial blood), the quantity of gas dissolved in 100 cc. of plasma is

FIG. 13-3 Description in text

$$40 \times \frac{100 \times 0.510^*}{760} = 2.68$$

The total CO_2 is, say, 56 volumes per cent. Then the combined CO_2 is $56 - 2.68 = 53.32$ volumes per cent.

The pH may now be calculated from the Henderson Hasselbalch equation (pp. 127 and 466)

$$\text{pH} = \text{pK}_1 + \log \frac{[\text{HCO}_3]}{[\text{H}_2\text{CO}_3]}$$

The value of pK_1 † for plasma is 6.10, therefore

$$\text{pH} = 6.10 + \log \frac{53.32}{2.68}$$

* $100 \times (0.510/760) = 0.0672$ is a constant factor by which the CO_2 partial pressure (in mm. Hg) is multiplied to give the volumes of dissolved CO_2 .

† K_1 includes the first dissociation constant of H_2CO_3 and a figure representing the dissociation of NaHCO_3 under the conditions existing in plasma.

SECTION TWO

Circulation

14

BASIC PROPERTIES OF THE HEART

The important characteristics of the heart include excitability, rhythmicity, conductivity, contractility, and distensibility

Excitation of Cardiac Muscle

The ability of a tissue to respond to a stimulus is spoken of as excitability or irritability. In the case of muscle, the response is the development of a potential difference and shortening of its fibers. The motion of the heart is controlled by these changes of the potential difference between the inside and the outside of individual myocardial fibers. For many years the monophasic action potential of the heart recorded with one electrode on injured or depolarized and supposedly inactive tissue, and the other electrode on active or normal tissue has been employed to show or to reveal the time course of depolarization and repolarization of the myocardial muscle membrane. Measurement of this action potential has been employed to correlate changes in the state of the membrane with observed variations in excitability and with the simultaneous cardiac electrogram or myogram. Use of the monophasic action potential, however, has numerous drawbacks and, at best, can serve only as a record of the average time course of the membrane potential change in many cells.

The studies of Weidmann, 1949, and Woodbury, 1951, showed that the potential difference across a limited area of muscle membrane of a single heart fiber could be faithfully recorded in the beating heart by use of an intracellular microelectrode of the type developed by Ling and Gerard, 1949. Glass tubes of about 1 mm external diameter are drawn out to an extremely small tip of about 0.2μ . When these are filled with concen-

trated potassium solution and inserted through the fiber membrane into the sarcoplasm, they can be used to measure the potential difference between the outside and inside of a single fiber in the beating heart. By cutting off the tip of the glass capillary electrode and suspending it on a wire, the electrode is free to move up and down. Thus artefacts from heart movements are minimized and recordings from human hearts during cardiac surgery have been made. Where studied simultaneously the transmembrane potentials from fibers in the intact heart are qualitatively and quantitatively similar to those recorded from single fibers of isolated preparations of either atria or ventricles. Information thus obtained concerning the state of polarization of the muscle membrane serves as a much better basis for correlation with studies of excitability and refractoriness than the less direct and more variable measurements obtained with surface electrode techniques (fig. 14.1).

TRANSMEMBRANE POTENTIALS OF VENTRICLE AND ATRIUM Figure 14.2a shows the potential changes that are observed when a capillary microelectrode is inserted into a single fiber of a rhythmically beating ventricle. When both the microelectrode and the indifferent electrode are outside the cell there is no potential difference. When, however, the tip of the microelectrode penetrates the membrane of a single myocardial fiber, a sudden potential of 80 to 90 mv is recorded with the inside of the fiber negative to the indifferent electrode. This resting potential difference across the muscle membrane remains at the same value as long as the tissue is quiescent. Following stimulation, however, there is an extremely rapid phase of depolarization (1 to 2 msec) and change in the

FIG 14-1 Microelectrodes used for determining transmembrane potential in single myocardial fiber as modified by Alexander and Nastuk from Ling and Gerard

membrane potential so that the intracellular microelectrode momentarily becomes positive with respect to the indifferent electrode. Therefore, at the peak of the action potential, the membrane is not only depolarized but actually exhibits a reversal of polarity or exhibits overshooting amounting to 15 to 30 mv, and lasting 6 to 15 msec. Immediately after this reversal there is a plateau of about 100 msec and then a moderately rapid repolarization of the membrane for 100 to 150 msec, as the resting potential is restored. On pulling back the electrode the potential jumps back to the zero level. It is believed that use of an intracellular microelectrode gives a true picture of the time course of depolarization and repolarization in a single cardiac muscle fiber and provides an accurate measurement of the size of transmembrane potentials.

Transmembrane potentials recorded from the atria and auricles in the open chest dog (or from single fibers of isolated preparations) are not significantly different from those of the ventricles except that following depolarization, the atrial records show an immediate slow phase of repolarization without an intervening plateau such as occurs in ventricular muscle (fig. 14.2b).

The temporal relationship between the action potential of a single fiber and the local ventricular electrogram of the intact and *in situ* heart is shown in figure 14.2a. The upstroke of the action potential coincides with the R wave of the electrogram, the plateau with the R-T segment, and the phase of repolarization with the T wave. Although the mechanism is unexplained, the tem-

poral relation between the electrical and mechanical activity is very close (fig. 14.2c). Contraction starts a few milliseconds after depolarization, and tension reaches a peak when the membrane undergoes repolarization. The state of contraction is maintained as long as the fiber is depolarized, and relaxation sets in as soon as the resting potential is re-established. Under some conditions it has been possible to obtain dissociation between mechanical and electrical events, i.e. electrical activity is obtainable when there is no longer a recorded mechanical response.

The transmembrane potential and mechanical response of cardiac muscle are very sensitive to certain inorganic ions. Changes in concentration of potassium, calcium, and to a lesser extent sodium, have a profound effect on the excitability and contractile response of the mammalian myocardium. Magnesium has little action in the presence of normal calcium concentration, but when the latter concentration is decreased both magnesium and strontium have a marked effect on membrane potential. It is possible that changes in myocardial function which are encountered in man in disease states can be explained on the basis of the known effects of these ions on the membranes of cardiac muscle fibers.

TRANSMEMBRANE POTENTIALS OF SPECIALIZED TISSUES Of the 3 specialized tissues in the mammalian heart, i.e., the sinoatrial node, the atrioventricular (A-V) node, and the ventricular conducting system (Purkinje fibers), only the latter has been studied extensively by microelectrode techniques. Figure 14.2c illustrates the electrical

FIG. 14.2A Transmembrane action potential of a single ventricular fiber (lower curve) and simultaneous ventriculogram of the intact heart *in situ*. The upstroke of the action potential coincides with the R wave of the electrogram, the plateau with the R-T segment, and the phase of repolarization with the T wave (After Brooks and associates). B Normal transmembrane potential recorded from a single fiber of the intact auricle (After Brooks and associates). C Transmembrane action potential of a single Purkinje fiber in a nonpacemaker activity. Note slow loss of resting potential during diastole (After Brooks and associates). D Spontaneous activity recorded from Purkinje fiber in a pacemaker area. Note slow depolarization during diastole and then abrupt onset of spontaneous depolarization (After Brooks and associates). E Temporal relation between action potential and mechanical contraction recorded from a papillary muscle (After Dudel and Trautwein).

peculiarities of Purkinje fibers in the dog heart. In contrast to the constant diastolic membrane potential in auricular and ventricular muscle, there is in the ventricular conducting system a slow depolarization throughout diastole when local electrical activity is induced by a distant

pacemaker. When pacemaker activity originates in the local area there is in addition a slow upward curvature in late diastole which continues until a level of instability is reached and a more rapid depolarization, the action potential, spontaneously begins (fig. 14.2d). This peculiarity was first de-

scribed by Bozler. The assumption is made that normal pacemaker activity in the sino atrial, A V nodal tissue, and in undifferentiated ventricular muscle of the mammalian heart is similar to the above when they act as pacemakers, but as yet this has been shown to be true for these areas only in the frog and turtle heart.

As to be expected, the electrical properties of the pacemaker region change with factors that alter heart rate. Vagus stimulation, acetylcholine and hypothermia lower heart rate by decreasing the rate of diastolic repolarization and thus lengthening the time taken to reach a critical level at which an action potential is initiated, whereas sympathetic stimulation and epinephrine injection by inducing a faster rate of depolarization with an earlier firing, accelerate heart rate.

MECHANISM OF TRANSMEMBRANE POTENTIAL. What causes the resting potential and what causes this potential difference to change during myocardial contraction and relaxation is not known. There is no doubt that the state of membrane permeability is the basis for excitability. About all that is known is that at rest potassium is not diffusible and that sodium is freely diffusible through the muscle membrane, and that this is caused by metabolic activity. Largely through the work of Hodgkins and associates, ion movements that may be responsible for change in membrane potential have been partially identified. It is assumed that the resting potential across the myocardial membrane depends upon the concentration gradient of potassium to which the membrane is not permeable. It is believed that depolarization arises from an increased permeability which permits sodium ions to move from the extracellular phase (rich in sodium) into the cardiac fibers, while repolarization arises as the result of increased permeability to potassium ions which now move from the cell (rich in potassium) to the outside. Thus, following each action potential the inside of the fiber has gained a small quantity of sodium ions and lost a comparable quantity of potassium ions. In order to maintain ionic equilibrium, the shifts have to be reversed during the period of diastole. The ions must be 'pumped' against electrochemical gradients and this necessitates metabolic energy.

Experimental verification of the preceding is difficult but for the turtle heart at least, it has been demonstrated that potassium is released from the myocardium during its activity (fig. 14-3). To study this, potassium⁴² was injected into the peritoneum of a living turtle. A few hours later, the heart was cut out and the coronary

FIG 14-3 K^{42} effluogram of a turtle ventricle (From Wilde and associates.)

circulation perfused with radio inactive Ringer's solution. Samples of the coronary outflow were collected at short intervals and counted for the isotope. The results show a large increase in potassium⁴² outflow associated with each period of activity, that is with each systole, and when corrections are made for the travel time between the release of the potassium in the muscle fibers and the arrival at the venous outflow, then the extra potassium⁴² release occurs some time during the Q-T interval of the ECG.

From what has been said, our knowledge of the electrophysiology of the heart is obviously of a descriptive nature. Answers are not available to such fundamental queries as to (1) the nature of change in selective permeability and in transmembrane passage of ions in the presence of altered permeability, (2) the linkage between depolarization and mechanical shortening of muscle, and between metabolism and active ion transport.

Rhythmicity and Conductivity

To produce efficient pumping of blood, the complex mass of myocardial fibers must contract more or less simultaneously. The conducting system is responsible for periodic initiation of excitation and the rapid spread of excitation to all parts of the ventricular walls so that the conduction is sufficiently simultaneous to produce effective pumping. This is a stereotyped and repetitive sequence of events during each cardiac cycle.

Cardiac tissue in addition to nerve fiber and

ganglion cell is made up of 3 types of syncytial muscle each with a different embryological origin specialized nodal tissue, Purkinje fibers, and ordinary cross striated cardiac muscle. The first two are concerned with initiation and conduction of impulses through the myocardium, the last with muscle contraction. The specialized tissue consists of the sino atrial (S A) node, the atrio-ventricular (A V) node, the A V bundle, its bundle branches, and the Purkinje system (fig 144). This specialized tissue ends by a gradual end to-end transition into ordinary heart muscle. While it is generally considered probable that these peculiar specialized cells are the agents which conduct the stimulus to the ventricles, absolute proof that the sympathetic fibers which accompany the bundle and its branches have nothing to do with conduction is yet to be produced. Procedures involving cutting, crushing, ligation or injection must, of necessity, damage both these characteristic cells and the nerve cells also because of their intimate admixture.

The time of arrival of excitation in various regions of the mammalian heart has been determined in different ways for the epicardial surface from the deflection obtained by placing one electrode directly on different areas of the epicardium and a second electrode on a distant part of the body, or from paired contiguous electrodes, for the nodal and specialized conducting tissue from the deflection obtained with intracellular elec-

trodes, for the ventricle proper from deflections obtained with multiple intramural electrodes.

IMPULSE INITIATION Keith and Flack, 1907, suggested that the S A node embedded in the right atrial wall near the entrance of the superior vena cava is the focus in the mammalian heart from which each heart beat normally starts. Evidence of such origin is that (1) its excision or inactivation causes cessation or slowing of the atrial or ventricular contractions, (2) temperature change of the node but not of the surrounding tissue changes heart rate, (3) the node becomes electrically active before any other region of the heart. This cannot be regarded as positive proof of origin from the S A node but rather from this general region which includes other types of cells including ganglion cells.

Although spontaneous and repetitive depolarization arises normally only in this region, there are other areas in which electrical activity can arise under some circumstances and initiate cardiac contraction. When the S A node is destroyed or inactivated, the A V node becomes the sight of impulse formation and develops spontaneous depolarization. In turn, in the presence of inactivation of the A V node, the ventricles develop a slow rhythm. Since both ventricles receive the excitation through natural pathways and contract in a coordinated way, the rhythmical center is the A V bundle. If both bundle branches are cut, impulse initiation arises in the ventricular

FIG 144 Showing the specialized tissue of the mammalian heart. SVC, superior vena cava, IVC, inferior vena cava, S, membranous part of interventricular septum, L, left branch of bundle, R, right branch of bundle.

muscle The natural rate of automaticity of these areas is of a descending order of magnitude, the S-A node being 70 to 80 per min, atria 60 per min, A-V node 40 to 60 per min, and ventricles 20 to 40 per minute. It is obvious that normally, the atria, A-V node, and ventricular tissue can not set the heart rate because the S-A node repolarizes and automatically discharges more rapidly than any of these tissues. Hence, an impulse from the S-A node will always depolarize these tissues before either could initiate a rhythm. On occasion, however, an ectopic focus in the atrium or ventricular muscle can assume a rhythm faster than that of the S-A node, and hence, it becomes the pacemaker.

PATHWAYS OF CONDUCTION Following each spontaneous depolarization in the region of the S-A node, near the mouth of the superior vena cava, the activation process is transmitted rapidly throughout the muscle of both atria at about 1 meter per sec, and reaches the outermost por-

tions of the atria in about 50 msec (fig 14 5a). No specialized tissue appears to be present although the transmission is thought to follow at least partially, certain direct muscular fasciculi, thus, the impulse reaches the A-V node in advance of its arrival at the wall of the left atrium. The plan of activation of human atria has not been directly studied.

As the depolarization approaches the interatrial septum, it reaches a mass of specialized tissue, the A-V node, which is located near the posterior margin of the interatrial septum near the entrance of the coronary sinus into the right atrium. Complete dissociation of the auricles and ventricles follows cutting, tying, or crushing of an A-V node or bundle, thus creating what is called complete heart block. Delay of the impulse for from 80 to 120 msec, normally occurs at the A-V node, for the activation process travels slowly (0.2 meters per sec) through this tissue. Although the cause is unknown, this delay is helpful for it

FIG 14.5A Spread of activation through right auricle of dog. Auricle viewed from right side showing superior and inferior venae cavae, coronary sinus and atrial appendage. Time of activation in milliseconds following activation of the S-A node (From Puech). B, Frontal plane section showing spread of activation through the ventricular septum and ventricular walls of the canine heart. Lower left part of septum is activated first at time zero. Time of activation of other portions in milliseconds. (From Sodi-Pallares). C, Spread of excitation on the ventral surface of the dog heart. permits completion of atrial contraction and emptying during diastole of the ventricles. The aggregate potential by these few fibers is too small to be recorded except locally. After leaving the A V node, the wave of excitation passes rapidly (4 to 5 meters per sec) by the common A V bundle, its branches, and by the Purkinje network of subendocardial fibers to spread throughout the endocardial surfaces of both ventricles. The exact course by which the wave of excitation is distributed throughout the ventricular musculature from the endocardial surface is not definitely established except that it penetrates the ventricular wall from endocardial to the epicardial surface. Present evidence indicates that such spread of excitation is not by anatomical muscle bundles but by the specialized tissue. By some this is believed to be not merely a subendocardial layer but a profuse myocardial network ramifying in many muscle planes and extending deeply into the myocardium. This would cause almost simultaneous activation of much of the ventricular muscle mass. At all events, the intra-ventricular septal surface is excited first, the papillary muscles next, but conduction is so fast that the inner surfaces of both ventricles are excited almost simultaneously, the whole of the endocardium being activated in about 50 msec (fig 14 5b). Excitation of the ventricular muscle is much slower (0.4 meters per sec) and proceeds first through the septum and then through the lateral walls of the ventricles from endocardial to epicardial surfaces. This is entirely different from the spread of excitation in the atrial muscle which is radial. Muscle activation occurs first in the subendocardial layers of the midportion of the left ventricular septum to spread inward, this is quickly followed by inward activation from the right endocardial surface of the septum. Within 10 to 20 msec after first activation of the septum, deflections are recorded on the anterior surface of the left ventricle along the interventricular groove near the apex. Within 25 to 30 msec, all the right ventricular surface is activated. Regions of the lateral wall of the left ventricle are excited slightly later (at 25 to 35 msec) since the wall is much thicker. Finally, at 40 to 45 msec, the epicardial surface over the pulmonary conus region of the right ventricle and the base of the left ventricle and septum respond. In general, excitation of the epicardial surface occurs 1 to 20 msec later than its endocardial counterpart. Many investigations with more refined techniques have confirmed the original findings of Lewis that the maximum difference in time of excitation of differ-

ent regions of the ventricular surfaces is also quite small, being of the order of 10 to 20 msec, and that surface excitation of the ventricles proceeds from point to point as it does in the atria (fig 14 5c). In the human, the patterns of activation have not been detailed but are believed to be similar to those in the dog heart. However, the time for activation might be twice as long because of the much thicker myocardium.

EFFECT OF CARDIAC NERVES ON RHYTHMICITY AND CONDUCTIVITY. The inherent automaticity and conduction properties of the heart can be altered antagonistically through the action of the sympathetic and vagus nerves to the myocardium. The parasympathetic fibers from the right vagus terminate mainly near the S-A node but some fibers spread throughout the atria. Most left vagal fiber endings supply the A V node and the A V bundle. Many endings are spread throughout the atrial muscle but they have not been demonstrated in the ventricles.

Stimulation of vagal fibers to the heart presumably results in the secretion of acetylcholine at the vagal endings in the heart causing slowing of the heart through S-A nodal depression (chronotropic effect), decrease in the rate of the depolarization wave through the atria and through the A V bundle, and an increase in the refractory period of the A V bundle. Very often, as to be expected from its anatomical distribution, stimulation of the right vagus affects mainly the heart rate and atrial contractility. Left vagal stimulation may result mainly in a partial functional heart block at the A V node. Very strong stimulation of either one or both vagi generally completely stops the rhythmical contraction of the S-A node or completely blocks transmission of impulses through the A V node and bundle so that impulses are no longer transmitted to the ventricles. Ventricular beats in the open chest dog can be stopped in this manner for at least a minute although the usual effect is for a few seconds only. The ventricles then establish their own slow rhythm. Vagal stimulation in the turtle or frog heart can arrest the ventricles for 2 to 4 hours.

The sympathetic fibers to the heart are derived from the cervical and upper thoracic ganglia. The cardiac fibers supply the S-A node, A V node, atrial muscle, and unlike the parasympathetics, the ventricular muscle as well. Sympathin, an epinephrine-like substance, secreted at the sympathetic nerve endings causes effects almost exactly opposite to those of acetylcholine. Stimulation of cardiac nerve fibers isolated from the stellate ganglia releases sympathin, increases the rate of

rhythm of the S A node, increases the rate of conduction through all parts of the heart, and increases the refractory period of the A V bundle, Purkinje system, and muscle fibers. Maximal sympathetic stimulation can, at times, almost triple heart rate. Epinephrine has essentially the same effects. Thus, sympathetic release or stellate stimulation increases the over all heart rate.

Contractility and Distensibility

CONTRACTILE PROCESS The chambers of the heart are surrounded by walls made up of bundles and sheets of myocardial fibers. The fibers form a syncytium which gives protoplasmic continuity between adjoining fibers and throughout an entire mass of cardiac muscle (fig. 14-6).

The major organized parts of the fibers are the myofibrils, the sarcosomes or cytochondria, and the sarcoplasm. The fibrils are the fundamental contractile units of the heart. The nature of the contraction and relaxation of muscle is on a theoretical basis and beyond the present scope. It is, however, generally believed that the contractile elements in cardiac, also skeletal and smooth muscle fibers, are formed from myosin, a protein of rather short molecular rods, and actin, a long continuous protein thread, both of which are dissociated in resting muscle and neither of which will contract independently. Excitation passing along the muscle results in the formation of actomyosin which is unstable in its extended or resting state and which now dissipates energy either by shortening or increased tension. Actomyosin is thus changed to its energy poor state and may accomplish work if it shortens.

In terms of metabolism, the fibrils are the structures which with the purpose of generating mechanical work utilize the metabolic agent which supplies chemical energy to be transformed into work. In the past, the assumption has been made, based on indirect evidence that the immediate source of energy or the metabolic agent in contracting muscle is the enzymatic hydrolysis of adenosine triphosphate or creatine phosphate. Direct measurements, however, show no such breakdown in a single muscle twitch and even a tetanic contraction can take place without significant decomposition of these compounds. Inorganic phosphorus is, however, liberated during the contraction from an unidentified precursor in just sufficient amounts to supply the required energy but whether this source is the phosphate bond energy of an unidentified compound such as another nucleotide has not been determined. At all events regeneration of such a substance is the

task of metabolism. Glycolysis as a source of such energy is carried out in the sarcoplasm but in a heart which cannot accumulate a large oxygen debt, this is scarce. Respiration is a function of the sarcosomes and presumably such regenerative processes are carried in the sarcosomes which are abundant in the heart. However, very little is known regarding the mechanism of reloading and muscle relaxation.

While there are some differences among the actomyosin complexes in skeletal smooth and cardiac muscle, the contractile mechanisms appear to be closely related. In functional characteristics, however, the myocardium resembles visceral smooth muscle more than skeletal muscle from the standpoint of autogenic excitation and inherent rhythmicity, and intercellular transmission of excitation and nervous control. Both have rapid depolarization and tend to remain depolarized for a period about equal to the duration of contraction, both are not directly innervated by motor nerves but waves of excitation originate in the muscle fibers and are conducted through the contiguous cells (although smooth muscle is not strictly speaking a syncytium) both are controlled by the autonomic nervous system by way of release of hormonal substances.

PREPARATIONS AND METHODS In the earlier investigations of the physical properties of the myocardium the hearts of the frog and tortoise were used. Later with the development of better techniques in methodology, the isolated hearts or heart lungs of warm blooded animals such as the cat and dog were used. Subsequently studies were made on the heart *in situ* in the open and closed chest anesthetized dog in the unanesthetized dog and more recently studies of the heart of the dog and of man *in situ* in which, by means of a heart-lung oxygenator system the systemic

FIG 14-6 Cardiac muscle fibers

circulation is maintained while only the coronary flow to the heart muscle is maintained, i.e., the left ventricle is empty and the right ventricle is a conduit for coronary venous return. These studies have been very fruitful and have revealed some of the fundamental characteristics of the myocardial process.

In estimating the myocardial or contractile response in these preparations, measurements of interest are the contractile force (contractility) and the distensibility (extensibility) of the myocardium. The term "contractility" although very useful is rather difficult to define. For purposes of consideration, increase in contractility signifies that the mechanical response during contraction is faster (steeper gradient), higher (greater amplitude), generally shorter in time, and that the muscle has a more abrupt and rapid relaxation. Similarly, a decrease in distensibility (extensibility) occurs if the resistance to stretch (muscle tension) increases in a muscle strip or the pressure within a ventricular cavity at rest rises. Such comparisons should be made at the same resting muscle fiber length or size of ventricular cavity.

Such measurements are comparatively easy in isolated strips of myocardium but they are difficult in the whole heart especially within the body. Both are measured in the beating, exposed, empty, or full heart by stretching all or a small portion of the ventricular mass and then determining by use of a strain gauge arch or by direct measurement the isometric tension developed at different muscle lengths during rest and during stimulation. Distensibility as well as contractility is also estimated in the beating heart by measuring the intraventricular pressure, stroke volume and stroke work responses to changes of ventricular volume (used as a gauge of myocardial fiber length). The ventricular volume in systole and diastole is determined directly by a mechanical plethysmograph or by a dye dilution technique. An index of directional change in ventricular cross section is obtained by a sonar technique, by change in resistance of a mercury filled rubber tube wrapped around the ventricle, by an intraventricular diameter gauge, and by surface calipers, or by electromagnetic plethysmography (see ch. 18).

FACTORS AFFECTING THE CONTRACTILE RESPONSE The impulse from the sinoatrial node over the cardiac syncytium constitutes the natural stimulus. Its intensity exceeds the threshold of response by 4 to 5 times. Quiescent heart muscle responds to all types of stimuli—mechanical, thermal, electrical, and chemical.

A Intensity of stimulation The existence but usually not the magnitude of the contractile response depends upon the intensity of the stimulus. When a quiescent ventricle is excited directly by properly widely spaced electric shocks of increasing intensity, all stimuli above threshold result in contractions of the same amplitude. This was called the "all or nothing response" by Bowditch (1871). It is due to the spread of the excitatory process to all parts of the cardiac syncytium. A single skeletal muscle fiber responds in the same way but an entire skeletal muscle gives an increasing response with increasing effective stimulus because more and more of the fibers which are insulated from each other now respond.

Although this reaction in cardiac muscle means that the response is not related to stimulus strength, it does not follow that contractile force cannot change with repetitive stimulation. As in a single skeletal muscle fiber with altered condition of the muscle, a minimal effective stimulus at one time may at another be subminimal should the excitability of the muscle be reduced. On the other hand, should the excitability increase, a subminimal stimulus may become effective and the size of the response may vary with the same stimulus if the conditions of the muscle are altered. This is illustrated by the fact that enhancement of contraction with the same intensity of stimulation can be observed to follow increased cardiac work without change in frequency of the heart beat, and increased frequency of stimulation from slow to fast rates (fig. 14.7a). This is called *Treppe* or staircase. If the stimulus is too close to the previous contraction the mechanical response becomes small or may disappear. Thus, by some unknown mechanism each preceding contraction alters the internal condition of the muscle to change its responsiveness.

B Spacing of stimuli The existence and actual magnitude of the contractile response is dependent upon the time of the stimulus relative to the previous contraction (fig. 14.8). In the beating heart, stimuli are generally not effective during the period of contraction since the muscle remains depolarized throughout the period of contraction, and since the muscle must be repolarized in order to induce a new state of contraction. This period is called the absolute refractory period.

During early relaxation, excitability increases progressively but only stimuli still stronger than normal are effective. This is called the relative refractory period. On occasion this refractory period is followed by a subsequent phase in which

FIG 147A Staircase phenomena due to change in frequency of stimulation. Pressure change in right ventricle during isometric contraction. Perfused heart. S A node crushed. Frequency of stimulation of left auricle 1.5, 4 and 15 per sec. pressure scale mm Hg (After Rosenblueth 1950a). B, Summation of contraction in isolated papillary muscle of cat heart. Temperature 24°C. Left single contraction from single stimulus, right in complete tetanus from repetitive stimulation. Frequency of stimulation 200 per sec (After DiPalma). C, Response of left ventricular diameter of a dog running on a treadmill at 5 per cent grade. Recorded with very slow camera. A ventricular diameter was determined continuously by a sonar technique. Top of record represents diastolic diameter, bottom of record, systolic diameter, difference is stroke volume change in diameter. Left, dog is at standing rest. Arrow onset of exercise. Note that during exercise diastolic diameter decreases and stroke volume diameter does not increase (After Rushmer 1959).

a subnormal stimulus gives a contraction (super normal period)

This prolonged period of refractoriness normally present in heart muscle prevents the passage of a second impulse over the heart until the preceding contraction is over, and thus allows the ventricles to relax and fill with blood before another contraction can occur and also permits the maximum development of tension by the myocardium. By contrast, the refractory period of skeletal muscle is very brief since in skeletal muscle the duration of depolarization lasts only 1/300 of a second. Therefore, a rapid series of stimuli timed to fall just after this short refractory period will produce a rapid series of shortenings of skeletal muscle which fuse into an apparently

maximal contraction (tetanus) which is maintained as long as stimulation continues or until fatigue occurs.

It is obvious that an effective stimulus not coming from the sinoatrial node can affect the cardiac rhythm. A long pause follows the contraction caused by the artificial stimulus (fig 149). The artificially induced contraction is called an extrasystole or premature contraction. The long interval following the extrasystole is termed the compensatory pause since its duration is such that when the next normal beat is resumed, it occurs at precisely the same time as it would have appeared had no premature contraction been provoked. The occurrence of the long pause is explained as follows. The normal impulses pass from the auricle to the ventricle in a perpetual stream and in orderly sequence. When the ventricular muscle is stimulated artificially during diastole, and an extra contraction induced, the normal impulse when it arrives from the auricle at the usual time finds the ventricle already in the contracted state and, in consequence, refrac-

FIG 148 Diagram illustrating excitability cycle of heart muscle during contraction and relaxation. Upper curve, isometric, middle curve, excitability changes. 1 control excitability at rest, 2 zero excitability during contraction, 3 to 6 recovery of excitability during relaxation, 6 to 7, super normal excitability. Length of arrows indicates relative intensity of shocks required to obtain mechanical response. Bottom curve resulting effects on amplitude of contraction (After Wiggers).

FIG. 14-9 Myograms of frog's ventricle showing effect of excitation by break induction shocks at various moments of the cardiac cycle. The line 0 indicates in all tracings the commencement of the beats during which the shocks were sent in. It will be noted that in 1, 2 and 3 the heart is refractory to the stimulus. The signal (the break in the horizontal line) indicates the moment at which the stimulus was applied. The latent period (hatched area) does not alter as this figure shows. See text. The extrasystoles increase in height from 4 to 8 each being followed by a compensatory pause. (After Murrey)

tory. The impulse is therefore ineffective. Not until the arrival of the next normal impulse is the muscle in a condition to respond. This accounts for the fact that the time elapsing between the normal beats preceding and following respectively the premature contraction is equal to the length of two normal cardiac cycles. In other words the heart after the interruption in its rhythm again gets into step.

The long refractory periods of the cardiac muscle serve to preserve the cardiac rhythm. The absolute refractory phase makes the summation of contractions and the production of tetanus impossible. The relative refractory period tends to discourage the occurrence of a second contraction before sufficient time has elapsed to allow the complete relaxation of the muscle from a preceding contraction. When a premature contraction does occur its refractory period serves to restore the normal rhythm.

The problem of identification of the boundaries of the refractory period is an old one and

the boundaries are not always in accord with the previous considerations. The absolute refractory period may be altered by various agencies. It is shortened by a rise in temperature and by rapid heart action. It is prolonged by the action of certain drugs. Vagal stimulation shortens the refractory period of the atrial muscle but has no effect upon that of the ventricular muscle. This refractory period does not necessarily last throughout the contraction period but the muscle may respond by a contraction in early diastole to a stimulus applied at the very end of systole. Presumably this arises from the fact that in any muscle mass composed of so many fibers a considerable number have repolarized and are responding by contraction to the stimulus while a great majority of the fibers are still in the depolarized state. In addition when very strong ventricular stimuli up to 30 ma. and of 10 to 10 msec duration are used in the open chest dog there is in some hearts practically no absolute refractory period. It is also possible to show summation and tetanic response in isolated cardiac muscle of the rat under normal condition and of the frog and cat under unusual conditions of temperature and drugs. For example papillary muscle maintained at a temperature of 26° C. or less exhibits summation and tetanus similar to that seen in skeletal muscle (fig. 7b).

C. The effect of stretch. When an isolated ventricular strip is moderately stretched its tension rises progressively and upon electrical stimulation the amplitude and duration of its contraction increase (fig. 14-11). This relationship between length and contractile response which is firmly established for the amphibian and mammalian heart has been demonstrated in various ways. Muscle tension rises progressively as the whole mass of an isolated heart with perfused coronary arteries and contracting isometrically is stretched. Intraventricular pressure rises as the intraventricular volume (index of fiber length) is increased (1) by vagal stimulation owing to the resultant slower heart rate and increased diastolic stretch and filling (2) as the return of blood to the heart is augmented by infusion in the isolated heart, heart lung open and closed chest anesthetized dog or (3) as the exit of blood from a ventricle is temporarily blocked in the isometrically contracting heart in the open chest dog (fig. 14-10).

Despite the preceding in any one ventricle the relation of the contractile response to muscle length at any one length is not constant but can

FIG 14 10 (Right) Effect of plethora and hemorrhage on the relationship between left ventricular end diastolic volume and left ventricular systolic pressure in the anesthetized dog. Estimate of trend based on data from experiments (After Holt.) (Left) Pressure volume curves of the left ventricle in the open chest dog under isometric conditions. Broken line curves relation of ventricular end diastolic and systolic pressure, respectively, to ventricular end diastolic volume under normal conditions. Solid line curves, relationship of ventricular end diastolic pressure and systolic pressure respectively, to ventricular end diastolic volume following administration of epinephrine (35 γ) intravenously. To obtain the curves, the pulmonary venous return to the left ventricle was occluded and the ventricle emptied of blood by manual compression. The aorta was then occluded and successively known volumes of blood were injected into the ventricular cavity and the ventricular pressures recorded. Note that ventricular distensibility with epinephrine is increased during systole but is unchanged during diastole (After Ulrich and Kramer.)

be made to vary, or varies spontaneously under many conditions including the normal state, i.e., ventricular volume at rest can vary without corresponding changes in diastolic pressure (change in distensibility), while the pressure or output of the ventricle during systole can vary without change in diastolic volume (change in contractility). As illustrated in figure 14 10 left, epinephrine causes no change in resting distensibility whereas it increases distensibility during systole. These active changes in distensibility and contractility can be brought about under many conditions and are generally caused by nervous and humoral influences. Thus, the heart is not a passive servant of the peripheral circulation, it does not merely pass on what it receives but is capable of changing its performance at the same diastolic size, thereby initiating circulatory modifications irrespective of primary changes in filling

of the heart by venous return and in the arterial resistance to flow.

Some of the cardiac nerve fibers are quite potent in this respect. Vagal stimulation leads to depression of vigor of atrial contraction (inotropic effect). Histologically, however, vagal fibers have not been demonstrated to reach the ventricles and if cholinergic substances are released in the atria, they are presumably destroyed before they reach the ventricles. Despite this, attention is called to experiments in which continuous stimulation of vagus nerves in the neck of the open chest dog resulted in a decreased stroke volume and stroke work of the left ventricle, for the same left atrial pressure and in the presence of a constant (but high) heart rate. This suggests a depressor action of the vagi on the ventricles.

The effect of sympathetic fibers on the myocardium has been observed by stimulating elec

trically the stellate ganglia directly or indirectly through activation of the carotid sinus receptors. Such stimulation increases the force of both atria and ventricles, and shortens the period of contraction much more than can be accounted for by an increase in heart rate. With selective stimulation, when all known connections to the peripheral vascular bed have been previously cut, only the positive inotropic effect can be demonstrated in which the arterial blood pressure and cardiac output rise greatly through augmented force of contraction. Stimulation of stellate fibers to the heart, epinephrine injection or treadmill exercise in unanesthetized dogs reduce ventricular volume while maintaining or increasing stroke volume, they also give more rapid myocardial relaxation or increased distensibility during diastole thus facilitating diastolic filling while during ventricular systole the myocardium contracts more rapidly, ventricular pressure rises more rapidly and blood ejection is more complete (fig 14 7c). Finally, if in the open chest dog the perfusion pressure in the carotid sinus is decreased, the circulatory response to such baroreceptor stimulation is dominantly an increased heart action, the effector portion of this reflex appears to be sympathetic fibers from the stellates to the heart, since, following their section these effects disappear and cannot again be induced.

D Other determinants In addition, myocardial hypoxia (within limits), an increase in muscle temperature, an increase in the calcium content of the blood, all increase the contractile force. Conversely, deletion of functional cardiac muscle blocks, by crushing, burning or coronary occlusion,

decrease in temperature, addition of acetylcholine, increased concentration of inorganic ions in the blood such as potassium and magnesium will decrease the excitability or the contractile force of the myocardium. Temporary functional deletion of contractions also occurs when two opposing impulses from different directions block each other out. Smaller responses also occur when different fractions of heart muscle are excited more slowly than others. This happens with beats from ectopic foci or with abnormal impulse distribution as in bundle branch block.

E Isometric versus isotonic contraction The tension or contractile force developed by a contracting ventricle is different in the isometric and isotonic states (fig 14 11). When a muscle first contracts isometrically and then is allowed to shorten abruptly, the tension produced falls abruptly because a portion of the energy of contraction is used to overcome the high resistance from viscosity of the myocardium. This situation is comparable to that during systolic ejection since blood cannot be ejected from a ventricle without shortening of its fibers. In general, the contractile energy lost in overcoming myocardial viscosity and in creating tension between muscle layers is less at large diastolic volumes. Similarly, a relaxed myocardium responds to a rapid stretch by an immediate increase in tension which progressively diminishes as the muscle remains stretched. This has its counterpart in the intact heart in which, if inflow is rapid, the ventricular myocardium exerts tension to resist rapid elongation, thus stopping filling in early diastole while a slow inflow would prolong the period of diastolic filling.

FIG 14 11 Tension developed by stretched isolated muscle strip during rest and isometric contraction (After Rushmer 1955)

During late diastole the tension developed between ventricular muscle layers is minimal. The myocardial layers of the two ventricles which are oriented in different directions contract in different directions and shorten by different amounts during systole. Since these layers are firmly fixed to each other, some of the tension from the shortening myocardial fibers will be used to stretch the connections. This is wasted energy which opposes ventricular ejection. During ventricular relaxation, however, this stored energy is released and is helpful in early diastolic filling. Here also, the greater the systolic and diastolic volumes, the less the contractile energy lost in creating tension between muscle layers.

According to the law of Laplace ($T = P R$), the tension (T) developed in the ventricular wall is related to the pressure developed within the cavity and to the radius of the cavity. For the active ventricle, this indicates that the greater the ventricular size, the greater the wall tension needed to maintain a given intraventricular pressure.

FUNCTIONAL CHARACTERISTICS OF THE SYSTEMIC AND PULMONARY CIRCULATION

The hemodynamic characteristics of the systemic and pulmonary circulations have profound effects on the function of the heart. The principal function of the heart is to convert or change chemical energy into mechanical energy or work so that blood is moved through the cardiovascular system. The external work performed by the heart is measured by the quantity of blood ejected and the pressure developed during each ventricular contraction. The magnitude of both factors is determined by conditions in the circulatory bed which is served by the right and left ventricles. In turn, the amount of external work or useful work performed by the ventricle balances precisely the frictional loss of energy as the blood flows through the vascular circuit.

Figure 151 illustrates diagrammatically some of the primary characteristics of (1) the systemic circulatory system of man beginning at the aorta, extending to the venae cavae and emptying into the right atrium, and (2) the lesser circulatory system or the pulmonary circulation consisting of the right ventricle, the pulmonary venules, the veins and the left atrium. The ventricles pump the blood from the terminal reservoirs of the collecting systems, i.e., the atria into the distributing systems under an initial pressure sufficient to insure a continuous capillary flow as well as a return of the blood to the heart.

The Systemic Circulation

VOLUME FLOW

The anatomical complexity of the circulation may obscure some basic facts which should be stressed. The volume flow of blood through any part of the circulation must equal that flowing through any other part, i.e., the flow through all the arteries equals that through all the capillaries, all the arterioles, all the veins, the right ventricle, etc. There may be regional shifts of flow so that some arteries or capillaries carry more or less flow than in other arteries or capillaries, or there may be a small difference in the blood vol-

umes put out by the two ventricles but the former does not affect the relative total flow through the capillaries and arteries while the latter can only exist momentarily for a few heart beats, else the organism dies.

DIAMETER AND CROSS-SECTIONAL AREA If the left ventricle is regarded as a cylinder, then its diameter might be 6 cm. The diameter and cross-sectional area of the ascending aorta approximate 2.5 cm and 4.5 cm², respectively. The large branches of the aorta have a total cross-sectional area which is approximately the same as that of the parent vessel, but the total cross-sectional area of all arteries is much greater. In the periphery as the vessels become very narrow and short their total cross section becomes very large because of the large number of vessels involved. The total cross section of the arterioles with an individual diameter of 0.16 mm and length of the order of 0.15 mm might be 400 cm² whereas the cross section of the capillaries might be 4500 cm² (based on an estimated capillary diameter of 0.08 mm, length 0.05 cm, and about 3,000 million capillaries). This is about 700 times that of the aorta. The figure for the number of capillaries is probably quite low since the capillary bed does not inject very well and there is every reason to believe that not all capillaries are open or shut at the same time, i.e., their state of patency varies with different physiological conditions. The cross-sectional area of the venules is also high, approximating that of the capillaries but with their confluence into veins and then into the venae cavae, their total diameter and cross section progressively diminish so that the diameter and cross section of the latter are about two and four times, respectively, those for the corresponding aorta and arteries.

BLOOD CONTENT An important function of various parts of the circulation is the dynamic storage of blood. Its importance lies in the fact that it is this blood which is mobilized in time of stress to fulfill the needs of the body. The blood content of the various portions of the systemic

FIG 151A. Schematic representation of the cross sectional area, blood distribution, velocity and pressure in different regions of the systemic and pulmonary circulations. ?—values not available, dotted waves of pressure and velocity indicate estimated trends only.

circulatory tree bears no relation to its cross sectional area (fig 151). Quantitation of the blood volume existing during life in different parts of the vascular system is fraught with great difficulty, and the values obtained are only approximate. They are, however, helpful in orienting our thinking. The aorta contains about 100 cc, or 2 per cent of the blood volume of 5500 cc. The arteries contain about 8 per cent of the blood volume, the arterioles about 1 per cent.

The capillaries probably contain from 75 to 250 cc, or about 5 per cent of the blood volume. Since the capillaries are about one half a millimeter long, the blood remains in the capillaries not more than 1 to 2 seconds. This figure for blood content of the capillaries is obviously quite variable since not all capillaries are patent at one time.

Thus the blood content of the arterial or high pressure system is quite small, being about 800

FIG 15 1B See figure 15 1A

cc, or 15 per cent of the total volume. The systemic venous system accommodates the major portion (at least 50 per cent or about 3200 cc) of the blood volume, the four heart cavities (600 cc or 12 per cent), the pulmonary circuit 1000 cc or 18 per cent. Thus, the low pressure system or, as it is sometimes called, the extra arterial system which is made up of the systemic venous and pulmonary circuit up to the left ventricle contains about 80 to 85 per cent of the blood volume.

The blood content of different areas is not constant but is continuously changing and is avail-

able for redistribution to other vascular areas where it may be needed. The volume in any one compartment depends not only upon the basic anatomical size of the bed but upon dynamic changes induced by passive and active changes in capacity and content, i.e., distensibility. Although obviously very important it is very difficult to make comparisons of distensibilities of different anatomical compartments of the vascular system. Such comparisons would be based upon plots (preferably *in vivo*) showing the relations of percentage increase in volume (dv)/(dV) of the vas-

$$T = Pr$$

FIG 152 Illustrated are the lumen diameters, wall thickness, relative amounts of different tissues and wall tensions in the various blood vessels. *Lower left*, tension-length diagrams of elastic (1) and collagen fibers (2) presented alone and in combination (3). *Lower right*, balloon demonstrating pressure-tension relation. The pressure (P) within the balloon is equally transmitted to all parts of the contained air (Pascal's law), and the tension (T) in the balloon varies with the radius (r) in that portion 1 a Place's Law (Modified after Burton. *Physiol Rev* 1931 31, 619 and Wolf. *Science* 1952 115, 243.)

cular compartment to the increase in intravessel pressure (dp). Experimental data pertaining to distensibility of vessels containing much smooth muscle or which have an active response such as arterioles (resistance vessels), veins, or cardiac chambers, present a rather confusing picture since passive changes in their lumina is normally counteracted by "active" changes of the wall. This balance is very easily changed. Despite this, from available information the different distensibilities are suggested in figure 15.1 by the thickness of the lines. The distensibility of the capillaries has not been documented.

A. Basic control. Such storage can be on a long term basis (blood reservoir) and/or it can change rapidly during a cardiac cycle (compression chamber). Both are dependent on the blood content of the cardiac cavities and of the vessels at zero internal pressure and on their distensibility, i.e., change of diameter and length with change of internal pressure, in turn, the basic distensibility of the cavities is governed by the myocardial resistance to stretch. For example, the distensibility of a heart cavity actively changes if, for the same resting size or volume, the pressure within the cavity is altered. As pointed out in chapter 14, the distensibility of the ventricles can be grossly altered by nervous, humoral, and other influences. The distensibility of the vessels is governed by their content of elastic and collagen tissue and smooth muscle (fig. 15.2). All varieties of blood vessels except the arterioles, capillaries and venules have a prominent component of elastic tissue, and in some vessels such as the aorta, as much as 40 per cent by weight is elastic tissue. The elastic fibers with their great range of extensibility before their elastic limit is reached, produce maintenance tension without energy expenditure against the normal blood pressure. In the wall of every type of blood vessel except the capillary, there are white collagenous fibers in a matrix penetrating between the other elements. The collagenous fibers act in a similar way to the elastic fibers but, because of the architecture of the wall, are stretched only at higher than normal blood pressure and have a protective supporting role (fig. 15.2). If, however, the vessels reacted in a purely passive way based on their content of collagen and elastic fibers their internal pressure would be determined only by the volume of contained blood and, at any constant mean pressure the mean volume of blood within them would also not change. However, many types of vessel contain much smooth muscle which does not contribute significantly to the elastic tension of

the wall. Its function is to produce active tension under vasomotor stimulation or local action of various chemicals (vasodilator and vasoconstrictor substances and oxygen lack) and so change the size of the lumen. Such vascular tone adjustment is seen in most vascular areas. It counteracts distensibility by inducing smooth muscle reaction which, at times, is strong enough to induce a net decrease in vascular lumina in the presence of an elevated pressure. Such activation will, of course, change completely the pressure-volume relationship in a vascular bed or area.

B. Aorta and its arterial branches. The pressure-volume relationship or distensibility of the isolated aorta has been exhaustively studied *in vitro*. The distensibility varies widely in different aortae in the same age group (fig. 15.3). There is no statistically significant correlation between age and absolute distensibility. However, aortic size or capacity increases considerably with age so that the average diameter of the aorta may exceed that of the sum of its branches and the contained volume at a diastolic pressure of 80

FIG. 15.3 Influence of age on the volume-pressure relations of human aortas. Each curve represents the average values for a given age group. Vertical lines represent standard deviations (Remington and associates *Am J Physiol* 1948, 153, 293).

moving fluid Surrounding this in the interstitial spaces is the so called tissue fluid which is of a gel like consistency

It is still debatable whether the bulk of exchange occurs across the entire surface area or is restricted for most molecules to the pervious intercellular cement Ions and small molecules diffuse across the capillary wall at such an incredibly fast rate (at least 100 per cent exchange within 1 minute) that it has been suggested that the whole capillary wall is permeable to these substances The penetration, however, of capillary walls by water and dissolved substances appears to take place solely by processes which require no energy transformation by the capillary endothelial cells From this has arisen a general belief that the capillary walls, or specifically the intercellular cement, is pierced with numerous ultramicroscopic openings or pores with an average diameter of about 30 Å which are generally too small to allow the passage of plasma protein molecules, but are of sufficient size and number to account for the observed rates of passage of water and nonprotein constituents of the plasma Considerable evidence has been adduced that lipid soluble molecules such as oxygen and car-

bon dioxide, can penetrate rapidly the plasma membranes of the capillary endothelial cells and are not restricted to the aqueous intercellular spaces Finally, the evidence is fairly clear that penetration of large molecular aggregates and formed elements such as the red and white cells, occurs through the intercellular portion of the wall

Although the preceding generalization is probably true, one must not lose sight of the fact that capillary permeability is by no means uniform throughout the body For example, skeletal muscle capillaries are about one hundredfold less permeable to water than the glomerular capillaries Using as a gauge of permeability the protein concentration of the lymph draining different regions, it is found that liver lymph may contain 7 per cent protein (plasma has 6 per cent), lymph from lungs, heart, kidney and intestines, 3 to 4 per cent protein, skin, 1 per cent protein

The functional anatomy of the capillaries has been worked out for some cold blooded animals, for the rat and dog mesentery through microscopic observations of the *in vivo* vessels, and for the myocardium by both anatomical and microscopic observations (fig 15 6) Briefly, blood flows generally from the arterioles directly into a metarteriole, and then into capillaries The metarterioles lead directly into channels which are main thoroughfares from the capillary bed to the venules The true capillaries concerned with interchange between blood and tissues are interanastomosing side branches of the main channels through the bed At the ostia of each capillary is a small pre capillary sphincter of smooth muscle which is controlled by nerves presumably from the sympathetic nervous system, in the same manner that these nerves control the arterioles and metarterioles In the body, the metarterioles and their precapillary sphincters undergo periodic contractions at intervals of 15 seconds to 3 minutes When the tissue is in a resting state, the constrictor phase of this rhythm predominates and the precapillary sphincters may be completely closed When the tissue becomes active, the dilator phase of the metarterioles predominates and the precapillary sphincters are open Thus, in skeletal muscle, it is believed that the increase in blood flow with exercise comes in large measure from this opening up of large numbers of additional capillaries It is believed that the factors that affect the degree of constriction and relaxation of the metarterioles and the precapillary sphincters during vasomotion are the same factors that affect arteriolar diameters

FIG 15 6 Diagram of a functional unit of the capillary bed, A.V.A. metarteriolar venular anastomosis (Chambers and Zweifach)

These are the nervous and hormonal stimuli and local conditions in the tissues. Thus, sympathetic stimuli and epinephrine in the blood intensify the constrictor phase of vasomotion in most areas of the body in the same manner that these two constrict the arterioles. On the other hand, vaso dilator substances decrease the vasoconstrictor phase. The significance and value of this arrangement generally to capillary beds and to over all circulatory dynamics remains to be established.

Although controversy has raged for many years, at present it is believed that change in capillary diameter is on a purely passive basis, i.e., by change in intracapillary pressure or in extravascular tissue pressure, supposedly, the active changes in capacity previously described by many workers is probably due to the activation of smooth muscle whose presence was unsuspected at that time in the metarterioles and A V capillaries.

E Veins Since the systemic veins contain such a large proportion of total blood volume they must function as blood reservoirs. The responses by which they may counteract distending forces and thus prevent excessive pooling of blood have been of great interest and have been documented in animals and human experiments. As the venules merge to form larger veins, they acquire a layer of connective tissue and then distinct muscle fibers. These vessels have a larger blood content than the corresponding arteries. Their walls are also much thinner and contain less elastic tissue but have a rather well developed muscular coat. When the volume of blood in a normally partially collapsed vein is augmented, the intravascular pressure barely increases until the vein becomes round and has a certain degree of fullness. The volume increase up to this point is similar to the filling of a collapsible tube without distending the walls. True distension now occurs when further volume increments lead to an elevation of intravascular pressure (fig. 157). Veins excised or within the organism have a very low distensibility when the increase in volume is rather rapid. With prolonged elevation of intravenous pressure, there is a delayed compliance or passive yielding of the venous walls which is attributed to the visco-elastic properties of the smooth musculature. Thus although initially the low distensibility of veins may prevent blood pooling, the delayed compliance favors it. It is estimated that the ability of the venous system to take up blood is at least 100 times that of the whole circulatory system. Thus, if 1000 cc of blood is transfused in a human, about 990 cc will

reside in the extra arterial or low pressure system, and 10 cc in the arterial system. The pressure in the whole circulation might rise by 5 mm Hg.

The diameter of these venous capacitance vessels may be changed either passively by external forces (gravity, respiration or pressure breathing) or actively by contraction or relaxation of their walls. There is considerable evidence to indicate that the venous system (including the pulmonary system) behaves somewhat like an elastic bag. For example, change in posture has no particular effect on their state of contraction when human subjects are bled or transfused with about 500 cc of blood the pressures in the central veins, the pulmonary artery, and left atrium rise and fall in parallel as the blood volume is changed by bleeding or transfusion (fig. 158).

While this leads to the conclusion that the venous system operates in a passive manner it must also be emphasized that this may be true only if the induced changes in central blood volume are moderate or gradual and not in the nature of emergency reactions. It is easy to demonstrate that a fixed pressure volume relationship need not apply to the veins and venules for they are the most sensitive of all vessels to all types of mechanical, chemical and temperature impacts. For example, the trauma attendant to dissection or to needle insertion may completely close a medium sized vein. In addition they are supplied with vasomotor nerves through the action of which the distensibility and capacity of the venous system can be actively and greatly changed. This provides a means by which the volume of the venous system can change within wide limits without significant corresponding changes in venous pressure. Such innervation has been demonstrated for the vena cava and veins of the hand.

FIG. 157 Venous distensibility patterns with different degrees of vasomotor tone (Alexander, *Circulation Res.*, 1954, 2, 405)

FIG. 158 Effects of changing total blood volume (by transfusion (+) or bleeding (-)) upon aortic (A P) pulmonary artery (P A P) left ventricular diastolic (L V D P) and central venous pressures (C V P) (Gauer and associates *Circulation Res* 1956 4, 79)

lumb and mesentery in animals. Active contraction or relaxation of the venous smooth muscle (venoconstriction or dilation) can be elicited by activation of local stretch receptors in the venous walls and reflexly by activation of the baroreceptors (stretch receptors) in other veins and in the aorta and carotid arteries and by direct local action of adrenergic or cholinergic substances (fig. 157). Reflex venomotor activity has also been measured in normal subjects by means of pressures developed within isolated segments of superficial veins. An arm superficial vein segment without tributaries is temporarily isolated by applying pressure at the segment ends so that the volume is held constant and vein contraction can be reflected by an increase in pressure which is recorded continuously by an indwelling needle

connected to a pressure manometer. Strong contractions are caused by the Valsalva maneuver, cold exercise and hyperventilation. Persons with postural hypotension show little or no segment or central venous response to these stimuli, indicating impaired reflex venomotor activity. Although the entire venous bed may be regarded as a large variable blood depot, the central systemic veins constitute the most important part of this depot for supplying the right heart. It is estimated from observations in dogs that the pressure-volume curve of the venae cavae in the intact living dog can be varied by 15 to 20 times and with only a small effect on venous pressure. This means that translocation of large volumes of blood to the pulmonary and systemic arterial circuit is easily effected.

VELOCITY CHANGES

A In different vessels (fig 15 1) Just as the cross-sectional area varies greatly in different parts of the cardiovascular system, so does the velocity of blood flow. Since the velocity of flow is inversely proportional to the cross-sectional area of the vessel through which it flows, velocity will be maximal in regions of the circulation with the smallest total cross-sectional area. Hence, the blood velocity in the aorta is the most rapid of that in any part of the body, but even here the average velocity of about 40 cm per sec, is low. In the capillaries, it is least, at about 0.07 cm per sec. This slow rate of passage in the peripheral capillaries, of course, provides time for the exchange of materials across the capillary membranes or walls. After passing into the veins, the blood again accelerates as the cross-sectional area progressively decreases. However, since the caliber of the veins is larger than that of the corresponding arteries, the velocity of venous blood flow never becomes equal to that of the arterial blood and generally equals about $\frac{1}{4}$ of that in the arteries. For example, the flow of blood along the two venae cavae which together have a cross-sectional area some 4 times as great as that of the aorta, is only about 8 to 10 cm per sec under resting conditions.

Although the average blood velocity is low, the peak velocity of blood flow may be high since this changes greatly from moment to moment during each heart beat in the systemic arterial system. In the ascending aorta near the aortic valves, the peak velocity during systole may be 120 cm per sec, during most of diastole, the velocity may approximate zero. Further down the thoracic aorta and in the abdominal aorta, the small backflow present in the ascending aorta at time of closure of aortic valves is greatly accentuated and extended, while forward flow during diastole is increased. In the major aortic branches these violent fluctuations of velocity, although somewhat damped, are largely retained. However, except for the coronary, femoral, and axillary arteries, backflow disappears, and the flow curve

is often patterned after its corresponding pressure pulse. At the capillary level, these fluctuations in velocity are pretty well removed so that a smooth rate of flow is attained. In the venules and as the veins become larger, fluctuations or variations in the velocity of flow again reappear. In the venae cavae near the right atrium, blood velocity may become much greater during ventricular systole than during its diastole, indicating that contraction of the myocardium itself draws blood towards the heart. During inspiration, the whole flow curve in the venae cavae is greatly elevated.

B Across a blood vessel Finally, the velocity of flow will vary in different portions of the cross-sectional area of a blood vessel, especially in the larger vessels (fig 15 9). In the larger vessels there is a cylindrical layer of blood which adheres to the vessel wall and wets it. Inside this motionless layer is another cylindrical fluid layer which flows and rubs against it, and inside this there is another flowing faster, and so on, until the central axial core of blood is reached which has the maximum velocity. In arterioles and vessels of quite narrow caliber red cells are concentrated pretty much in the axial part of the blood stream so that plasma flows along the walls. As a result, the red cells move faster than plasma by a significant amount, and hence, the hematocrit in capillaries is somewhat less than that of the larger vessels. The effect of this is, of course, to change the distribution of the velocity in the various parts of a cross-section of such a vessel.

The flow of blood is laminar or streamlined in most portions of the circulatory tree. When the velocity of flow is increased above some critical level, turbulence develops. The formula $RVD/v = a$ critical constant for turbulence (Reynolds number) expresses the conditions producing turbulence in fluid flowing through tubes of constant diameter in which, v is viscosity, D is density, V is mean velocity, R is tube radius. This indicates that turbulence occurs when low viscosity fluid flows through tubes of large diameter at quite high velocity. If this formula ap

FIG 15 9 Schematic representation of the variable velocity of blood flow in vessels. Flow is fastest in the central axial stream and progressively decreases to zero at the vessel wall.

plies to the cardiovascular system, the big variable is the blood velocity since the blood viscosity and vessel diameter do not change greatly. Blood flows rapidly through the biggest arterial channels and with the highest velocities at the roots of the aorta and of the pulmonary artery. It is debatable whether the critical level for turbulence is normally exceeded at these points during the rapid ejection phase of ventricular systole.

PRESSURE CHANGES

A Kinetic and potential energy, lateral and end pressure. Of the energy developed by the left ventricle, more than 98 per cent is normally in the form of potential energy, 1 per cent or less as kinetic energy. When the left ventricle pumps out blood, it increases the radius and length of the aorta and its large branches to store potential energy as tension in the arterial walls. Because of the motion (velocity) of the blood during ejection, a certain amount of kinetic energy is also transferred to the blood. During exercise with a very large cardiac output or in the presence of aortic stenosis, as much as 10 to 50 per cent of the energy expended by the heart is used for increasing blood velocity. Ultimately, however, most of the potential energy is changed to kinetic energy to

produce flow through vascular elements, and then is finally dissipated as heat through friction. The kinetic energy of flow can have a real effect on intravascular pressure. This can be demonstrated by inserting into the flowing bloodstream small catheters or cannulas connected to pressure manometers (fig 15 10). With the catheter opening pointing upstream, end pressure or potential energy is measured, with the opening at right angles to direction of flow, lateral pressure or the pressure actually pressing on the vessel is measured. In the vessels of humans, end pressure and lateral pressure are almost equal except in the aorta and its immediate branches in which the kinetic energy is sufficiently high from prevailing blood velocity to cause the lateral pressure to be significantly lower, i.e., lateral pressure is inversely proportional to the blood velocity (Bernoulli effect). At rest, the average aortic lateral pressure is about 1 mm less than the end pressure, with exercise, the difference might be 15 mm Hg. If one is recording phasic aortic pressure throughout the cardiac cycle, then with exercise the lateral pressure might be 40 mm Hg less than the end pressure during the period of rapid blood ejection (first third of systole). Ultimately, most of the potential energy is converted into kinetic energy in producing flow. In this exchange no energy is lost. However, as blood progresses from the aorta to the atrium, the intravascular pressure decreases to very low values. This permanent loss of energy or pressure arises from fluid friction developed within the vessels with gradual change of energy into heat.

B In different vessels (fig 15 1). Pressure in the aortic arch reaches a maximum during mid systole, and a minimum at the end of diastole. The numerical difference between these pressures is called the "pulse pressure." Similarly, pressures in the thoracic and abdominal aorta and their major branches, i.e., the carotid, the radial, and especially the femoral, show that the values for the systolic pressure increase and those for diastolic pressure decrease, i.e., pulse pressure increases. In still smaller arteries, the pulse pressure progressively diminishes, systolic pressure falling more than diastolic. However, this does not represent a frictional loss of energy but merely a replacement or shift in the temporal relations of pressure during a cardiac cycle, since the mean pressure, for example, in the femoral arteries is the same as that in the aorta.

As the arteries divide and subdivide, the caliber of the individual vessels diminishes and the pressure gradients become correspondingly steeper,

FIG 15 10 Reproduction from original record of lateral upstream and downstream phasic pressure patterns taken at the subclavian level in the aorta of a large open chest dog by means of 3 strain gauges adjusted to identical zeros and sensitivities. The patterns and pressure values of the 3 curves are almost identical at systolic pressure 139 mm Hg, diastolic pressure 115 mm Hg, heart rate 150 minute.

particularly in the arterioles and capillaries. Not only is the pressure gradient steeper, but the oscillations of pressure during a cardiac cycle are reduced to a minimum at the time the arterioles are reached. At the arterioles there is a pronounced decrease in pressure gradient, a second abrupt decrease in the capillaries with almost no residual pressure fluctuations. A more gradual pressure decline occurs in the venules and veins until a negative pressure is actually reached in the central veins owing to the effect of the subatmospheric pressure within the thorax.

FUNCTIONAL CHARACTERISTICS OF THE PULMONARY CIRCULATION. In many respects the pulmonary vascular bed (pulmonary artery through pulmonary veins) is similar to the systemic circuit but certain differences deserve emphasis. The pulmonary circulation is a low resistance circuit, arterioles being essentially absent; the pulmonary vessels supply only one type of tissue (alveoli) so vasomotor requirements are low; pulmonary blood volume is less than that in the systemic circuit; extravascular conditions (within the thoracic cage) are fairly uniform (fig. 15-1).

The main pulmonary artery and its branches are structurally similar and of about the same or slightly larger diameter than the aorta, but their walls are one third the thickness and their branches are much shorter and of very small capacity. Small arteries in both systems have thick muscular walls. Arteries less than 0.1 mm in diameter are endothelial tubes without muscle. There are no vessels corresponding to arterioles, i.e., no small bore high resistance vessels. The capillaries are somewhat larger, appear to take off very densely from the above endothelial tubes and have multiple anastomoses. There are numerous A-V shunts. The pulmonary veins are short and contain less blood than the systemic veins.

The pulmonary artery and pulmonary bed in general are many times more distensible than the systemic portion of the arterial circuit and probably represent the most distensible part of the low pressure system. *In vivo* pressure-volume curves of the entire pulmonary vascular bed and of the pulmonary veins (and left atrium) have pretty much the shape of venous pressure-volume curves in the relaxed state (fig. 15-11). The blood volume of the pulmonary system is only 800 to 1200 cc., of which 75 to 100 cc. is in the capillaries and the rest is in the major arteries and veins. Since the pulmonary vessels are a low pressure distensible system, a minute increase in outflow pressure at the left ventricle or an in-

crease in pressure at the right ventricle results in a sizeable accumulation of blood in the lungs. With change in posture in man it is estimated that as much as 400 cc. goes into and out of the lungs. Thus the blood volume of the pulmonary vascular bed (about 25 to 30 per cent of circulatory blood volume) has an important reservoir function and is about the most important depot for supplying the left heart.

There is some evidence that the distensibility of the pulmonary vessels can be altered. This is based on the findings that the pulmonary vessels contain considerable smooth muscle; plastic casts of two sides of a lung are very different if one side is perfused with adrenaline up to the moment of plastic injection (this especially affects vessels less than 25 μ in diameter); stimulation of the carotid body chemoreceptors decreases pulmonary vascular resistance; extreme hypoxia (4 per cent oxygen) in one lung causes vessel constriction in that lung; intrapulmonary artery injection of acetylcholine decreases the pulmonary hypertension caused by breathing a low oxygen mixture. It is obvious however that the functions of dilation and constriction have been demonstrated under rather extreme conditions. There is thus no strong evidence that the distensibility characteristics (pressure-volume) of the pulmonary circulation can be significantly altered under normal

FIG. 15-11 Pressure-volume relationship of the pulmonary vascular bed. Injections and withdrawals made at 10 second intervals. Dots pressures immediately after end of each injection. Circles pressures 5 seconds after end of injection. Crosses pressures immediately after withdrawal. (Sarnoff and associates, *Physiol.* 1952 171-235.)

conditions and, hence, it is believed to be mainly a passive vehicle for blood flow. Present experimental evidence (fig. 15.8) supports the view that the pulmonary circulation together with the systemic veins or capacitance vessels form a functional unit or reservoir in which passive and/or active changes in the capacitance system regulate the store of blood in the pulmonary reservoir where it is handled passively.

Since the stroke volume and mean velocity of flow are almost identical in the aorta and pulmonary artery, the kinetic energies of the two bloods are the same, but because the potential energy imparted to the blood by the right ventricle is much less, the kinetic factor is a greater proportion of the energy output of the right ventricle. Phasic variations in blood flow velocity are possibly even more marked in the pulmonary artery than in the aorta. In contrast to the systemic circulation a markedly pulsatile flow is retained in the pulmonary capillary bed during rest and after exercise. During systole blood is accelerated in the right ventricle and pulmonary artery by contraction of the right ventricle. The blood gains kinetic energy or energy of motion. As blood distends the arterial tree, the latter acquires potential energy (elastic and hydrostatic). At the same time, energy is partially dissipated by resistance to systolic flow in the small vessels. During diastole the potential energy in the arterial tree is partly lost in hysteresis, and the remainder is dissipated in elastic recoil as blood flows through the resistance of the small vessels. By the end of diastole, the pressures in the vascular bed are almost equilibrated and capillary flow practically ceases.

The resistance to blood flow in the pulmonary circulation is about one thirteenth that of the systemic circulation. This is because there are no high resistance arterioles, the pulmonary capillaries are large and very numerous, the pulmonary vessels are so easily distended passively, and large portions of the pulmonary bed are only partially used normally. The pressure pulsation in the pulmonary artery of 22/8 (mean 13 mm Hg) is fairly well maintained in the capillary bed and pulmonary veins since the capillary flow is so pulsatile during a cardiac cycle. However, the capillary pressure has not been directly measured. Phasic pressures taken indirectly through a catheter passed through the pulmonary artery until it is "wedged" in its small branches have been assumed to represent "capillary" or left atrial pressures since the blood obtained through the catheter is well-oxygenated. However, what such

recorded phasic pressure curves represent has never been clearly defined. The pressure gradient through the pulmonary bed is quite small. Its highest pressure (pulmonary artery 13 mm Hg mean) drops to about 7 mm Hg in the left ventricle at the end of diastole and at the site of outflow from the pulmonary circuit. This pressure gradient of about 6 to 7 mm Hg causes to flow through the pulmonary circuit the same volume of blood as flows through the systemic system with a pressure gradient of about 90 mm Hg.

T. INTERRELATION BETWEEN CALIBER OF VESSELS, INTRAVESSEL PRESSURE AND WALL TENSION. The law of LaPlace is that the tension (T) in the wall of a cylinder is directly proportional to the product of the intracylinder pressure (P) and the radius of the tube (R), i.e., $(T = P \times R)$. This has been graphically portrayed using a rubber balloon (fig. 15.2). With partial inflation, the upper part of the balloon expands largely; the distal portion only slightly. Internal pressure is the same throughout, but the greatly expanded portion of the balloon with the large radius has a high tension as evidenced by its resistance to indentation, while in the slightly distended area the walls are soft and easily deformed. Burton has pointed out the application of this law to the ventricular cavities and the vascular system and has calculated the wall tension in the various vessels. In the aorta with a radius of 1.2 cm, it takes the highest wall tension of 170,000 dynes per cm length to support the transmural pressure of 100 mm Hg, while in the capillaries with a radius of 4 μ , it takes the lowest tension only 16 dynes, to support a blood pressure of 30 mm Hg. In the same capillaries in the legs while standing the pressure can be 100 mm Hg. Thus it takes only about 3% as much wall strength in the capillaries as in the aorta to support the same range of internal blood pressure.

As has already been pointed out, the tension in a vessel wall that resists the prevailing internal pressure is supplied by the elastic tissue at normal pressures and by the collagenous fibers at higher pressures. A second important function of the elastic tissue is to make possible a graded constriction or dilation under vasomotor change induced by active wall tension change via smooth muscle. When, however, elastic tissue is absent or in very small amounts, vessels can only be completely closed or open when under vasomotor tone. Intermediate diameters would not be possible. This may explain why tissues deficient in elastic tissue but with smooth muscle, such as A-V shunts and precapillary sphincters, are al-

ways either widely open or closed. Thus, with the combination of elastic tension and active tension, grading of degree of vessel constriction is possible but only over a limited range. If the pressure in a vessel is reduced far enough, its wall will eventually reach its unstretched length and the elastic tissue is not functioning. At pressure lower than this, in spite of elastic tissue there will be no elastic tension to provide the automatic adjustment needed for stability; the vessel will become unstable and close. Such "critical closing pressures have been experimentally demonstrated in many vascular beds and may under certain circumstances approximate a prevailing blood pressure of 100 mm Hg.

INTERRELATION BETWEEN PRESSURE, FLOW AND RESISTANCE. Hemodynamics is the study of the forces which cause, alter, and regulate the flow of blood through the body. The central problem in hemodynamics is, 'What is the relation between the rate of flow of blood in the vascular bed and the pressure which drives it?' Knowledge and understanding of the factors that determine the shape of the curves of flow and pressure is essential to proper interpretation of the changes in blood flow and blood pressure in normal or pathological physiology.

A simple association of pressure and flow can obviously serve as an index of total peripheral resistance (TPR) to flow in the cardiovascular system

$$\frac{\text{(aortic pressure)}}{\text{(aortic flow)}} \text{ or } \frac{\text{(pulmonary artery pressure)}}{\text{(pulmonary artery flow)}}$$

or to local resistance in single bed or organ, for example

$$\frac{\text{(renal artery pressure)}}{\text{(renal artery flow)}}$$

Such measurements and calculations have been used extensively in recent years in clinical and experimental investigation and, especially in the aorta, to separate the resistance changes due to central or cardiac factors from those due to peripheral factors. The architecture of the whole circulatory distributing system is such that the organs are supplied through many parallel shunts. In this the total peripheral resistance (TPR) is

$$\frac{1}{\text{TPR}} = \frac{1}{r_1} \text{ plus } \frac{1}{r_2} \text{ plus } \frac{1}{r_3} \dots \frac{1}{r_n}$$

but since the aorta supplies all the regions with pressure and flow, TPR can be calculated as mean aortic pressure divided by cardiac output. A

little reflection will indicate, however, that the resistance to flow can arise from active changes in the smooth muscle of the particular vascular bed in question, or it could be related to passive changes in the geometry of the same vascular bed due to internal and external variations of the pressure. The above approach does not permit separation and quantitation of active and passive changes in vessel size which is essential to the proper understanding of pressure and flow relations. In a modified form, some physical laws derived from hydrodynamics have application to the flow of blood, and they will be considered next.

A Poiseuille's Law. Generally stated the volume (F) of blood flowing through a circulating system increases with the perfusing pressure (P) and decreases with the resistance (R) to flow as indicated by the equation $F = P/R$. This is Poiseuille's experimental law which is expressed in more detail as

$$F = (P_1 - P_2) \frac{(\pi r^4)}{(8L)} \frac{(1)}{(\eta)}$$

in which F is flow per unit of time, P_1 is pressure at an upstream point in the tube, P_2 is the pressure at a downstream point in the tube, π is 3.1416, r is the tube radius, L is tube length, η is fluid viscosity. Poiseuille's experiments were based upon measurements of stream lined flow (nonturbulent) in nondistensible tubes with Newtonian fluids at constant temperature. This means that flow is augmented by an increase in any factor in the numerator and decreased by any factor in the denominator. Thus, flow would decrease by one half if tube length is doubled or if blood became twice as viscous. Blood is caused to flow from one point to another in a tube by the difference of pressure between such points. This means that doubling the pressure gradient ($P_1 - P_2$) along the tube will double the flow. Change of radius is much more effective in changing flow for doubling the radius will increase flow 16 times.

The resistance to flow, defined as the ratio of the driving force to the flow, is obtained by a rearrangement of the above formula in which

$$R = \frac{P}{F} = \frac{(8L)}{\pi r^4} \frac{(\eta)}{(1)}$$

Resistance to flow is made up of two distinct factors. These are the viscosity (η) or inner friction of the fluid and the geometry of the tube

$$\frac{(8L)}{(\pi r^4)}$$

FIG. 15.12 The relationships of flow, pressure and resistance in nondistensible tubes using Newtonian fluids (dotted lines) at constant temperature (Poiseuille's law) and blood in vessels (solid lines). See text for details.

which is made up of the radius and length. In his system the resistance was constant since both the viscosity and the geometry of the tube were unchanged and did not change with rate of flow or pressure. A plot of flow versus pressure gave a straight line through the origin and one of resistance versus pressure a horizontal straight line (fig. 15.12).

B Application of Poiseuille's law to the circulation. The applicability of this law *in toto* to the circulation depends upon whether resistance is independent of pressure and flow. In the circulatory system peripheral resistance is a measure of the totality of all factors affecting blood flow. These include change (decrease) in apparent blood viscosity (which is known to occur with increase in perfusion pressure occasioned by the movement of the red cells to form a central axial rod), the existence of stream lined versus turbulent flow, the length of vessels and the cross sectional areas of the blood vessels. The latter is determined by the extravascular pressure provided by surrounding tissue by mechanical dilation with rising perfusion pressure by opening of new capillaries and vessels with change in metab-

olism and with rising perfusion pressure and by active changes in the state of contraction of the muscular walls through vasomotor nerves humoral substances and metabolic products.

The flow pressure curves obtained with blood in vascular beds are quite different from those obtained in the artificial system used in Poiseuille's experiments. The chief differences are the curves do not pass through the origin and flow is insignificant until a critical level of pressure is attained (called by Burton the critical closing pressure). The curves for dilated vessels are almost linear but with increasing tone the curves become sigmoid and then convex to the flow axis. At sufficiently high pressures the curves tend to become straight lines pointing toward the origin. The resistance is almost constant at high pressure but rises as the pressure is reduced to reach very high values near the critical closing pressure. Such deviations could arise if (1) the geometric factor of Poiseuille's law is not constant but varies with the distensibility of the blood vessels and (2) blood has anomalous viscosity so that the viscosity factor of Poiseuille's equation varies with the rate of flow and hence the driving pressure. While experimental evaluation is difficult it does appear that vessel distensibility is the major factor responsible for the deviation of *in vivo* pressure flow curves from Poiseuille's law. This in turn is related to the active tension or contraction of smooth muscle in the vessel walls and to the combined effects of elastic and collagenous fibers in the architecture of the vessels. Apparently anomalous viscosity is a minor factor. While the viscosity of moving blood does change i.e. with increased flow rates there is an axial accumulation of red cells any change of viscosity from such accumulation of red cells is complete at very low flow levels and throughout most of the physiological range of flow viscosity does not change appreciably with flow. This is borne out by the experimental observations that flow pressure curves using fluid of normal viscosity such as plasma are essentially similar to those obtained when blood is used but when blood is used in rigid nondistensible tubes the flow pressure curves are almost linear within the physiological range.

C Use of peripheral vascular resistance as an index of vasomotor activity. In view of the multiplicity of factors which affect peripheral resistance in the cardiovascular system it remains to be seen to what extent changes of peripheral resistance may be used to interpret vasomotor activity. Still, in studies of peripheral circulation reactions

it is desirable to measure the peripheral resistance. This represents the ratio of transmural pressure to the rate of flow through the organ or region being studied. Vascular tone or vasomotor action represents the active contraction of the muscular walls of the blood vessels and is influenced physiologically by vasomotor nerve impulses, humoral substances and metabolic products. The fact that changes in intravascular lumen occur with altered intraluminal pressure on a purely physical basis points up the difficulty in establishing to what extent alteration of peripheral resistance may be used to interpret vasomotor activity.

The interpretation of changes in peripheral resistance in the presence of an alteration of vasomotor activity associated with a rise or fall of blood pressure or blood flow is difficult. In this instance changes in vasomotor activity cannot be deduced unless it is possible to know in some way what portion of the change in peripheral resistance would have resulted from the observed alterations of pressure or flow alone. It is obvious that as long as either arterial pressure or the blood flow remain constant while the other is changing or if pressure and flow change in opposite directions the fluctuations of peripheral resistance correctly indicate the direction and roughly the magnitude of alteration of vasomotor activity. A fairly satisfactory and practical way of estimating change in vascular tonus due to vasomotor activity when pressure and flow change in the same direction is to determine during a control period the pressure flow relationship over the range of flows anticipated during the experimental period and thereafter to compare these with the pressure flow ratios during the experimental period. Their difference would be caused by a vasomotor change. Possibly the most useful approach is to calculate resistance values from directly measured levels of pressure and flow while either the pressure or flow is controlled by a pump. This type of measurement has been made in the conscious dog and man.

ELECTROCARDIOGRAPHY

Electrocardiography may be defined as that branch of physiology which is concerned with the recording and analysis of the electrical activity of the heart. The electrocardiograph is an instrument which receives the electrical impulses as they vary during the heart cycle and transforms them into a graphic record. The electrocardiogram is the graphic record which has been inscribed by the electrocardiograph.

Instrumentation

The first electrocardiogram was obtained in 1887 by Waller who employed a capillary electrometer as his electrocardiograph. It was Einthoven who became the real father of electrocardiography when he described the string galvanometer in 1903. This instrument became the standard apparatus for the recording of electrocardiograms until it was largely supplanted by the vacuum tube, amplifier-driven oscillograph in the 1930's. This type of instrument was later modified by stepping up the amplification to a strength adequate to drive a mechanical lever arm so that directly written records might be obtained either with an ink writer or a hot stylus applied to specially waxed paper. Recently transistorized modifications of the vacuum tube type of oscillographic instrument have come on the market. Common to all these instruments is the property of faithfully inscribing the variations of the cardiac voltages on an accurate time scale abscissa.

The cathode ray oscilloscope has been employed for specialized research in electrocardiography and recently it has been adapted by means of the sweep circuit to give a constant visual display of the electrocardiographic pattern which can be monitored during surgery or other critical clinical conditions.

Depolarization and Repolarization of Cell Aggregates

The electrocardiogram which is recorded from body surface electrodes is the result of a vast

number of systematically propagated electrical events taking place in the individual muscle cell fibers of the heart. We have seen that the individual myocardial fiber is depolarized and repolarized with large voltage fluctuations across the cell membrane, but with only small potential differences being recorded outside the cell. How then does the transmembrane action potential relate to the electrocardiogram recorded first from the surface of the heart and ultimately from the surface of the body?

It must be remembered first that the depolarization of a portion of a fiber initiates a flow of current from the polarized zone to the depolarized zone. This flow of current propagates the wave of depolarization until the entire tissue is depolarized. Since the heart is really a syncytium of muscle fibers, it follows that if one portion of the muscle becomes depolarized it will initiate a wave of activation that will eventually depolarize the entire heart. That such is indeed the case is shown by the fact that extra systoles may be produced by touching the epicardium of the exposed heart at surgery or by touching the endocardial surface with a cardiac catheter during diagnostic studies. The localized point of depolarization initiated by the mechanical stimulus is propagated to the entire heart muscle.

THE ISOLATED MUSCLE STRIP

The relationship between the surface electrocardiogram and the spread of depolarization through the muscle is illuminated by experiments on isolated strips of heart muscle. Figure 18-1 illustrates the sequence of events when a wave of activation sweeps over a strip of myocardium with electrodes applied directly to its surface. On the resting polarized muscle there is no difference of potential since all parts of the surface are equally positive in charge. Hence the galvanometer records only a straight line at zero potential. When the strip is stimulated at the region of the negative electrode to the left of the drawing this zone becomes depolarized and is

electrically neutral. The other end of strip is now positive with respect to the depolarized zone and the galvanometer records a positive deflection. As the wave of activation approaches the

positive electrode more and more positivity is recorded until the cell is completely depolarized whereupon there is no longer a potential difference, and the recording galvanometer drops the tracing abruptly to the zero line.

When the positive electrode is placed in the middle of the strip positivity is recorded until the wave of activation passes beneath the positive electrode whereupon the recording drops abruptly to a negative potential which returns to the zero line when the strip becomes completely depolarized. In a series of simple but beautifully conceived experiments Craib was able to show that this phenomena could best be accounted for in terms of the migration of a dipole across the length of the muscle strip.

A dipole may be conceived of as two points of opposite electrical charge separated by a small but infinite distance. If these points are connected by a wire it is understood by convention that current will flow along the wire from the positive pole to the negative pole. (In point of fact the electrons actually flow from the negative to the positive pole.) If the dipole is immersed in a volume conductor such as a pool of weak saline solution, then a three dimensional field will be set up with the lines of current flow distributed in a pattern as illustrated in figure 16.2. Isopotential lines are arranged at right angles to the lines of current flow. Thus all points which lie on the plane perpendicular to the center of the axis connecting the two points of the dipole are at zero potential. The human electrocardiogram may be analyzed in terms of the body surface potentials generated by a series of dipoles within the heart and distributed throughout the body which behaves as a volume conductor.

This concept may be clarified by reference to an isolated heart muscle strip immersed in a volume conductor as shown in figure 16.3. In the resting state the strip is polarized with in

FIG 16.1 Depolarization of a strip of myocardium with electrodes in direct contact with tissue. During the resting stage no difference of potential is recorded. When stimulated at arrow depolarization begins and stimulated end becomes negative to opposite end. Positivity is recorded from positive electrode until activation is completed whereupon no more difference in potential exists and recording drops to zero. With positive electrode in middle of strip positivity is recorded until the activation wave arrives under the electrode. Since the plane that divides a dipole is at zero potential the recording drops immediately to zero. As soon as the dipole passes the electrode maximum negativity is recorded and it gradually lessens until the return to zero when activation is completed.

numerable dipoles distributed about the surface of the strip, positive charges on the outside and negative charges on the inside. Since the positive charges facing the electrode are exactly balanced by the positive charges facing away from the electrode, there is no difference of potential, and no deflection is registered on the galvanometer or on the electrographic tracing.

When a stimulus is applied to the end of the strip facing away from the electrode, depolarization begins at that point. The dipoles at the point of stimulus are obliterated by a flow of current across the stimulated membrane, the electrical resistance of which has dropped precipitously. The stimulated area then loses all surface charges, but this entire area now is electrically negative with reference to the remainder of the strip which is still positively charged. Thus, the plane that divides the depolarized from the polarized portion may be considered as an interface separating the positive and negative poles of a dipole, and the propagation of the wave of depolarization down the muscle strip may be thought of as the sweep of a dipole across the length of the muscle strip. As the dipole approaches the electrode higher and higher voltages are recorded as the electrode intersects isopotential lines of higher and higher voltage. Maximum potential is reached when the dipole arrives at the end of the strip nearest the electrode. When the entire strip becomes depolarized, it suddenly becomes electrically inert and the galvanometer and electrogram immediately fall to zero.

In figure 16.4 are illustrated the electrograms

which are inscribed with electrodes placed at the stimulated end of the strip and at the midpoint of the strip.

REPOLARIZATION

The process of repolarization we have seen from the monophasic action potential recorded by the micropuncture technique from the single fiber is of long duration in contrast to the rapid spike of depolarization. Since the resting transmembrane potential is fully restored after each beat, the total electrical charge of repolarization must be equal and opposite to the discharge of depolarization. If it were presumed that repolarization followed the same pathway across the muscle strip as the wave of depolarization, then one would expect that the repolarization wave should be inscribed by the recording oscillograph as a slow deflection opposite in direction to the depolarization spike but encompassing the same area. While this is indeed the case in the isolated muscle strip electrogram, it is not the case in the normal human electrocardiogram in which the depolarization and repolarization deflections usually have the same direction, and the areas of the two are rarely if ever the same. The reasons for the paradoxical orientation of repolarization in the human electrocardiogram will be discussed in a subsequent section.

Since repolarization is of long duration, different phases of it are proceeding simultaneously in various portions of the muscle strip and indeed throughout the heart (fig. 16.3). Repolarization,

FIG. 16.2. Electrical field of a dipole in a volume conductor. Solid lines are current flow. Dotted lines are isopotential lines. (From Fulton.)

FIG 16.3 Depolarization and repolarization of a strip of myocardium immersed in a volume conductor. Electrode E connected to positive pole of recording galvanometer which is paired with a distant electrode at near zero potential. The advancing dipole at the border between activated and inactivated muscle produces an electrical field which moves toward the electrode. The electrode is intersected by isopotential lines of increasing force until all difference of potential is extinguished by completion of depolarization. Recovery occurs in all parts of the muscle simultaneously but is completed at the stimulated end first thus producing relative negativity at the side facing the electrode and giving rise to a negative repolarization wave.

therefore, cannot be analyzed as a sequence of propagated electrical events and cannot be viewed as a wave front sweeping across the muscle. Changes in temperature, chemical environment and pharmacological agents may produce marked alterations of the repolarization wave without noticeably affecting the depolarization spike.

CURRENT OF INJURY

When a portion of myocardium becomes injured, whether it be mechanically, chemically or thermally, the cell membranes in the injured area become more permeable to sodium ions which leads to a lessening of the ionic concentration gradients of sodium and potassium across the cell membranes and thus to a reduction of the charge density in the resting polarized state. This reduction of positivity in the injured area produces a gradient of charge from the uninjured to the injured zone. A current flows from the area of high positivity to the area of low positivity, this current is called the current of injury. It flows during the resting polarized state.

Figure 16.5 shows how the injury current affects the depolarization and repolarization waves of the electrogram of the isolated muscle strip. Prior to injury the polarized muscle strip gives rise to no potential difference and the electrogram tracing is at zero. Upon injury of a portion of the strip near the electrode, the tracing shows the onset of a negative deflection since the charge density at the injured area is less than that over the remainder of the strip. The injured area is thus electrically negative to the noninjured area. When the strip is stimulated from the noninjured side the dipole of the depolarization wave sweeps toward the electrode producing a positive deflection. The tracing shows an increasing positive spike until the entire strip has become depolarized whereupon the electrogram deflection falls to the zero potential line which is well above the origin of the depolarization spike. Repolarization then begins at the zero potential line giving the appearance of elevation of the repolarization wave.

If the electrode is placed on the opposite side of the strip, then the injury potential displaces the baseline upward from the zero line. The depolarization spike is negative, and its termination at zero falls below the point of origin. The repolarization wave commencing at this point gives the appearance of depression of the repolarization wave. Thus, the injury potential produces elevation of the origin of the repolarization wave when the electrode faces the injured zone and depression

FIG 16.4 Form of complexes inscribed from electrodes placed at positions E_1 and E_2 during depolarization of a strip of myocardium suspended in a volume conductor. Each electrode paired with a distant indifferent electrode. Tracings on the left side are related to E_1 while tracings on the right relate to E_2 electrode.

sion of the origin of the depolarization wave when the electrode faces the noninjured zone.

Another form of the injury potential may become apparent when the injured zone fails to depolarize. In this situation the resting injury potential produces depression of the isoelectric line so that the activation potential begins from a negative position. As the dipole of the depolarization advances toward the electrode, increasing positivity is inscribed until the activation wave arrives at the border of the injured zone where it is blocked. At this point, the injured zone maintains its weakly polarized state, but the noninjured zone has become depolarized making it electrically negative to the injured zone. The persistence of the dipole at the completion of activation maintains positivity at the electrode until the repolarization process in the uninjured

FIG 16.5 Sequence of electrical changes in myocardial atrip which has been injured at end near electrode E_1 . When portion of atrip becomes injured there is leakage of ions and reduction of surface charge density making injured zone less positive than noninjured zone. A dipole is thus produced at border of injured zone with negative pole facing the electrode during the resting phase. Isoelectric line is therefore displaced downward to negative position. Following stimulation the dipole of depolarization sweeps toward electrode producing positive force which neutralizes effect of injury dipole. In 5A the injured zone becomes depolarized and injury dipole is abolished. Upon completion of depolarization recording falls to original zero position. As repolarization is completed from left to right the injury dipole is re established and tracing returns to negatively displaced isoelectric line giving appearance of elevation of onset of repolarization deflection. If electrode is on opposite side of atrip isoelectric line is displaced upward and onset of repolarization appears to be displaced downward. 5B shows the sequence when injured zone fails to depolarize. The impulse is blocked at the boundary of the injured zone which remains polarized and therefore during aystole presents a dipole with its positive pole facing the electrode holding the recording in a positive position until repolarization returns the tracing to the negative isoelectric line. This phenomenon is called the monophasic injury wave.

zone slowly returns the tracing to the isoelectric line. The resulting complex representing a fusion of depolarization and repolarization waves has been called the monophasic injury wave (fig 16 6).

The Mammalian Electrocardiogram

NOMENCLATURE

The mammalian electrocardiogram contains three major components during each cardiac cycle (fig 16 6). According to the nomenclature devised by Einthoven, the component produced by atrial activation is called the P wave, the one produced by ventricular activation is the QRS complex, and the component produced by ventricular recovery is the T wave. The P wave is separated from the QRS complex by an isoelectric interval called the PR segment. Individual deflections in the QRS complex are labelled as follows: if the initial deflection is negative (downward from the baseline) it is a Q wave, the first positive (upward) deflection is an R wave, and a negative deflection following the R is an S wave. Subsequent positive and negative deflections in this complex are labelled R' and S', respectively. The interval between QRS and T is the ST segment. The junction between the end of the QRS complex and the ST segment is called the ST junction or J point. A small after potential called the U wave is sometimes seen following the T wave. The duration of the components and the intervals between them vary with species and age. The intervals also vary inversely with heart rate. In the normal adult human the P wave is 0.07 to 0.12 seconds in duration, the PR interval measured from the beginning of the P wave to the beginning of the QRS complex is 0.12 to 0.20 seconds, the QRS complex is 0.05 to 0.10 seconds, and the QT interval measured from the beginning of the QRS complex to the end of the T wave is 0.26 to 0.45 seconds at normal heart rates.

THE DISTRIBUTION OF ELECTRICAL FORCES IN THE BODY

In accordance with dipole theory, the wave front of activation is considered to be a polarized surface with positive charges on its leading side and negative charges on the trailing side. The axis between each pair of positive and negative charges is perpendicular to the polarized surface, and the density of charges is considered to be a constant. Atrial and ventricular activation are

schematically described by the development of polarized surfaces which spread across the myocardium and are extinguished when they reach a margin of the myocardial syncytium or an area of activated muscle. Laws governing the distribution of electricity in a volume conductor define the electrical field produced in the body by such polarized surfaces.

When viewed from a sufficiently distant point P, a polarized surface can be represented by a single central resultant dipole with its axis perpendicular to a plane intercepting the boundary of the surface and its charge proportional to the area of this plane (fig 16 7a). The electrical potential (V_p) at a distant point in a large volume conductor containing a dipole with charges close together is proportional to $M \cos \theta / R^2$, where M is the electrical force on the dipole (determined by the quantity and distance between charges), R is the line from P to the center of the dipole axis, and θ is the angle between R and the dipole axis. Polarity of V_p is determined by the charge on the polarized surface facing P. The direct relationship between V_p and $\cos \theta$ indicates that potential at P is maximal when the dipole axis is parallel to R and zero when it is perpendicular to R. V_p is also proportional to the solid angle at P which is subtended by the boundary of the polarized surface (fig 16 7b). This solid angle is equal to the area cut on a unit sphere by lines drawn from its center at P to all points on the boundary of the polarized surface. When two or more polarized surfaces subtend solid angles at P, the resultant V_p is proportional to the sum of the solid angles with due regard

FIG 16 6 A single electrocardiographic complex giving nomenclature of the deflections and the intervals (Burch and Winsor)

FIG. 16.7A Calculation of positive potential (V) at point P when polarized surface S is considered as a single dipole. Arrow indicates axis of dipole. If P is located on a unit sphere, then $R = 1$. As point P moves away from the dipole axis, its potential diminishes as $\cos \Theta$ diminishes from 1 toward zero. The numerical value of $\cos \Theta$ is given by the distance on the axis from the center of the circle to the perpendicular dropped from P . M = dipole moment. **B** Illustration of solid angle principle. Two charged surfaces S_1 and S_2 have similar charge density but different areas, and opposite orientation of charge. At point P_1 , the net potential is positive because S_1 subtends a larger solid angle than S_2 . At point P_2 , the net potential is negative because S_2 subtends the larger solid angle. **C** Determination of voltage at point P when strength of dipole is represented by vector E . Voltage is proportional to $E \cos \Theta$ and is found by drawing perpendicular from the lead line terminus of vector. Distance from center of dipole to perpendicular on lead line determines voltage at P .

for their sign. The electrical potential at any point in the body or on its surface can theoretically be predicted in terms of the solid angles subtended by polarized surfaces developed in the heart during activation, and this has been done in a qualitative fashion. However, it is impossible to derive information about the size and orientation of the polarized surfaces from the resultant solid angles. It has been more practical to analyze

tracings recorded at a distance from the heart in terms of resultant vectors which indicate the magnitude and mean direction of electrical forces developed during the cardiac cycle without any implications about the polarized surfaces responsible for them. When viewed from a distance, the total electrical forces of the heart at any instant can be considered as a single dipole that is described by a vector oriented in the direction

of the dipole axis with magnitude proportional to the dipole moment. This vector represents the sum of many individual vectors each of which describes a dipole at a polarized surface.

Vector Analysis and Electrocardiographic Leads

A vector quantity is represented geometrically by an arrow with its direction and length related to the direction and magnitude of the quantity it describes. It can be shown that electrical potential (V_p) at a point P in a volume conductor is proportional to the geometric projection of an arrow representing a dipole vector onto a line (the lead line) drawn from P to a point of zero potential at the center of the dipole axis. V_p is proportional to $E \cos \theta$ when E is the magnitude of the dipole vector and θ is the angle between the vector and the lead line (fig. 167C). An electrocardiograph will record this potential if one electrode is placed at P and the second electrode is placed at a point of zero potential. However, when two electrodes are placed on the body surface, the tracing recorded represents only the difference between potentials of the same order of magnitude at each electrode and does not give any specific information about the potentials at either point. Einthoven described a method for vector analysis of such tracings recorded from electrodes on the body surface at a distance from the heart. He assumed as a first approximation that electrical forces of the heart originate in a relatively small area at the center of a homogeneous volume conductor, and that the regions where each arm and the legs join the trunk are points equidistant from each other. The extremities behave as linear conductors connected to the trunk so that an electrode placed anywhere on an extremity is equivalent to one at its junction with the trunk. Electrodes placed on each arm and a leg are then considered to be located at the apices of an equilateral triangle with the heart at its center, and differences in potential recorded between these points represent the projection of vector forces originating from a dipole at the center of the triangle onto lead lines drawn between its apices. Potential differences between the extremities are customarily recorded in three standard limb leads obtained by connecting two of the limb electrodes at a time in the electrocardiographic instrument in the manner illustrated in figure 168. The polarity of the electrode connections is such that a positive charge facing the left shoulder will produce a positive deflection (upward from the base line) in

lead I, and a positive charge facing the foot will produce positive deflections in both leads II and III. Einthoven deliberately arranged the polarity of lead II in a manner inconsistent with the other two leads so that ventricular activation would produce positive deflections in all three leads of most normal records. The differences in potential are recorded in the three leads according to the following relationship: $I = VL - VR$, $II = VF - VR$, $III = VF - VL$, where VR, VL, VF represent potentials at the right arm, left arm and left leg respectively. Since the three leads form a closed circuit the algebraic sum of their potential differences at any instant is zero. Because of the reversed polarity of lead II, this relationship (Einthoven's law) is actually $I - II + III = 0$ or $I + III = II$. The validity of this equation does not depend on any assumptions relating to the electrical homogeneity and geometry of the volume conductor or location of the heart.

It is possible to derive the potentials at each extremity from these bipolar leads if Einthoven's hypotheses are correct. That is, if the extremity electrodes are equivalent to the apices of an equilateral triangle on the surface of a homogeneous volume conductor with a point source of electrical potential in the center, then $VR + VL + VF = 0$ and it can be demonstrated algebraically that $VR = -(I + II)/3$, $VL = (I - III)/3$, and $VF = (II + III)/3$. However, if

FIG. 168 Einthoven triangle, R = right arm, L = left arm, F = foot. Mean electrical axis is derived from lead I and lead III QRS complexes by drawing perpendiculars from the lead lines at points determined by amplitude of QRS. Intersection of perpendiculars determines the mean electrical axis.

Einthoven's hypotheses are correct it is also possible to obtain an indifferent electrode of zero potential from a network connecting the three extremities, and then one may record potentials at any point in the body with an exploring electrode. Wilson demonstrated that the potential (VT) at a central terminal connecting the three extremities through equal resistances is equal to the mean of the potentials at the extremities, and so $VT = (VR + VL + VF)/3 = 0$ in this special situation. Differences between resistances at the three skin-electrode interfaces which would affect VT are minimized by a high input resistance in the circuits of modern electrocardiographic instruments. Although Einthoven's hypotheses are only a first approximation of actual conditions, several studies suggest that changes in VT are so small during the cardiac cycle that they can usually be disregarded for most clinical purposes, and the central terminal is considered to have a constant or "zero" potential. Tracings which record differences in potential between an exploring electrode and the central terminal are called "V" leads and are often described as "unipolar leads" to indicate that they essentially represent changes in potential at the site of the exploring electrode. The exploring electrode in V leads is always attached to the positive pole

of the electrocardiograph so that when a positive charge faces the exploring electrode a positive (upward) deflection is recorded. Since the central terminal is considered to have a zero potential, the lead lines of the V leads extend from the exploring electrode to the center of the cardiac dipole axis, and projections of vector forces on these lines can be analyzed as described previously. Clinical electrocardiograms usually include six V chest leads recorded with the exploring electrode at the positions indicated in figure 16-9. The normal precordial lead V₁ displays a small R wave due to the initial activation of the septum from left to right. The small R is followed by a deep S wave due to activation of the free wall of the left ventricle which produces electrical forces directed to the left and away from this electrode. Leads V₅ and V₆ are more or less the inverse of V₁. They usually show a small Q wave followed by a large R wave. In the intermediate leads progressing from V₂ to V₄, there is increasing R wave amplitude and decreasing S amplitude. Usually at V₃, there is approximately equal R and S amplitude. This is referred to as the transition point. Occasionally the transition point will be as far to the right as the V₂ position or as far to the left as V₄.

Goldberger suggested that the potential at an

FIG 16-9 Positions of the chest electrodes for 6 standard precordial leads. V₁, 4th intercostal space to right of sternum. V₂, 4th intercostal space at left of sternum. V₃, 4th interspace at midclavicular line. V₄, 5th interspace at midclavicular line. V₅, 5th interspace at anterior axillary line, same level as V₄. V₆, mid axillary line, same level as V₄ and V₅. Below are shown general form of QRS in normal precordial leads. V₁ represents transition zone from predominant negativity on the right to predominant positivity on left (Lipman and Massie).

extremity could be obtained simply by disconnecting one extremity electrode from the central terminal and recording the difference in potential between it and the remaining two electrodes. Such tracings have the same configuration and $1\frac{1}{2}$ times the amplitude of a V lead recorded with exploring electrode on the same extremity. The Goldberger arrangement for recording 'augmented' extremity leads (named aVR, and aVL and aVF) is incorporated into the lead selector switch of modern electrocardiographic instruments.

Knowledge about the pathway of activation of the mammalian heart and the geometry of lead lines as developed from the Einthoven hypotheses can be utilized to schematically describe the effects of cardiac activation on the extremity leads. Ventricular activation can be described by a series of instantaneous vectors each of which is the resultant of dipoles representing the polarized surfaces present at that instant. It is usual to consider only three or four such instantaneous resultant vectors (fig. 16-10):

- 1) Initial activation of the septum is represented by a small vector directed to the right and forward.
- 2) Simultaneous activation of the lower septum, free wall of the right ventricle and anterior left ventricle is represented by a resultant vector directed to the left, forward, and downward.
- 3) Continuation of the activation process in the postero-lateral left ventricular wall after its completion in most regions of the right ventricle is next represented by a large vector directed to the left and backward.
- 4) Terminal activation of the postero-basal left ventricle and upper septum is represented by a small vector directed backward and upward.

The interval between these instantaneous vectors is 0.01 to 0.015 seconds in the dog heart and approximately twice as long in the human heart. One can roughly predict the configuration of tracings in various leads by projecting these hypothetical vectors onto the appropriate lead line, or one may derive the instantaneous vectors from the recorded tracings. For example, potentials recorded at the same instant in two standard limb leads are measured and plotted in arbitrary units along the appropriate lead line axes of an equilateral triangle, starting from the center of the line and extending toward the end with the proper polarity. Perpendiculars drawn from either end of the linear plots on two lines will meet at points which define the origin and terminus of the instantaneous mean vector responsible for that particular deflection. Derivation of a series of

instantaneous vectors in this manner is a laborious process and requires special equipment to record two leads simultaneously. A single vector depicting the mean direction of the total electrical forces developed during ventricular activation can be derived by plotting the algebraic sum of positive and negative deflections in QRS complexes from each of two leads on the appropriate lead lines and dropping perpendiculars as described above. The similarity between this derived vector, called the 'mean electrical axis', and the true mean cardiac vector depends on the validity of the Einthoven hypotheses. The electrical axis is described according to a system of polar coordinates with 0° at the right-hand end of a horizontal line, positive values are below and negative values above this line (fig. 16-8). In normal humans the electrical axis commonly falls between 0° and $+90^\circ$ displacement in a

FIG. 16-10 The four major dipole vectors generated during ventricular activation giving rise to the deflections of the QRS complex. By Einthoven's hypothesis these vectors may all be considered as originating from a single point at the center of an equilateral triangle. When the termini of all resultant instantaneous vectors are connected a loop is described. The loop is the vectorcardiogram.

clockwise direction beyond $+90^\circ$ is called right axis deviation, and displacement in a counter clockwise direction beyond 0° is called left axis deviation. The electrical axis is influenced by the position of the heart, changes in the functioning myocardial mass or the pathway of activation and changes in the conducting medium surrounding the heart. A change in the direction of the long axis of the heart produces a shift in electrical axis in the same direction. The electrical axis will shift toward an area of hypertrophied myocardium and away from an area of infarcted myocardium. Since the electrical axis is determined from body surface potentials, it will also be influenced by changes in the conducting medium, such as the introduction of air or fluid into the pleural space. The electrical axis determined from the limb leads represents the projection of spatial vectorial forces onto a frontal plane defined by the Einthoven triangle, an additional lead having a lead line in an anteroposterior direction is required to estimate the spatial orientation of these forces.

The problem of whether the direction of electrical forces originating from a dipole in the heart can be accurately determined from limb lead tracings has been investigated by placing an artificial dipole generator in or near the human heart. The frontal plane projection of the dipole axis was determined with fair accuracy from the limb lead potentials. However, recent studies with a dipole generator in torso models indicate that the eccentric position of the heart in the body significantly distorts its electrical field. For example, when the dipole generator in the torso model is placed in the region of the heart, a relatively smaller electrical potential is recorded at the right shoulder than at the left shoulder or pubic region so the right shoulder must be more "distant" from the heart in an electrical sense than the other apices of the Einthoven triangle. The irregular contour of the body surface and differences in tissue conductivity cause less distortion in the electrical field than does the eccentric location of the heart.

The validity of the assumption that the electrical forces of the heart at any instant can be considered to originate from a single resultant dipole depends on the distance from the heart at which the potentials are recorded. The solid angles subtended at a distant electrode by polarized surfaces in various regions of the heart will not be significantly influenced by the relatively small differences in their distance from the electrode,

and dipoles representing each surface may be considered to originate at a single common point. On the other hand, when the electrode is close to the heart, the solid angle subtended by an adjacent region of myocardium will be much larger than that subtended by any other region of similar area, and dipoles from various regions cannot be considered to originate at a single point. Instantaneous forces of ventricular activation may be described by a resultant dipole vector when they are recorded from an electrode more distant than 2 heart diameters from its surface.

Recent studies suggest that potentials recorded from exploring electrodes on the chest wall also represent to a major degree electrical forces from single instantaneous dipole vectors. When Wilson introduced the use of V chest leads, he pointed out the similarity of the tracings to those recorded with direct epicardial leads. He emphasized the concept of Lewis that the large rapid deflection in a direct epicardial lead (the intrinsic deflection) represented the activation of myocardium directly under the electrode, and suggested by analogy that the major deflection in chest surface leads (the "intrinsicoid" deflection) also represented local activation of myocardium closest to the electrode and could be used to time the arrival of the activation process in that area. However, it appears likely from recent studies that the major deflection in chest leads represents a change in direction of the instantaneous resultant cardiac vector rather than local activation of adjacent myocardium.

Although the process of ventricular activation has been schematically represented by four instantaneous resultant vectors, it is described more adequately by a great number of such instantaneous vectors distributed at short intervals throughout the cardiac cycle. A line joining the termini of all the instantaneous resultant vectors will form a loop representing the sequential change in amplitude and direction of the resultant electrical forces throughout the cardiac cycle. Such a loop can be derived by graphic or electronic integration of potentials from two simultaneously recorded leads. When a loop is obtained by electronic integration on an oscilloscope, it is called a vectorcardiogram. The spatial orientation of the loop can be derived by using three leads with mutually perpendicular lead lines to obtain projections of the loop onto three planes. The hope that most information about the electrical forces of the heart could thus be derived from three mutually perpendicular leads stimulated

several investigators to devise leads that are approximately orthogonal in an electrical sense. The recently proposed orthogonal lead systems employ networks of electrodes and resistances to minimize the distorting influences of cardiac eccentricity and body geometry. It is not feasible to evaluate the relative merits of these newer lead systems at the present time.

THE RECOVERY PROCESS AND THE VENTRICULAR GRADIENT

The recovery process, which is simply a reversal of changes that occur during activation, is characterized by deflections of much longer duration and lower amplitude than the activation process. Atrial recovery produces a prolonged deflection (T_a or T_s wave) which continues through the PR interval and into or beyond the QRS complex, but it is generally of such low amplitude that it is clearly defined only in tracings where P waves are widely separated from the QRS complexes, as in heart block. The T_s is opposite in direction to the P wave in tracings obtained from strips of atrial muscle and also from the intact heart which indicate that the recovery process follows the same sequence as activation since the two processes have opposite electrical signs. Ventricular recovery occurs during inscription of the ST segment and T wave. The ST segment corresponds to the plateau and the T wave corresponds to the rapid final phase of repolarization recorded from single myocardial fibers. The electrocardiogram generally shows little or no deflection from the base line during inscription of the ST segment when large areas of myocardium are undergoing recovery simultaneously. The T wave occurs when recovery is complete in some areas but is continuing in other regions. The T wave recorded from muscle strips is opposite in direction to the QRS, as expected when recovery occurs in the same sequence as activation, but this is not true in direct leads on the surface of the intact ventricle where the T wave is in the same direction as the major deflection of the QRS. This indicates that the sequence for completion of recovery is opposite in direction to the activation process, and therefore occurs later at endocardium than at epicardium.

It has not been possible to map the sequence for completion of the recovery process in different regions of the heart by methods used to study the activation process because there are no rapid 'intrinsic' deflections that can be correlated with change in potential in local areas. However, vec-

tor analysis has been used to study both the instantaneous and mean resultant forces of the recovery process. The instantaneous forces during ventricular recovery produce a loop in the vectorcardiogram which is oriented in the same general direction as the loop inscribed during activation. The relationship between the orientation of the electrical forces during activation and recovery has been expressed in vector terms by Wilson, Ashman and Beyer, and others. These investigators determined the net area enclosed by QRS deflections and that enclosed by ST and T deflections in the limb leads, and used these areas (which represent the product of time and voltage) to plot mean vectors called $\bar{A}$ QRS and $\bar{A}$ T respectively. The resultant of these two vectors is called the ventricular gradient $\bar{G}$. If $\bar{A}$ T was equal in amplitude and opposite in direction to $\bar{A}$ QRS, as expected on a theoretical basis from electrograms of muscle strips, their resultant or ventricular gradient would be zero. The degree to which the actual $\bar{A}$ T deviates from the theoretical one is expressed by the vector $\bar{G}$. The gradient is thus a reflection of the difference between the sequence of activation and recovery. The normal ventricular gradient is explained on the basis of a delay in recovery of the subendocardial region due to local differences in some metabolic or mechanical factors which influence the recovery process. QRS amplitude and duration may change due to a difference in the activation pathway as occurs with a premature ventricular beat or bundle branch block, without affecting the metabolic or mechanical factors which determine the normal ventricular gradient. Changes in amplitude or duration of the QRS are then accompanied by equivalent changes of the T wave in the opposite direction and $\bar{G}$ may remain unchanged. Such T wave changes are called secondary, in contrast to primary T wave changes due to factors which specifically influence the recovery process and are therefore accompanied by changes in the gradient. Primary T wave changes may occur after exercise or eating, with decreases in coronary perfusion due to atherosclerosis or in a variety of other physiological and pathological situations. Calculation of changes in ventricular gradients should theoretically allow one to differentiate between primary and secondary T wave changes, but this has not proven very useful in clinical electrocardiography because of the wide range of normal gradients and the fact that both

physiological and pathological factors can cause either primary or secondary T wave changes

Abnormalities of the Electrocardiogram

LEFT VENTRICULAR HYPERTROPHY

Enlargement of the left ventricle commonly gives rise to four deviations from the normal electrocardiogram not all of which need be present to establish the diagnosis (fig 16 11) These deviations are (1) increased voltage in the leads exploring the left ventricle, (2) increased duration of the QRS complexes, (3) rotation of the mean electrical axis toward the left and posteriorly, and (4) secondary ST and T wave abnormalities over the left ventricular leads

The increased voltage is seen primarily as increased negativity over the right precordial leads V_1 and V_2 , and increased positivity over the left precordial leads, V_5 and V_6 . The reasons for this increased voltage are not entirely clear. It may be that the hypertrophied myocardial cells have a greater charge density or that closer proximity to the chest wall of the enlarged ventricle imparts a higher voltage to the exploring electrode which subtends a larger solid angle. It has been postulated that the increased thickness of the hypertrophied left ventricle permits the activation wave of this area to continue unopposed after completion of activation of the right ventricle. Increased positivity is inscribed in a leftward and posterior direction as the left ventricular free wall completes its prolonged activation.

Sokolow has shown that if the absolute sum of the positivity in V_5 and the negativity in V_1 is 3.5 mv or more there is a strong statistical likelihood of left ventricular hypertrophy. These values, however, may be seen in normal young adults particularly if there is a thin chest wall.

The increased duration of the QRS appears to be due to the longer time necessary for the wave of activation to spread from endocardium to epicardium through the thickened ventricular wall. In many cases of left ventricular hypertrophy, the onset of the intrinsoid deflection is delayed over the left precordial leads beyond 0.05 seconds, and the total duration of QRS may be 0.10 or 0.11 seconds.

Since the thickest portion of the free wall of the left ventricle lying just beneath the atrioventricular groove faces the region of the left shoulder and is the last part of the left ventricle to be depolarized, it is not surprising that hypertrophy of the ventricular wall directs more and more voltage toward the left posterior shoulder region.

In the limb leads, the mean electrical axis lies in the 0 to -90° quadrant (left axis deviation). The posterior displacement is seen in the horizontal plane vectorcardiogram, and it may be apparent in the precordial leads by a shift of the transition zone to the left.

When left ventricular hypertrophy becomes severe, the QRS changes are usually accompanied by ST and T wave abnormalities which may vary from flattening of the T waves in the left precordial leads to depression of the ST segment with downward slanting of ST and deep T wave inversion in these leads.

The exact mechanism by which these ST-T changes are produced is not understood. Some believe that they are secondary to the increased area of the QRS. Others believe that they may be primary changes perhaps due to relative ischemia of the subendocardial layers of the hypertrophied ventricular wall.

RIGHT VENTRICULAR HYPERTROPHY

The right ventricle is thin walled and lies in an almost direct anterior anatomical position. Normally the voltages generated by this ventricle are greatly overbalanced by the voltages coming from the much greater mass of the left ventricle. The right ventricle may undergo a great deal of hypertrophy before its muscle mass begins to approach the mass of the left ventricle. In the lesser stages of hypertrophy of the right ventricle, the electrocardiographic changes are the result of rotation of the heart on its long axis in a clockwise direction when viewed from the apex. The enlarging right ventricle restricted anteriorly by the sternum pushes the left ventricle around toward the left and downward toward the diaphragm. The electrical forces are still dominated by left ventricular voltages which may be somewhat smaller than normal since they are opposed by larger right ventricular voltages. The net effect is to direct the major left ventricular voltages posteriorly and inferiorly toward the foot producing a vertical electrical axis in the frontal plane as visualized in the limb leads. In the precordial leads there is a delay in transition with an S wave persisting through V_4 and perhaps V_5 . These changes are due primarily to rotation of the heart by the enlarging right ventricle. They are likely to be seen in chronic cor pulmonale due to pulmonary disease and in mitral valvular disease.

In severe pulmonary valvular stenosis, in severe pulmonary hypertension, and in advanced stages of mitral valve disease there may be sufficient

RIGHT VENTRICULAR HYPERTROPHY

LEFT VENTRICULAR HYPERTROPHY

FIG 16 11 Electrocardiogram patterns of right and left ventricular hypertrophy

right ventricular hypertrophy to exceed the muscle mass of the left ventricle. In this situation the major voltages are generated in the right ventricle, and the major electrical forces are directed anteriorly and to the right.

In the frontal plane, the limb leads show right axis deviation with a mean electrical axis usually greater than $+105^\circ$. The precordial leads show predominant positivity in V_1 with R usually far exceeding S in amplitude. The transition toward the left discloses a progressively diminishing R wave and an increasing S wave. This is opposite to the normal QRS precordial transition.

ST and T wave changes similar to those seen in left ventricular hypertrophy may be seen in right ventricular hypertrophy. These changes will be seen in those leads showing maximal positivity, that is, in V_1 and V_2 and in II, III, and in AVF. Their pathogenesis is just as uncertain in right ventricular hypertrophy as it is in left ventricular hypertrophy.

RIGHT BUNDLE BRANCH BLOCK

Although Lewis and his associates carried out experiments in which one or the other of the major conducting bundles was interrupted and changes in the electrocardiogram were observed, it was the work of Wilson and his associates that firmly established the nature of bundle branch block. The concepts described here stem from their beautiful and precise experiments.

Recalling the normal sequence of activation of the heart it will be remembered that the right side of the septum becomes depolarized very soon after the left side and that the free wall of the right ventricle is depolarized simultaneously with the free wall of the left ventricle and that the greater thickness of the left ventricle produces voltages far in excess of those produced by the right ventricle. Thus, the only rightward directed voltages seen on the normal electrocardiogram are those generated initially in the septum and in some instances a small late voltage from a late activation of the pulmonary conus.

When the right conducting bundle is blocked either by cutting it experimentally or by some pathological process, the activation of the right ventricular free wall is greatly delayed (fig. 16-12). The first portion of the QRS complex up to about 0.04 seconds precedes normally as it records the activation of the left ventricle. When the left ventricle has become completely depolarized, there still remains a considerable portion of the right ventricular free wall which has not been depolarized. Since the impulse cannot be trans-

mitted almost simultaneously to all parts of the right ventricular endocardium through the blocked Purkinje fibers the wave of activation must be slowly transmitted directly through the muscle in a tangential direction rather than in the normal direction of endocardium to epicardium. This slow late right ventricular activation wave, now unopposed by left ventricular forces and not having the high proportion of internal cancellation voltages characteristic of normal transmission, produces a large voltage directed anteriorly and to the right which appears late and prolongs the QRS to a duration of 0.12 seconds or more.

This late right ventricular voltage is inscribed in the electrocardiogram as a late slurred R wave in V_1 and aVR and a late slurred S wave in V_6 , V_5 and aVL.

LEFT BUNDLE BRANCH BLOCK

Interruption of the left conducting bundle causes delay in activation of the left ventricle. The first portion of the heart to be activated is now the right side of the septum by way of the right bundle branch. The septum is thus activated from right to left producing a large voltage directed leftward. This large leftward voltage is opposed to a small degree by a rightward voltage from the almost simultaneous activation of the free wall of the right ventricle, but because of the greater muscle mass of the septum the net initial voltage is directed toward the left. The effect on the electrocardiogram is to produce initial positivity in leads I, V_5 and V_6 . The normal septal Q wave is thus abolished in these leads.

The wave of activation is transmitted through the septum to the free wall of the left ventricle through which it passes slowly in a tangential direction from apex to base. It is probable that there is also some transmission from the anterior and posterior septum circumferentially so as to envelope the free wall in the activation wave. The slow activation of the left ventricle continues to produce leftward directed voltages which are inscribed in the electrocardiogram as broad notched or slurred R waves in the left precordial leads V_5 and V_6 . Duration of these complexes is 0.12 seconds or greater. In general the ST and T waves are opposite in direction to the QRS complexes. If the concept of the ventricular gradient is a valid one this divergence of the direction of QRS and T would be considered to be secondary to the increased area of the QRS. The large increase in the magnitude of the QRS vector would necessitate a reversal of the direction

FIG. 16.12. Patterns of right and left bundle branch block

of the T vector in order to preserve the magnitude and direction of the ventricular gradient. Whether or not the ventricular gradient is adequate to explain the ST and T abnormalities of

left bundle branch block, one would expect to see abnormalities in the repolarization waves simply because the pathway of depolarization is so drastically altered from normal in this condition.

MYOCARDIAL ISCHEMIA, INJURY AND NECROSIS

In animal experiments epicardial leads applied directly to the surface of the heart have been used to study the electrocardiographic changes associated with impairment of the coronary blood flow (fig 16 13). When a coronary artery is gradually compressed, the first change seen in tracings from the area of myocardium supplied by that vessel is a deep and symmetrical inversion of the T wave. This symmetrical form of T wave inversion is referred to as T wave inversion of the ischemic type. It is believed to be due to delay in recovery at the epicardial region so that there is reversal of the normal order of repolarization.

The ischemic T wave inversion is rapidly reversible if adequate circulation is restored to the myocardium. When the blood supply to the myocardium is more drastically impaired by sudden ligation of a coronary artery, the direct epicardial tracing shows the rapid onset of elevation of the ST segment. This elevation may be almost as high as the QRS complex and may yield a wave form closely resembling the transmembrane action potential obtained with micropuncture of a single myocardial fiber. The ST elevation is believed to be due to a strong current of injury directed away from the electrode and causing

marked depression below the zero line of the point of origin of the QRS complex. This ST displacement may be accompanied by ischemic changes in the T waves. This injury pattern is also rapidly reversible upon restoration of adequate blood flow.

When a coronary artery is permanently ligated, a portion of the myocardium becomes infarcted. The presence of electrically inert necrotic myocardium results in alterations of the QRS complexes of the direct epicardial lead. If the infarction is completely transmural from epicardium to endocardium this mass of tissue contributes no potential of its own, but simply conducts to the surface the potentials which are to be found in the underlying cavity. The depolarization wave in this case is a purely negative QS complex identical to that found in the left ventricular cavity. The repolarization phases contain elements of injury and ischemia patterns derived from adjacent viable portions of the myocardium.

Exploration of the adjacent areas of myocardium about a zone of necrosis discloses a zone of injury surrounding the necrotic areas (fig 16 13). Complexes recorded from the injury zone are characterized by marked elevation of the ST segment without significant change in the morphology of the early portion of the QRS. The

FIG 16 13 Schematic diagram of direct epicardial leads taken over an area of myocardial infarction and over adjacent zones of injury and ischemia. Also shown is a chest lead facing the infarct and a lead from the opposite side of the heart. At C cavity negativity is reflected in the epicardial lead over the necrotic zone. At A is recorded a monophasic injury wave over the injured zone. At B the complex reflects a combination of necrosis and injury. At D there is only T wave inversion of the ischemic type over the ischemic zone. At E_a over the chest the complex combines features of all three zones and on the opposite side of the heart there are reciprocal changes of increased positivity of the R wave and depression of ST. (From Barker)

injury zone is surrounded by a zone in which the T waves show inversion of the ischemic type. This is called the ischemic zone. Beyond it lies normal muscle disclosing normal QRS T complexes.

Electrocardiograms made from the surface of the body include potentials from the entire heart, and therefore, the precise localization of zones of necrosis, injury, and ischemia cannot be derived from the clinical electrocardiogram. When infarction is present, all of the phenomena observed in the three zones will be reflected in the appropriate electrocardiographic lead. Even a precordial lead which may be taken very closely adjacent to a large area of infarction is influenced by electrical events in other parts of the heart and is likely to disclose elements derived from all three of the zones of necrosis, injury, and ischemia.

Thus the classical pattern of myocardial infarction consists of a deep wide Q wave, ST segment elevation, and T wave inversion. Muscle necrosis cannot be identified with certainty from the electrocardiogram without the appearance of a pathological Q wave which indicates a removal of electrically active myocardium. ST and T wave changes of injury and ischemia may occur when myocardium becomes temporarily or even chronically hypoxic but not sufficiently so to produce muscle death. On the other hand, there may be myocardial necrosis in areas completely surrounded by viable tissue or in subendocardial zones such that the general pathway of activation might not be markedly altered. In such intramural or subendocardial infarctions abnormal Q waves may not appear even though injury and ischemic ST and T changes may be present. In such cases the presence of muscle necrosis cannot be proven by the electrocardiogram. Evidence of its presence might, however, be obtained by other clinical means.

LOCALIZATION OF INFARCTION ON INJURY

The general anatomical localization of areas of cardiac infarction may readily be made by the standard nine or twelve lead electrocardiogram. Each lead constitutes, so to speak, an electrical view of the heart from a different point in space (fig. 16-14). In accord with both solid angle and dipole analyses, positive electrodes record maximum positivity when the wave front of ventricular activation is advancing directly toward the electrode. Thus, the early positivity in V_1 derives from the left to right activation wave across the septum. V_1 and V_2 derive their positive deflections mainly from the anterior left

ventricle near the septum. V_4 positivity derives mainly from the anterior free wall of the left ventricle, and V_4 and V_6 positivity originates mainly from the activation of the lateral left ventricular free wall. Lead aVF and lead III receive their positive potentials from the postero-diaphragmatic wall of the left ventricle and aVL its positivity from the high lateral left ventricular wall. In general then, a positive electrode receives its maximal positive forces from the area of myocardium toward which it faces.

Infarction of myocardium abolishes positive forces, and this loss of positivity is reflected maximally in those leads which face the infarcted area. Loss of positive forces advancing toward the electrode leaves unopposed forces moving away from the electrode. The result is the appearance of Q waves in leads facing the infarcted areas of myocardium. ST and T wave changes of injury and ischemia derived from adjacent viable tissue are also reflected in these leads but may be considerably more widespread into leads which do not demonstrate alterations in the QRS.

The appearance then of the infarction pattern in leads V_1 , V_2 and V_3 indicates anteroseptal infarction; in V_3 and V_4 anterior infarction; in V_4 and V_6 lateral infarction; in aVF and III posterior or diaphragmatic infarction; in aVL high lateral infarction. Depending upon the size and extent of the infarct there may be various combinations of these such as posterolateral when the changes are in aVF and V_6 or anterolateral when the changes are in V_1 , V_4 and V_6 . Sometimes the appearance of right bundle branch block associated with the anteroseptal infarction pattern gives evidence of extensive involvement of the septum.

Left bundle branch block in most instances completely obscures the pattern of myocardial infarction because of the gross alteration of the pathway of activation, particularly because the reversal of the direction of depolarization of the septum produces initial positivity in the left ventricular cavity and thus prevents the appearance of Q waves over an area of infarction of the left ventricular free wall. Only when there is extensive destruction of the lower septum and apical portions of the left ventricle does a Q wave appear in the left precordial leads in the presence of left bundle branch block.

LOCATION OF MYOCARDIAL INJURY

Well known clinical conditions illustrate the electrocardiographic effects of temporary injury to subepicardial and subendocardial heart muscle.

FIG 16-14 Patterns of acute anterior and posterior myocardial infarcts

When subepicardial myocardium is injured whether by disease such as pericarditis or by the intentional instillation of irritating substances into the pericardial sac elevation of ST segments appears in all leads except those which explore primarily the heart cavities (aVR and V₁). In other words leads taken from electrodes facing the injured surface display positive ST segment displacement. On the other hand when there is subendocardial injury such as may occur in coro-

nary insufficiency during an attack of angina pectoris there is ST segment depression in many of the leads exploring the free wall of the left ventricle. In this case injury to the side of the myocardial wall facing away from the electrode produces negative ST segment displacement. The principle is borne out by the observation that a localized infarct on one side of the heart leading to elevation of ST segments in leads from that side will produce ST depression in leads

recorded from the opposite side of the heart. In acute posterior infarction with Q waves and ST elevation in leads III and aVF there will often be found ST depression in leads V_2 and V_3 . The ST depressions in the anterior leads are said to be reciprocal to the elevations in the posterior leads.

DRUGS AND ELECTROLYTES

Digitalis produces a characteristic alteration of the ST and T complex which might sometimes be mistaken for an injury effect (fig. 16-15). The change consists of a shortening of the QT interval and a sagging of the ST segment. The sagging ST has a 'scooped-out' or 'cuplike' concavity that is easily recognized. This electrocardiographic sign of digitalis effect is not related to the adequacy of the dose of the medication nor to drug intoxication.

Quinidine and procaine amide have similar effects on the electrocardiogram. The earliest sign is prolongation of the QT interval with apparent stretching out of the entire ST-T complex. Later on as the dose is increased slowing of conduction through the ventricle is produced with resulting widening of the QRS complex. Normal complexes of 0.06 to 0.08 second duration may be prolonged to 0.12 to 0.14 second by increasing quinidine or procaine amide doses. Upon finding such prolongation most clinicians would elect to stop the drug or reduce its dose for fear of stopping all conduction and precipitating ventricular standstill.

Among electrolyte ions calcium and potassium appear to be the most significant in their effects on the ECG. Hypocalcemia leads to prolongation of the QT interval which is rather strikingly different from that found in quinidine effect. With low serum calcium the ST segment itself becomes long but it remains flat and is followed by a normal appearing T wave of normal duration. Micropuncture studies of transmembrane action potentials have shown that the long ST segment is due to prolongation of the plateau phase of the recovery process. The later phases continue at their usual rates.

Elevation of the serum calcium has the opposite effect of shortening the ST segment by shortening the plateau phase of the monophasic action potential. The T wave itself appears undisturbed.

Reduction of serum potassium appears to have two effects: one on the ST-T complex and one on the U wave. When the potassium level in the serum falls to about 3 mEq per liter, the ST begins to sag and the T wave becomes lower as

the U wave becomes more prominent. The T and U seem to merge into a single wave separated only by a slight indentation or dipple on the crest. This gives the impression of markedly prolonged QT which is really not the case. With very low levels of potassium the ST segment becomes depressed below the base line and the U wave exceeds the T in height. This gives the appearance of a stepwise ascent of the ST-T complex. This pattern is usually seen with serum potassium of 2 mEq per liter or less.

Elevation of serum potassium leads first to an increasing amplitude of the T wave in leads where the T is normally upright. The increasingly tall T waves have a tentlike appearance with similar slopes on the upward and downward limbs. With higher levels of serum K (8 mEq per liter approximately) the PR interval becomes prolonged and the QRS begins to widen out as conduction becomes impaired. At about 9 mEq per liter, the P wave disappears entirely and the QRS takes on a bizarre shape merging with the tall T wave to produce a distorted sine wave-like

DISORDERS OF THE HEART BEAT AND THEIR INVESTIGATION BY GRAPHIC METHODS

The following is a convenient classification of cardiac irregularities

- A *Affections of rhythm due to impaired conduction through the A V bundle*
 - I Stem of bundle
 - (1) Delayed conduction
 - (2) Missed beats, partial heart block
 - (3) Complete heart block
- B *Wolff Parkinson White syndrome*
- C *Affections due to abnormal impulse formation*
 - I Extrasystoles
 - (1) Ventricular
 - (2) Nodal
 - (3) Auricular
 - II Paroxysmal tachycardia
 - Auricular, nodal and ventricular
 - III Auricular flutter
 - IV Auricular fibrillation
 - V Ventricular fibrillation
- D *Alternation of the heart*
- E *Affections due to vagal influences*
 - I Sinus arrhythmia
 - II Phasic irregularity
 - III Sinus bradycardia
 - IV Sino auricular block
 - V Auriculoventricular block

A Affections of Rhythm Resulting from Impaired Conduction

I IN THE A V NODE OR STEM OF THE BUNDLE AURICULOVENTRICULAR BLOCK

In animals, conduction from auricle to ventricle can be depressed or blocked by crushing, cutting, or the application of cold to the A V bundle. This strategic point in the pathway of the excitation wave is also attacked by disease, and conduction through it may be depressed or completely abolished. Depression of conduction through the node or bundle varies in degree. Three stages are recognized

(1) Delayed Conduction

In this stage conduction is merely slowed; every impulse reaches the ventricle. The intervals between the auricular and ventricular systoles (A, V, intervals) are lengthened and may have a duration of 0.5 second, though, as a rule, they are considerably shorter than this. The condition can be recognized only by means of the electrocardiograph or a venous pulse tracing. Lengthening of the P R interval in the former tracing, or of the a-c interval in the latter, beyond the normal maximum of 0.2 second is taken to indicate delayed conduction (fig. 17.1).

(2) Missed Beats—Partial Heart Block

When impaired conduction reaches a certain degree, impulses from time to time fail to reach the ventricle and a beat is missed. The auricular beats are perfectly regular, and in this way the condition differs from sino-auricular block (p. 204). A ventricular beat may be missed only occasionally and at irregular intervals. The P R interval of the electrocardiogram, or the a-c interval of the venous pulse, may generally, though not invariably, be seen to lengthen progressively for several heart cycles preceding the dropped beat. The periods of delayed conduction preceding the missed beat are called, after their discoverer, the *Wenckebach periods*. The interval of the cycle succeeding the missed beat is shortened again to near the normal length. In a further stage of the condition the beats are dropped more frequently and may be spaced at either regular or irregular intervals in the tracing. When the grade of block is still more advanced, impulses fail to penetrate the bundle after every second auricular beat, or three, or even four auricular contractions may occur before an impulse reaches the ventricle, i.e., the ventricle responds only to every third or fourth auricular beat. So, an auriculoventricular rhythm becomes established in

FIG 171 Upper tracing, delayed conduction, lead I. Lower tracing, incomplete heart block, lead I (missed beats). (Kindness of Dr John Hepburn.) The diagram below (after Lewis) represents incomplete heart block. The thin rectangles A represent contractions of the auricle; the thicker ones V, contractions of the ventricle. The obliquely directed lines represent conduction over the A-V bundle; the slower the conduction rate, the more oblique the line. The gaps in the lower rectangles indicate missed beats of the ventricle. It will be noted that delay in conduction increases progressively in successive cycles until a beat is missed. Heavy vertical lines = $\frac{1}{5}$ sec.

which the two chambers beat in the ratio of 2:1, 3:1, or 4:1. The first of these is seen most frequently, the second is the least common (fig 171).

(3) Complete Heart Block

When the A-V node or bundle offers an absolute barrier to the passage of the impulse, the dissociation of the rhythms of the two ventricles is complete (fig 172). The auricles beat at their own rate of about 70 per minute and the ventricle at its inherent rate of about 35. The latter is then spoken of as the idioventricular rhythm. Both ventricles beat simultaneously. This fact suggests that when the ventricle assumes this rate it is under the control of some single region possessing the power of rhythmical activity. From

experimental investigation it appears that the controlling center is the A-V bundle below the site of the lesion. The speed with which a particular region of the heart can develop and discharge impulses apparently determines its ability to dominate other regions. It has been mentioned that when a region of higher rhythmicity is destroyed or isolated, the region next in order of rhythmical power assumes the role of pacemaker (ch. 14). When for instance the S-A node is destroyed or isolated, the A-V node assumes control, and when this or the upper part of the bundle is separated from the tract of tissue below, the lower lying portion takes over the government of the ventricular rate.

Partial and complete heart block are accompanied by changes in the rhythm of the arterial

FIG 172 Complete heart block, lead I (kindness of Dr John Hepburn)

pulse. When beats are missed occasionally the pulse intermits either at regular or irregular intervals. In the more fully developed conditions marked slowing (bradycardia) of the pulse occurs. Visible pulsations in the veins at the root of the neck may occur, for the auricle, in contracting upon a larger volume of blood accumulated as a result of the infrequency of the ventricular contractions, causes a pronounced wave to be transmitted along the jugular. A certain proportion of the venous pulsations may be seen to be associated with an arterial pulse. Sometimes a sound may be heard over the heart at the time of the isolated venous pulsation since the auricular contraction is unusually forceful and the sound vibrations thus set up are not smothered by the first heart sound which, in the normally beating heart, follows so closely upon auricular systole.

The venous pulse tracing and electrocardiogram show characteristic features. The *a* and *P* waves of the respective records occur at the usual times, but the ventricular complex (*c* and *v* in the venous curve and *QRS* and *T* in the electrocardiogram) is absent, a gap appearing in the tracing each time a beat of the ventricle is missed. In incomplete heart block, as one would expect, a relationship between a ventricular complex and a preceding auricular wave can always be made out, whereas in complete block there is no relationship. In the venous pulse, for example, the *a* and *c* waves may occur simultaneously, and produce a large *a + c* wave. Or the *a* and *v* waves may coincide. Corresponding effects are produced upon the electrocardiogram.

Temporary heart block may result from various toxic agents, e.g., digitalis, strophanthus, quinine, etc., which exert a specific effect to depress auriculoventricular conduction. Heart block may be a sequel or an accompaniment of several acute infectious maladies, e.g., diphtheria, rheumatic fever, etc. It is produced in animals by asphyxia. Increased vagal tone is sometimes responsible for delayed conduction over the A-V bundle. Partial heart block is not uncommonly seen in the course of rheumatic fever and is then, in many instances, of vagal origin, being temporarily abolished by atropine. Persistent heart block due to increased vagal tone and abolished by atropine occasionally occurs. Some cases are congenital.

Stokes-Adams syndrome. This condition was first described by Adams (1827) and later by Stokes (1842). Its features are a slow pulse and syncopal attacks or convulsive seizures usually epileptiform in character. The term includes any condition of vascular origin in which these features are associated, and it is probable that the underlying morbid state upon which the syndrome depends is not identical in all instances (see also carotid sinus, ch 21). In the majority, however, the slowed

cardiac action is the result of the heart block, and the cerebral symptoms result from temporary periods of cardiac standstill or ventricular fibrillation. Occasionally seizures may result from sudden slowing of the pulse such as that which occurs when the heart rhythm shifts back and forth between normal rhythm and complete heart block. Such episodes have been documented repeatedly in human electrocardiograms. In recent years Zoll has been able to treat a number of such patients successfully by use of an external electric artificial pacemaker. Recently tiny transistorized pacemakers have been developed for long term treatment of Stokes-Adams syndrome. These require that a small wire electrode be sutured directly to the myocardium. Isoproterenol has proven to be the most potent pharmacological agent for treatment of this condition.

B. Wolff-Parkinson-White (WPW) Syndrome

In this rare congenital anomaly the P-R interval of the electrocardiogram is shortened and the QRS complex prolonged. The P-R interval is 0.12 second or less and the QRS complex extended to over 0.10 sec. The shortened P-R interval may be due, in some cases, to an accessory conducting strand between auricle and ventricle. Butterworth and Poindexter fashioned an extra electrical conduction pathway in the dog's heart, which, when stimulated, produced an electrocardiogram similar to that characteristic of the syndrome. Wood and Wolferth, in the histological examination of the heart of a patient which had shown this syndrome, also found three accessory pathways from the right auricle to the ventricle.

On the other hand, cases of the WPW syndrome occur in which no anatomical anomaly in the conducting system can be demonstrated, and even when such exists there is no conclusive evidence that it is the cause of the accelerated auriculoventricular conduction. Prinzmetal and his colleagues have produced typical WPW complexes in dogs by applying a noninterrupted direct current of subthreshold strength to the A-V node, but such complexes could not be induced after severance of the A-V bundle—an indication that the impulses traverse the normal A-V connections. These investigators carried out a large number of similar experiments in which the movements of the heart were recorded by high speed cinematography, and the records analyzed after slowing down to half speed. They conclude from their observations that the accelerated conduction of the WPW syndrome is due to shortening of the delay of the impulse at the A-V node to a

fraction of the normal which amounts to about 0.12 seconds

These experiments have thrown considerable doubt upon the anatomical explanation of the WPW syndrome. Prinzmetal and his colleagues consider it to have a physiological rather than an anatomical basis.

The prolongation of the QRS complex is attributed to early activation of a portion of myocardium followed by normal activation of the remaining muscle.

C Disturbances of Rhythm Due to Abnormal Impulse Formation

I EXTRASYSTOLES OR PREMATURE CONTRACTIONS

An extrasystole can be induced experimentally by stimulating the cardiac muscle at any time except during its phase of absolute refractoriness.

FIG 173 (After Lewis) I A diagram illustrating disturbance of the heart's mechanism when a systole is caused by exciting the ventricle during diastole. Ic initial cycle, Fe forced or extrasystolic cycle, Rc returning cycle and Rsc restored cycle. p is the premature or forced beat. Note that the auricular rhythm remains undisturbed. The forced and returning cycles are together equal in length to two initial cycles. II A diagram illustrating the event when a premature contraction is excited from the pacemaker. Stimulus production in the tissue which originates the heart rhythm is indicated by the line S-P. The impulse is supposed to discharge when it reaches the line x-x' and to fall at each contraction of the heart to the level y-y'. c and d are equal in length. III A diagram illustrating a premature beat arising in the A-V node.

FIG 174 Ventricular extrasystoles (bigeminal pulse p 196) arising in right ventricle-left axis deviation (ch 16) (kindness of Dr John Hepburn)

Extrasystoles occur in the human heart as a result of some abnormal process of impulse formation. Though extrasystoles may be associated with organic heart disease they more frequently occur in its absence. They may then be of reflex origin initiated from the abdominal viscera or be due to some form of intoxication e.g. digitalis, chloroform anesthesia, hyperthyroidism, excessive smoking, etc. Beattie, Brown, and Long produced extrasystoles in cats by stimulation of the hypothalamus (ch 66) and their occurrence in man following brain lesions has been reported by Lucke and by Korth, which indicates that in some instances they are of central origin. The auricle or the ventricle may be the site of origin of the premature contraction or the extra impulse may arise in the A-V node (see diagram fig 173).

(1) Ventricular Extrasystoles

The premature contraction occurs after the normal ventricular beat has ceased and the muscle has recovered from its absolute refractory state. It is not preceded by an auricular contraction and is not dependent upon an impulse received from the upper chamber (fig 174). The premature contraction is followed by a long pause. This is usually of just sufficient duration to cause the succeeding normal ventricular beat to occur at the instant that it would have occurred had there been no premature contraction. The cause of this compensatory pause has been explained elsewhere (p 145). Briefly, it is due to the normal impulse reaching the ventricle when the muscle is still refractory as a result of the premature beat. The interval between the normal beat and the one following the premature contraction is therefore equal in length to two normal cardiac cycles (fig 173 I). Sometimes, however, when the extrasystole occurs early in diastole and the heart rate is slow, there may be no compensatory pause. The auricular impulse then reaches the ventricular muscle after it has recovered

ered from the refractory state resulting from the premature beat, the auricular impulse therefore brings about a response at, or (as a result of some lengthening of the As Vs interval following the premature beat) slightly after the usual time. The normal ventricular systoles are then all equally or nearly equally spaced and the extra contractions are interposed here and there between them. That is, the time interval from the normal beat preceding the extra contraction to that following it is of normal length or but slightly lengthened. Premature beats of this nature are called *interpolated extrasystoles*.¹

(2) Auricular Extrasystoles

The premature contraction arises in the auricle at some point outside the S A node. The abnormal impulse reaches the ventricle along the usual paths and evokes a ventricular contraction, unless the auricular beat is so premature that sufficient time has not elapsed to permit the recovery of the ventricular muscle from its refractory state. The latter, except for its time relations, is approximately normal. An auricular extrasystole, therefore, causes a premature contraction of the whole heart. The premature auricular beat prevents the occurrence of the next normal auricular impulse and the pause of the auricle which follows the abnormal auricular contraction is usually precisely equal to a normal interval. This fact has been explained upon the assumption that, normally, impulse formation in the S A node is the result of the liberation of energy which has been built up during the previous quiescent period. Upon the occurrence of the abnormal impulse this store of energy, accumulated for the normal impulse, is discharged and a definite time interval must elapse before it is again built up to the required level (see fig. 17-3, II). Sometimes, however, the interval following the premature contraction is slightly lengthened, suggesting that the rate at which the S A node builds up its store of energy is lowered. In any event, there is rarely a long (compensatory) pause following the beat of the ventricle, the interval between the two normal beats, i.e., from the beat preceding to the one succeeding the premature contraction, being nearly always shorter than two normal cycles. In other words, the normal auricular impulse following the premature auricular contraction

upon reaching the ventricle does not "miss fire", as in the case of ventricular extrasystole, but calls forth a response from the ventricle.

(3) Nodal Extrasystoles

Extrasystoles occur sometimes as a result of impulse formation in the A V node or supraventricular part (stem) of the bundle. On account of its central position between the two chambers, impulses arising in the A-V node pass upward and downward to cause simultaneous or nearly simultaneous responses from auricle and ventricle. Sometimes the ventricular contraction may actually occur first, in which case it is suggested that the impulse has arisen in the stem of the bundle and so has its course to the ventricular muscle considerably shortened. The extra cycle is usually, though not invariably, followed by a compensatory pause (fig. 17-3, III).

In rare instances extrasystoles arise as a result of abnormal impulses initiated in the sino auricular node—*sinus extrasystoles*. Except for the interposition of the extra beat the rhythm of auricles and ventricles is but little disturbed. The interval following the extra beat is normal in length or slightly shortened.

The Effects of Extrasystoles upon the Characters of the Electrocardiogram and of the Arterial Pulse

THE ELECTROCARDIOGRAM In ventricular extrasystoles the electrocardiogram shows irregularity in the spacing of the ventricular complexes. The following characteristics are found:

(1) The intervals between the R wave caused by the premature beat and the corresponding waves of the normal beats preceding and following it, respectively, are altered in length. The interval between the last normal R wave and the premature R wave is short, while the interval following this to the next normal R wave is prolonged—compensatory pause. The time elapsing between the two normal R waves is usually equal to the length of two normal cycles.

(2) The premature R wave is not preceded by a P wave. Since the premature ventricular contraction occurs unrelated to auricular systole it frequently happens that a normal contraction of the auricle occurs about the same time as the ventricular extrasystole. P and R waves then become fused. At other times the P wave follows closely upon the premature R wave.

(3) The P waves are equally spaced and some appear which are not succeeded by a ventricular

¹ It should be noted that except in the case of interpolated beats there is not an extra or additional beat, as the term extrasystole seems to imply. The premature beat, in effect, displaces the normal beat.

complex (refractory period of the ventricular muscle) In the case of the *interpolated* type of extrasystole, however, each P wave is followed by an R wave, and no long pause is seen

(4) Ventricular extrasystoles also show abnormalities of the QRS complex which distinguish them from premature contractions of auricular or nodal origin An impulse arising in the heart below the point where the bundle forks will activate one ventricle slightly in advance of the other It is to be expected then that the QRS deflections of the electrocardiogram will be a record of unbalanced electrical effects This is actually the case (fig 17 4) In other words, if the extrasystole arises in the left ventricle its record will be deformed much in the same manner as that already described (p 184) for right bundle branch block If the premature beat arises in the right ventricle the electrocardiogram will show the features of a left branch defect

In *auricular extrasystoles* the electrocardiogram shows disturbances in the timing of both the auricular and the ventricular complexes, but, as already mentioned (p 193), a normal or only a slightly lengthened pause follows the extra beat The P waves are unequally spaced but each is followed by a ventricular complex The abnormal auricular wave may coincide with and be buried in the QRS complex of the preceding normal cycle

The records of *extrasystoles arising in the A V node* or *supraventricular part of the bundle* are variable according to the timing of the auricular and ventricular contractions When the auricles and ventricles are excited simultaneously, the P and R waves become fused When the two chambers are not activated simultaneously, the P precedes the R wave by a short interval, or the order of the waves may be reversed (R P interval)

THE ARTERIAL PULSE It has been demonstrated that several long recognized irregularities of the pulse are the result of extrasystoles For example, in the irregularity known as *intermittent*

pulse there appear from time to time relatively long intervals during which no beat is felt in the radial (fig 17 5a) The intervals are most pronounced when a premature contraction of the ventricle which is too weak to open the semilunar valves occurs This most commonly happens when the heart muscle receives the abnormal impulse during the earlier part of its relative refractory phase The premature beat may be detected by hearing a faint first heart sound which is not succeeded by a second sound (p 248) No pulse is produced in the radial at the time, nevertheless the extrasystole may be followed by a compensatory pause, and graphic records show as a rule that the gap in the radial tracing is just equal to two normal cycles That is, a beat is dropped completely from the arterial record The detection of an extra contraction of the ventricle, however, enables the irregularity to be distinguished from the missed beats of partial heart block (p 191) which may give an arterial tracing with similar characters

If ventricular extrasystoles which fail to open the semilunar valves are repeated after each normal beat, the long intervals separating the latter will cause pronounced slowing of the pulse rate The pauses between the arterial pulses are doubled in length and the pulse frequency as a consequence is reduced to half the normal Bradycardia produced in this way and sometimes termed *false heart block* is distinguished from true heart block by a study of the venous pulse or the electrocardiogram which reveals the extra ventricular complexes or the faint sounds of the extra contractions may be heard upon auscultation

When the extrasystoles are forceful enough to open the semilunar valves and occur regularly one after each normal systole, paired pulse beats each couple being followed by a long pause, are felt in the radial (fig 17 5b) This type of pulse irregularity, which is sometimes seen following overdosage with digitalis, is called the *bigeminal pulse* (*pulsus bigeminus*)

II PAROXYSMAL TACHYCARDIA

This may be defined as a condition in which the rate of the heart is greatly accelerated for a longer or shorter period without obvious cause The rate varies in different cases from 140 to 250 per minute The onset of the paroxysm is sudden and the increased rate is maintained for a variable length of time with perfect regularity, successive cycles usually not varying in length by more than a hundredth of a second The paroxysm lasts for only a few beats in some instances, in others it

FIG 17 5 (After Price) a intermission of the pulse, b pulsus bigeminus due to a single extrasystole with its succeeding compensatory pause occurring regularly after each normal beat *Ex S*, extrasystole

persists for a few minutes, hours or even days, though attacks of more than ten days' duration are very rare (Lewis) The attack ceases as abruptly as it commenced, the heart resuming its normal rate almost instantly

The paroxysm, it is believed, consists of a series of rapidly recurring extrasystoles which completely submerge the physiological rhythm The site of origin of the extrasystoles as in the case of single premature beats, may be in the auricle, the 1 V node or stem of the bundle, or in the ventricle (fig 17 6) The auricular type is the most common, each auricular impulse spreads to the ventricle and causes a contraction whose features as indicated by the electrocardiogram are normal The P wave is frequently inverted

When the impulses arise in the A V node or supraventricular part of the bundle, the P R intervals of the electrocardiogram are shortened Inversion of the P waves is common Or, the contractions of the two chambers may be simultaneous, the P waves being then buried in the ventricular (QRS) complexes Again, the contraction of the ventricle may occur before that of the auricle, it then sometimes happens that a progressive lengthening of the intervals between the R and P waves (R P interval) of the electrocardiogram is seen, ultimately an auricular beat is missed This is termed *reversed heart block* In other instances, as the R P intervals reach a certain length, a contraction of the ventricle occurs prematurely, and is not followed by a contraction of the auricle It is thought that the ventricular contraction is caused by the same impulse that caused the preceding auricular beat That is, the impulse arising in the node first excites the auricle, then re enters the junctional tissue, which has now recovered from its refractory phase, and passes downwards to the ventricle This is spoken of as *reciprocal rhythm*

When the impulses arise in the ventricle the QRS complexes have the characteristics of those caused by ventricular extrasystoles (p 194) The auricular rhythm is usually undisturbed but occasionally it is abnormal, for when a series of rapidly recurring contractions arises in the ventricle, the impulses may pass along the bundle in a retrograde fashion and activate the auricle to the exclusion of the normal impulse In other words, the ventricle then sets the pace, and the auricle follows In such instances the P waves are inverted and succeed the QRS deflections, or are buried in the ventricular complexes as in the nodal type mentioned above

III AURICULAR FLUTTER

There are two forms of this disorder, *pure and impure flutter* In both types the auricle beats

FIG 17 6 Top tracing, auricular tachycardia middle tracing nodal tachycardia, bottom tracing, ventricular tachycardia (Kindness of Dr John Hepburn)

at the phenomenally rapid rate of from 250 to 400 beats per minute, but in pure flutter the rhythm is regular, in impure flutter it is irregular Flutter differs from paroxysmal tachycardia in the following particulars

(a) The auricular rate of beating is usually much greater than that seen in paroxysmal tachycardia

(b) The disorder is of much longer duration, persisting unchanged for months or years, though it is sometimes transient

(c) The ventricle fails as a rule to follow the rate of the auricle, a state of relative heart block becomes established as a result of the comparatively long refractory phase of the functional tissue

(d) It is produced by the passage of the impulse over one or more circular pathways—*circus movement* (p 193)

Auricular flutter may become converted to paroxysmal tachycardia

In pure flutter the rhythm is remarkably regular (fig 17 7) The lengths of the auricular cycles

FIG 17 7 Pure flutter with a ventricular extrasystole (Kindness of Dr John Hepburn)

vary no more than a few thousandths of a second over comparatively long periods. In impure flutter this constancy of cycle length is not seen and varying degrees of irregularity occur. In flutter the auricular walls do not completely relax. That is, though the proportion of active to inactive fibers varies during the rapid beating, at no one time are all the fibers in the relaxed state. In the electrocardiogram, therefore, the level of the tracing between the P waves lies for the most part above the isopotential line, only touching the latter for an instant. The level of the tracing is continually changing and the electrical changes of the auricle are carried over to alter the form of the ventricular complex. On the other hand, the fibers are never all contracted at the same time, so that auricular systole as well as diastole is incomplete.

The ventricle rarely keeps pace with the racing auricle, the refractory phase of the conducting tissue being longer as compared with that of the auricular muscle. As a consequence, a state of relative heart blocks develops and an auriculo-ventricular rhythm of 2 to 1, or less frequently, of 3 to 1 or 4 to 1, becomes established. Sometimes there is variable block with 2 to 1, 3 to 1, 4 to 1, and occasionally even greater intervals occurring in the same strip of record. Should the ventricle respond to each beat of the auricle, as occasionally happens, serious circulatory disturbances follow, ventricular diastole is so shortened that the ventricle receives a greatly reduced load of blood. The output of the heart may be so reduced as a result that loss of consciousness resulting in death may follow.

IV AURICULAR FIBRILLATION

This condition so far as fundamental causes are concerned may be looked upon as an advanced stage of flutter. The auricular muscle is the seat of incomplete contractions which recur at a frequency of from 400 to 600 per minute. So incomplete are the contractions and so rapidly are they produced that the individual beats are scarcely distinguishable from one another. The auricular cavity is never emptied of blood and its wall is a quivering sheet of muscle. Auricular fibrillation is the most common of all the serious cardiac irregularities, being associated, according to

Lewis, in 60 to 70 per cent of all cases of cardiac failure in hospital practice. It is most frequently seen in mitral stenosis and in thyrotoxicosis (ch 57), but sometimes occurs in the absence of myocardial disease.

Only a proportion of the auricular impulses pass through the A-V bundle and activate the ventricle. The relatively long refractory period of the conducting tissue shields the ventricle from the high rate of the auricular beating. The arterial pulse, nevertheless, is usually considerably faster than the normal (100 to 150) though it may be normal or even slowed. Those impulses which reach the ventricle do so in a somewhat haphazard manner, and indeed one of the most characteristic features of fibrillation of the auricles is absolute irregularity in the rate and force of the ventricular beats. These features are expressed in the terms "*delirium cordis*", "*complete irregularity of the pulse*" or "*perpetual arrhythmia*", which were applied to the condition before its true nature was recognized. A proportion of the heart beats are frequently so weak that they fail to cause pulse in the radial. The apex beat is therefore much more rapid than the pulse. The former, for example, may be 150 and the latter only 60 or 70. The difference is called the *pulse deficit*. With treatment and improvement in the condition of the cardiac muscle, the pulse rate therefore may increase.

The venous pulse in auricular fibrillation is of the ventricular form, a waves are absent being represented by a series of rapid vibratory waves (f waves). Similarly in the electrocardiogram, small rapid undulations replace the P waves (fig 178).

THE UNDERLYING PROCESSES CONCERNED IN THE PRODUCTION OF FLUTTER AND FIBRILLATION OF THE AURICLES. The *circus movement theory* versus the theory of numerous separate points of excitation. The observation that fibrillation could be induced in animals by electrical stimulation has led to a much clearer understanding of auricular fibrillation and flutter in man. Lewis, employing faradization as the method of inducing fibrillation, studied the subject intensively and applying the results of the fundamental work of Mayer of Mines and of Garrey conceived that the excitation wave followed a circular pathway through the auricular muscle—the so called *circus movement*. That is to say, the wave starting at one place took a devious course through the cardiac musculature, returned to the point from which it started and reentered the path which it had previously traversed. Mayer induced a *circus movement* in the umbrella of the jellyfish (*Medusa*) by creating

FIG 178 Auricular fibrillation, lead 2 (after Lewis)

a local block and applying a stimulus to one side of the blocked region (fig 17 9, I, A) The contraction wave which resulted was forced as a result of the block to take a unidirectional course, and after completing the circuit of the disk of tissue returned to the region of the block which by this time had disappeared If the tissue from which the wave had been initiated was again excitable i e, had passed from the refractory state, the wave circled the ring a second time, then a third time, and so on repeatedly When, on the other hand, the disk was stimulated in the absence of a block a contraction wave set out in both directions and the two waves meeting, after having completed half the circumference of the strip, were suppressed at R (fig 17 9, II) That is further progress of the waves was arrested for each came to a region of tissue which, being occupied by the other wave was refractory

Mines and Garrey linked up Mayer's observations upon *Medusa* with the fibrillation of cardiac muscle Mines showed that a similar circular motion of the contraction wave could be induced in the cold blooded heart Muscular rings cut from the auricles of large rays were employed Garrey thought that he had refuted the prevailing belief at that time namely, that fibrillation of the auricle was due to the initiation of impulses from multiple foci throughout the auricular muscle—as proposed originally by McWilliam Garrey found that if he cut a small piece from the fibrillating auricle the severed tissue at once ceased to fibrillate an event which he contended could not occur if numerous points of excitation existed, but such would naturally result if the impulses travelled over a circular pathway from which other parts of the auricle were excited He induced a circulating contraction wave in large annular strips cut from turtles ventricles

Evidence was obtained by Lewis which seemed to show that the impulses in the fibrillating auricle travelled in the natural rings of muscle encircling the openings of the *vena cavae*

The theory of circus movement has been very widely though not universally accepted Brans and Katz contended that if a circus movement is responsible for flutter and fibrillation more than one circulating wave must exist They base this conclusion upon the observation that if after experimental flutter or fibrillation has been established the auricles (or in the case of ventricular fibrillation, the ventricles) are separated from one another by crushing between them the rapid beating persists with little change in each of the separated parts Scherf, as a result of his failure to abolish auricular fibrillation by clamping or ligaturing the auricular muscle in the path of the supposedly circulating waves was one of the first (1928) to throw doubt upon the existence of a circus movement A little later Andrus and Carter

concluded, from their experimental results in which fibrillation was induced by a single induction shock applied to the auricular appendix that the waves did not originate and travel in a ring of muscle

The most recent and convincing evidence against the circus movement theory has been secured by Prinzmetal and his associates They induced auricular fibrillation in the application of aconitine to the auricles of dogs and observed the auricle by means of high speed cinematography They saw no indication of a circus movement Two types of activity were observed (a) contractions and relaxations of microscopic or minute segments of muscle, which they term the 'M' activity, and (b) stronger contractions and relaxations of macroscopic or larger muscle segments which appear upon the background of the innumerable 'M' contractions This type of movement they have designated the 'L' activity Both types of activity are heterorhythmic and utterly chaotic and apparently arise from numerous discrete ectopic foci

The Actions of the Cardiac Glycosides, such as Digitalis, and of Quinidine upon Fibrillation and Flutter, and in Heart Failure

DIGITALIS belongs to a class of drugs known as the cardiac glycosides, which also includes atrophantin ouabain (G strophanthin from *S. gratus*) and aqull Digitalis in therapeutic dosage exerts a threefold effect upon the action of the heart (a) It increases the force of the ventricular contraction both of the failing (hypodynamic) heart and of the normal myocardium as shown for the isolated papillary muscle of the cat by Cattell and Gold This is the drug's most valuable property Ouabain and strophanthin have a similar action (b) It depresses A V conduction and (c) it stimulates the vagus, a reflex effect through the carotid sinus and the vagus center (Heymans and associates)

These last two effects cause slowing of the ventricle in fibrillation and flutter, but exert no significant effect upon the rapid auricular rate of sinus tachycardia The depression of A V conduction shields the ventricle from the fibrillating

FIG 17 9 (Modified from Lewis) Black = contraction wave Description in text

auricle the weaker impulses fail to reach the ventricle the pulse therefore becoming slower and more regular. In therapeutic dosage the drug has little or no effect upon the rate of the heart if the auricular rate is normal. In overdosage the drug may cause complete blockage of impulse conduction in the A-V bundle. It used to be thought that digitalis was of value only in fibrillation or flutter but it has been shown conclusively within the last two decades that it strengthens the ventricular beat and is of the utmost value in cardiac failure whether or not either of these arrhythmias are present. The digitalis glycosides have been shown to be useful in converting supraventricular tachycardias back to normal sinus rhythm. This is probably mediated largely through the vagus effect but it is not at all clear why vagus tone should affect ectopic auricular foci.

Certain effects of the cardiac glycosides upon the metabolism of the myocardium have been demonstrated which help to explain their beneficial action upon the cardiac contraction: (a) They increase the oxygen consumption of the heart. (b) They increase the utilization of glucose and of lactic acid. (c) They cause a partial restoration of the adenosinetriphosphate and phosphocreatine contents of the failing myocardium in which these energy rich phosphate bond metabolites are depleted. In overdosage these drugs themselves cause depletion to the extent of 50 per cent or more of these materials.

The action of digitalis and other cardiac glycosides appears to be mainly in improving the utilization of chemical energy by the myocardium rather than by increasing the total amount of energy liberated though the latter probably also occurs.

The cardiac glycosides exert no beneficial effects upon myocardial insufficiency due to anoxia in thyrotoxicosis or in vitamin B₁ deficiency. The reason for this is unknown.

QUINIDINE (an isomer of quinine) also exerts a threefold action in fibrillation: (1) It depresses or abolishes vagal tone and so lengthens the refractory period of the auricular muscle and decreases the transmission rate. This action upon the vagus is therefore opposite to that of digitalis. (2) It acts directly upon the auricular and ventricular muscle lengthening the refractory period (by from 50 to 100 per cent) and slowing the transmission rate. (3) It depresses conduction in the junctional tissues—a direct action. The abolition of the fibrillation of the auricle and the restoration of the normal rhythm was believed on the basis of the circus movement theory to be due to the lengthening of the refractory period of the auricular muscle and as a consequence to closure of the gap of excitable tissue between the crest and tail of the wave (see fig. 17-9). In other words the head catches up to the tail. (Osler). But however

fibrillation is produced we know at any rate that quinidine restores the normal auricular rate and thus acts upon this arrhythmia in a manner different from that of digitalis. In the restoration of the normal auricular rhythm by quinidine fibrillation is frequently converted first to flutter.

The different effects of quinidine upon the heart interact in a complicated manner. For example its action upon the ventricular rate will be the resultant of the following three effects:

(1) Rapid auricular beating tends automatically to depress conduction through the A-V connections. Therefore when the rate of the auricle is reduced by the drug A-V conduction is increased.

(2) The reduction in vagal tone also increases A-V conduction.

(3) The direct effect of the drug upon A-V conduction as stated above is one of depression.

As a matter of fact (1) and (2) frequently overbalance the last effect (3) and some increase in the ventricular rate results.

Quinidine in overdosage produces severe toxic effects among which are auriculoventricular block, extrasystoles, paroxysmal tachycardia and even death as a result of ventricular fibrillation. The return of the normal auricular contractions under quinidine treatment is sometimes though rarely followed by the dislocation of an intra-auricular thrombus and death from embolism. Complete standstill of the heart has also been reported as a result of the paralysis by the drug of the sino-auricular and auriculoventricular nodes and other tissues capable of impulse initiation. Procaine amide has an action closely akin to quinidine. It appears to be less effective on the auricular arrhythmias than quinidine but being less toxic than quinidine it may be given intravenously. It is most useful in converting ventricular tachycardia back to normal rhythm by intravenous administration. It is also used orally in suppressing frequent ventricular premature beats.

V. VENTRICULAR FIBRILLATION

The ventricular muscle may pass into a state of rapid tremulous and ineffectual contractions closely similar in nature to the condition just described as occurring in the auricle. In animals ventricular fibrillation may be initiated by direct electrical stimulation of the ventricular muscle as was first shown by Ludwig in 1850. Mechanical stimulation of the ventricle especially by pricking the tissue in the A-V groove, ligation of a coronary artery (Porter) or certain chemicals and drugs in excess e.g. digitalis or calcium chloride may induce fibrillation. Levy found that chloroform anesthesia renders the hearts of experimental animals (cats) highly susceptible to fibrillation. A mere touch of a finger or instrument the stimu-

lation of a sensory nerve, section of the vagi or their paralysis by atropine, may set the ventricle fibrillating. The heart behaves as though sensitized by the anesthetic and ready at the least provocation to fibrillate. Adrenaline was found to greatly enhance the effect of chloroform—a fact which indicates the danger of adrenaline administration while a subject is under the effect of this anesthetic. Fibrillation may also ensue spontaneously under chloroform, and Levy found that the condition is more likely to supervene when the animal is passing from deep to light anesthesia. Cyclopropane, like chloroform, has the effect of sensitizing the heart to the action of adrenaline in inducing ventricular tachycardia and fibrillation, but these cardiac irregularities are rarely seen under ether anesthesia. Quinidine reduces the susceptibility to fibrillation during cyclopropane anesthesia.

The effects of ventricular fibrillation upon the circulation are incomparably more serious than those of the corresponding auricular condition. This is evident when the importance of the two musculatures in the dynamics of the circulation are compared (p. 244). In fibrillation of the lower chamber the propulsive force of its contraction is practically abolished and the circulation comes to an end, death follows within a few minutes.

From experiments upon animals it is believed that many instances of cardiac failure in patients under chloroform are due to fibrillation of the ventricles. This is generally considered to be of sudden onset, but it has been shown that when the condition is induced in animals by chloroform it is frequently ushered in gradually. A solitary extrasystole first occurs, which is followed after a time by coupling, tripling, and later by short runs of extrasystoles. Longer paroxysms of rapid beating follow. Finally as the tachycardia becomes more rapid it merges into fibrillation.

When fibrillation is induced suddenly as by electric shock its development may be somewhat different. According to Wiggers and his associates, only the first contraction is a true premature beat, those which follow are caused by reentry of the excitation wave. These investigators, who induced ventricular fibrillation in dogs by the application of single strong induction shock to the ventricle late in systole, recognize four stages in the development of fibrillation. In the *first* or *undulatory stage*, which lasts for only a second or two, the contractions are rapidly repeated but do not follow the same course over the surface of the ventricle, the electrocardiographic deflections show considerable variability in form. In the *second* stage of *convulsive incoordination*, which lasts for from 15 to 40 seconds, the contractions are more

frequent and involve smaller areas of the ventricular muscle. The contractions of different areas of the muscle are out of phase so that the ventricle appears to be pulled about convulsively. The *third* stage of *tremulous incoordination* lasts for 2 or 3 minutes, the surface of the muscle is broken up into independently contracting areas of ever decreasing size which are out of phase with one another. Thus, a tremulous appearance is given to the ventricles. The *final* stage of *atonic fibrillation* develops when the developing anoxia of the cardiac muscle causes weakening of its contractile force. This stage appears usually within from 2 to 5 minutes following the first stage and is marked by weak contractions or wavelets which travel only a short distance over the ventricular surface. It ends in complete cessation of all activity.

Ventricular fibrillation in man may result from

- a) Electric shocks—electrocution, lightning stroke
- b) Chloroform or cyclopropane anesthesia
- c) Coronary occlusion and other causes of severe anoxia
- d) Trauma to heart or chest wall
- e) Ventricular paroxysmal tachycardia in which fibrillation may be a terminal event
- f) Toxic doses of digitalis or quinidine
- g) Various diseases during the death agony

The fundamental factor or factors leading to fibrillation of the ventricles have been the subject of research by several investigators. Kebar and Hooker have found microscopical tissue changes in the dog's heart, in which fibrillation was induced by electric shock. There also occurred an increase in potassium in the outflowing fluid perfused through the heart. They attribute the fibrillation to a leakage of potassium from the cells and an unbalance of the potassium ion. The addition of potassium to the perfusion fluid brings the fibrillation immediately to an end and restores the normal beat. According to Nahum and Hoff the essential condition for the onset of fibrillation is the establishment of a block or blocks of the conducting system in a heart whose automaticity is simultaneously stimulated, either factor alone is ineffective. They found that the rapid injection of a concentrated solution of KCl throws the ventricles immediately into fibrillation. This does not occur if the injection is made slowly, for then automaticity instead of being stimulated is depressed, block of the conducting system occurs, but fibrillation does not ensue. Thus they believe that the two essential elements in the production of ventricular fibrillation are intraventricular block and automaticity of the ventricles. Ventricular fibrillation, though usually fatal, is not invariably so for rare instances have been reported in which the ventricles after fibrillating for

a brief period resumed their normal rate and recovery occurred. Two methods, chemical and electrical, have been used in attempts to restore the normal rhythm to the fibrillating ventricles. Hooker has shown the efficacy of an excess of potassium in stopping fibrillation and of calcium in restoring the normal beat in the hearts of dogs subjected to electric shock. A 0.5 per cent solution of KCl is injected under pressure into the carotid toward the heart, so that it reaches the coronary system. This stops the heart. When a 0.023 solution of CaCl_2 is then introduced by the same route, the normal cardiac rhythm in a successful experiment, is restored. Hooker and his associates showed that defibrillation of the dog's heart can be accomplished and the normal beat restored if a countershock, consisting of an alternating current of about one ampere, is passed through the heart. In fibrillation due to anoxia (e.g. caused by coronary occlusion) the heart may be defibrillated by either of these two means but the heart muscle is usually unable to develop a forceful contraction owing to the oxygen lack. Wiggers has modified Hooker's procedure by sending into the heart a series of shocks (3-7) of about one second duration and one or two seconds apart. He recommends that when fibrillation follows coronary occlusion cardiac massage should be practiced while the countershocks are being given, in order to increase the blood flow to the ventricular muscle. In fibrillation due to electrocution or other cause, the countershocks may be applied through the chest wall although much stronger currents (20 to 30 amperes) will be required.

A number of reports have appeared in the literature of human lives saved when patients suddenly developed ventricular fibrillation. In these cases the chest was rapidly opened and circulation restored by manual compression of the heart until defibrillating counter shock equipment could be obtained. The increasing number of such reports points up the necessity that all physicians learn the technic of thoracotomy and cardiac massage. It has been well established that unless circulation can be restored in less than 4 minutes, irreparable cerebral damage will have occurred, and even though heart action might be restored, a decerebrate patient will be the result.

D. Alternation of the Heart. Pulsus Alternans

This is a condition in which every second wave in a pulse tracing is of relatively small amplitude. This peculiarity of the arterial pulse is due to alternate variations in the strength of the ventricular systoles, and to a smaller quantity of blood being ejected into the aorta during the weaker beat. Figure 17-10 shows a typical sphygmogram of this condition. There is as a rule little or no difference in the lengths of the intervals between pulse beats. When a slight difference does exist, the interval succeeding the strong beat is then longer than that following the weak beat. It will be remembered that in the bigeminal pulse, which might in some instances be confused with alternation, there is inequality in cycle lengths (p. 196), but the longer interval follows the weak (premature) beat. Furthermore in alternation the ventricular rhythm does not share, or does so very rarely, in any irregularity of the pulse intervals which may occur in the arterial tracing. The electrocardiogram, for instance, shows no discrepancies in the length of the intervals between the R waves. The slight variations in the pulse intervals are attributed by Lewis to a slower rate of transmission of the weaker pulses to the periphery. When records are taken simultaneously of the apex and the arterial pulse, it is sometimes found that the weak beats of the former coincide with the strong beats of the latter. This discordance between apex and arterial beats is explained upon the assumption that those muscle fibers which contract during the weak apical impulses though less numerous are actually more effective in ejecting the blood than those causing the stronger thrusts at the apex (see, Theory of Alternation, below). The appearance of alternation in the electrocardiogram (e.g., alternate variations in the height of the R wave) is rare. When this so-called *electrical alternation* does occur the larger deflections sometimes correspond to the weaker pulse beats. But, it will be recalled in this connection that the deflections of the electrocardiogram are determined by the balance of the electrical forces developed during the cardiac contraction rather than upon their total value. Electrical alternation may occur without alternation of the pulse.

Sometimes it is not possible to detect pulsus alternans by palpation of the pulse, the variations in strength of the pulse beat being too slight to be perceptible, but it is clearly revealed in the sphygmogram (fig. 24-10). It may also be de-

FIG. 17-10 Radial tracing showing pulsus alternans (After Mackenzie)

tacted by means of a blood pressure armlet. The pressure in the armlet is raised gradually, when it is found that at a certain level the weaker beats are suppressed, but the stronger beats get through. The pulse at the wrist is then precisely half the ordinary rate. The pressure during the weaker beats may be as much as 25 mm Hg below that during the stronger, but usually the pressure difference is not more than 5 or 10 mm. Persistent alternation of the heart when the pulse is slow or of normal frequency is usually indicative of grave disease of the myocardium. Alternation sometimes also occurs at rapid rates of beating, e.g., *auricular fibrillation*, *paroxysmal tachycardia* etc., but it is then of less serious significance.

THEORY OF ALTERNATION The 'all or none' law states that the cardiac muscle responds maximally to any stimulus that is capable at all of evoking a response. It is apparently difficult to reconcile this principle with the varying force of the ventricular contractions in alternation, unless it be assumed that during the weak beat a smaller proportion of the heart fibers respond than during the strong beat. This is the prevailing view.

The heart it is thought must be in what has been called a *hypodynamic* state in order for alternation to occur. That is the heart muscle is so depressed that only half of its fibers have recovered from the previous contraction before the impulse arrives. These fibers alone contract and when the next impulse arrives they are still refractory, but those which had not previously con-

tracted have recovered their irritability and now respond. In this condition all beats are weak but equal. Should a ventricular extrasystole occur in such a heart the long pause which follows shifts the balance between the refractory and the non-refractory fibers and precipitates the alternating rhythm. After the long pause of the premature beat a larger proportion of fibers have had time to recover and are therefore able to respond to the impulse. The next impulse however finds the muscle in a partial refractory state, i.e. only a small proportion of the fibers have by this time recovered. They only can respond—a weak beat results. This small proportion of fibers when the next impulse arrives will in turn be refractory, but the larger proportion which had not previously contracted will now respond—a strong beat results. So the alternating rhythm is perpetuated, the fibers which responded during one contraction fail to contract at the next beat and conversely those which had failed to respond to one impulse respond to the next.

E. Irregularities Due to Variations in Vagal Tone

I. SINUS ARRHYTHMIA (Fig 17 11, I)

This is a condition in which rhythmical variations in the rate of the whole heart occur synchronously with respiration. It is due to alterations in the strength of the vagal influence upon the pacemaker (S A node) as a result of the respiratory excursions, the heart rate increasing toward the end of inspiration and slowing toward the end of expiration. It is a youthful irregularity.

FIG 17 11 I sinus arrhythmia II, sinus bradycardia III sino auricular block (kindness of Dr John Hepburn)

being very common in children, and may be considered a physiological phenomenon. That it is entirely of vagal origin is shown by the fact that it is abolished by atropine. It also disappears when the heart rate increases as a result of exercise, fever, etc., but is enhanced by deep breathing.

II PHASIC IRREGULARITY

In this disorder periodic slowing of the heart occurs for a few seconds quite independently of the respirations. It also is a vagal effect since it is abolished by atropine. The manner of its production is unknown. It occurs in convalescence from acute fevers, and sometimes during the administration of digitalis.

III SINUS BRADYCARDIA (fig 17 11, II)

This is a persistent slowing of the whole heart due to increased vagal tone influencing the sinoauricular node. The rate may be as slow as 40 per minute. Bradycardia of this nature occurs in apparently healthy persons, many of whom are athletes.

IV SINO AURICULAR BLOCK (fig 17 11, III)

The entire heart (auricles and ventricles) misses a beat at regular or irregular intervals. The condition thus differs from A-V block in which only the ventricle misses (p. 192). A complete set of waves is therefore dropped from the venous or electrocardiographic tracing, and the arterial pulse intermits. Since the condition is temporarily abolished by atropine and may be induced by stimulation of the vagus, it is probable that the missed beats are due to the action of the nerve upon the S-A nodes. Sinoauricular block sometimes results from digitalis administration.

V AURICULOVENTRICULAR BLOCK

Defective conduction between auricle and ventricle due to heightened vagal tone is occasionally seen; it is abolished by atropine.

ESTIMATION OF VOLUME OF BLOOD FLOW, VELOCITY OF BLOOD FLOW, VOLUME OF ORGANS, CAVITIES AND REGIONS: CIRCULATION TIME

Our knowledge of the *modus operandi* of the circulation has progressed no faster than advancement of methodology that has given answers to certain problems

Volume Flow of Blood

The most important measurement in the circulation is that of the volume flow of blood through the aorta or through any vital region or organ. This is so because the blood flow is most sensitive to a change in dilation in a vascular bed. If the blood pressure is doubled, the blood flow might also double but doubling the mean bore of a vascular bed might increase the blood flow by 16 times. In the past, advancement of flow methodology has been slow and limited in large measure to devices applicable under highly abnormal conditions. In use, the animals have been exposed to so much insult by anesthesia, surgery and trauma that the measurements do not necessarily have resemblance to normal values, i.e., the relative importance of factors regulating flow can be quite different. More recently, progress has been *much more rapid because of methods* applicable to the normal circulation in the resting and unanesthetized active states.

VISUALIZATION (HUMAN OR ANIMAL) Direct *in vivo* visualization with the aid of a microscope of the components of the microcirculation (terminal arteries, arterioles, capillaries, venules, and very small veins) offers a means for studying qualitatively the peripheral circulation and control of blood flow in various regions. When capillaries, arterioles or any of the above vessels are observed to decrease in diameter, they are assumed to have constricted and thus to decrease flow. However, interpretation is always difficult for the apparent change in flow could arise from decrease in perfusion pressure, enlargement of other already patent vessels, opening of other drainage vessels, or increase in pressure in the surrounding tissue. Despite this, such observations have contributed greatly to our knowledge of the circulation. Direct microscopic and high

speed photography have been used in the frog skin, bat wing, rat mesoappendix, dog omentum, lungs of the open-chest dog, transparent viewing chamber of the rabbit's ear, bulbar conjunctiva and skin of humans, and pial vessels of the brain through a transparent viewing chamber. Change in small terminal arteries (and arterioles?) has been visualized in the coronary circulation of the heart of the closed-chest dog and in humans with cinéphotography following injection of contrast medium directly into the coronary arteries. Progress using the latter approach has been very rapid in the last few years so that gross encroachment by an atheromatous process on the coronary arterial lumen can be detected. Future comparable advancement might permit detection of early small lesions and study of factors which affect their growth.

VENOUS DRAINAGE One of the oldest simplest and most satisfactory means of determining blood flow is to collect and measure the outflow from a cannulated vein draining a particular organ. The rate of flow can be read from a graduate, or from the change in weight of a collecting container on a scale directly read or indicated by a strain gauge mounted under the collecting container. It can be indicated by causing the venous blood to enter the bottom of a closed chamber and with a bellows in the chamber recording the increase in pressure or volume of displaced air as the fluid level rises or by recording in an open chamber the changing height of a float riding on top of the fluid. For very low rates of flow, drop recorders are used in which each drop shorts a pair of contacts in an electrical system or interrupts a photocell light beam. In all cases, the blood is generally returned to the circulation by some form of atraumatic pump that does not cause significant hemolysis of the red cells. Such collection of venous drainage has its modern counterpart considered in more detail in the next section in which total venous drainage in perfusion systems applied to humans and animals is collected and metered before its return to the body. In

general, this approach has the advantage that it does not interfere with the nervous control of the blood vessels which is the case when metering is done on the arterial side. It has the disadvantage that it generally measures only a portion of the arterial inflow since most organs have multiple venous drainage channels.

PERFUSION SYSTEMS FOR USE WITH ISOLATED ORGANS (WITHIN OR WITHOUT THE BODY), WITH REGIONS OF THE BODY, AND WITH THE WHOLE BODY For many investigations and to permit certain surgical procedures, it is desirable to have controlled perfusion of an organ, body region, or the whole body at constant controlled flow rates and/or at constant perfusion pressures which are the same or different from the prevailing aortic pressure. Over the years a very large number of such systems have been devised. Because of their practical use to the surgeon, the development of pumps or pump-oxygenator systems for maintaining blood flow at a constant rate or constant pressure has been rapid. Such pump systems have been used to perfuse many isolated organs and to perfuse in the unanesthetized as well as the anesthetized animal, the vessels of an extremity, the brain, liver, kidney, and the coronary vessels of the heart. Such mechanical pumps serve also as temporary replacement for the left ventricle, right ventricle, and the whole heart, i.e., the whole body including the coronary arteries is perfused with a pump. The minimal criteria that must be satisfied in such artificial systems are the blood must be maintained at a constant temperature, preferably near body temperature, it must be suitably oxygenated, the pH of blood should be maintained at approximately a normal level, the blood flow rate should be adjusted to that which normally exists without a pump, excessive trauma to the red cells must be avoided. To minimize hemolysis, valves to direct the flow are generally avoided, and blood is moved through rubber or plastic tubing by multiple fingers or by a continuous roller over the tubing.

The use of such systems for bypass of the right heart, left heart and whole heart is shown in principle in figure 18 1A, B, and C.

For the right heart bypass, the systemic venous return is prevented from entering the right atrium and right ventricle by special fenestrated catheters passed through the right appendage and tied in the superior and inferior venae cavae. The collected blood flows by gravity into a reservoir from which it is pumped through the pulmonary artery. The coronary venous drainage which under this arrangement continues to enter

the right atrium and fill the right ventricle, can by an appropriate catheter be made to drain into the same venous reservoir, thus insuring collection of total systemic venous flow. This type of bypass (1) permits measurement of coronary venous flow and coronary A-V oxygen and therefore, presumably gives an index of total coronary flow and myocardial oxygen usage, (2) permits hemodynamic studies on the left or right heart separately, (3) permits operative procedures on the right heart in the presence of a dry field.

For the left heart bypass, the pulmonary venous return is prevented from entering the left ventricle by a clamp between it and the left atrium. It is drained by gravity into a reservoir from which it is pumped into the aorta. Since the left ventricle is now mechanical with a constant output, this arrangement (1) permits study of those factors which regulate the vascular volume and the systemic venous return especially the state of the venous system and activity of the right ventricle (this can be determined from observation of the height of blood in the reservoir), (2) permits operative procedures on the left heart with a dry field.

For total heart bypass, the systemic venous return is prevented from emptying into the right ventricle and is drained by gravity into a reservoir from which it is pumped through some form of oxygenator to a second reservoir from which it is pumped by a second pump (set at the same flow rate) into the aorta. To obviate filling up of the left ventricle from bronchial flow drainage into the pulmonary veins and left atrium, a condition which is not prevented by this procedure, a catheter is inserted into the left atrium. Initially, the blood was oxygenated by passing it through a donor human or animal in which the lungs oxygenated the blood, later, the blood was passed through autogenous lungs. With present technical development of artificial blood oxygenators, this is not necessary and, after priming with blood, an artificial pump-oxygenator system can support the circulatory system for some time. After about 30 minutes of whole body perfusion physiological problems arise and postoperative recoveries may be poor. This will be considered in a later chapter.

Various expedients have been used to perfuse an organ or region (fig 18 1D). (1) The simplest arrangement is to connect the peripheral end of the artery (which feeds an organ or region) to a reservoir at an appropriate elevation so that it drains by gravity. The flow rate is read from

graduations on the reservoir or from one of the flow meters (described in this chapter) which is interposed. (2) Air expansion chambers are used which permit constant pressure perfusion. In this, the peripheral end of the artery of an organ is connected to an air chamber, the lower portion of which contains blood exposed to the desired pressure in the chamber. Flow into the organ is indicated by one of the appropriate blood flow meters interposed between the organ and chamber. The supply of chamber blood for infusion is replenished by letting it flow into the chamber from a convenient artery, under the animal's own blood pressure. (3) An end of a pump is connected to a local arterial source and the other end of the same pump to the artery of the organ or region being supplied. Either the perfusion pressure or flow rate can be varied separately. (4) The output side of a pump can be connected to a blood air reservoir in which the air pressure is maintained constant at any desired perfusion pressure level and whose outlet is connected to the organ being perfused.

These approaches obviously have the important advantage that they enable the investigator to study separately the peripheral factors in the organ or region that regulate flow.

MEAN FLOW RECORDERS (FIG. 18.2) Because of the imposed resistance to flow, most mean flow recorders are not suitable for use in the path of venous flow but are acceptable in the arterial system where a small drop in pressure across the meter is not so important. The types that have given much information regarding the operation of the cardiovascular system include the mechanical stromuhr, bubble flow meter, rotameter, and turbidimeter. Their present operation is extensive. In use, they have the disadvantages that they require anesthesia, injection of anticoagulant, insertion between the cut ends of the vessel in which flow is being measured, and their response time is slow, the fastest (the rotameter) being of the order of 90 per cent complete in 1 second. Despite this, and although arterial flow is highly phasic, these devices have been most helpful.

A Mechanical stromuhr The stromuhr of Ludwig is one of the oldest and best known. It consists of an ingoing and an outgoing cannula which are inserted, respectively, into the proximal and distal sections of a divided artery. The blood flowing from the artery into the instrument enters a small pear-shaped flask of known capacity filled with oil. Upon the entrance of the blood, the oil is forced over into another flask of identical

size but which has previously been filled with blood. The entrance of the oil forces the blood in turn into the peripheral section of the artery. The position of the flasks can be reversed by rotating through a semicircle and the process of filling and emptying repeated, or by appropriate means the flow can be automatically reversed in direction through the flasks. From the number of fillings of the flasks during the period of observation, the volume of blood flowing in a unit of time is readily calculated.

B Rotameter This device originally developed for commercial use was first adapted in 1942 to quantitation of blood flow. Basically the device consists of a vertical transparent tube with tapered bore within which the height of a float is determined by the rate of flow. With upward flow through the tube the float is lifted until it reaches a height determined by a balance of the downward force (weight of float minus weight of displaced fluid), and the upward force (pressure drop across the float times maximal cross-sectional area of float). As flow increases, the balance is altered, and the float rises to a new position at which the increase in the annular orifice is large enough to reduce the pressure drop across the float to that existing at the previous flow level. The position of the float may be read visually, or for continuous recording, the vertical position of the float is detected by an induction mechanism. It is possibly the best method for continuous and accurate quantitation of mean blood flow in the aorta and arteries. Flow quantitation is with an error of ± 5 per cent.

C Turbidimeter The turbidimeter consists of a turbine of known capacity per revolution which is driven by the flowing blood stream. In the turbine is a rotating magnet which induces a recordable signal in an adjacent coil and which indicates the number of turbine rotations. Because of starting frictional resistance to turbine rotation, the turbidimeter does not turn with less than 400 to 500 cc blood flow per minute and the pressure drop across it in operation is quite high. Consequently, it is used for measuring rather large flows and is used exclusively in the aorta.

D Bubble flow meter Mean rate of blood flow in arteries has been measured by timing visually or photoelectrically the passage of an injected air bubble through a glass tube of known length and volume which is placed between the cut ends of the vessel through which flow is being measured. Because of the resistance to flow from the long (1 meter) tube used the device cannot be

FIG. 18.1 Schematic representation of techniques *A* for right heart bypass *B* for left heart bypass *C* for total cardiac bypass *D* for studying regional blood flow while either perfusion pressure or blood is maintained constant.

FIG 181

used in veins. However, for quantitating flow in the smaller arteries, it is inexpensive and easy to use and has a linear calibration curve.

E. Thermostromuhr. Mean flow through ar-

teries or veins has been determined by several types of thermostromuhrs which operate on the principle that when a circuit is formed of two wires of different metals and one of their junc-

tions is at a higher temperature than the other, an electromotive force is produced in the circuit. The two thermal junctions are mounted in a plastic sleeve, and the proper temperature difference is created by a high frequency or direct current heater. This is either snugly fitted around an intact vessel or is inserted between the cut ends of a vessel so that the flowing blood is in close contact with the thermocouples and heater. A part of the heat is carried away by the flowing blood, hence the rate of cooling of the thermal element depends upon the rate of blood flow. Since the cross section of the vessel is held constant, volume of flow is related to the differential temperature of the two junctions provided environmental factors do not alter this relationship. However, several external and internal factors other than rate of blood flow influence significantly and unpredictably the flow readings by altering the relative rates of heat loss to the environment at the two junctions or the heat distribution between the junctions so that its reliability is questionable.

PHASIC FLOW METERS (FIG 18 3) These de-

FIG 18 24 Full scale sectional view of 0 400 cc per minute rotameter constructed of lucite or plexiglass showing tapered flow chamber, metal float with soft iron upper rod extension, float rest at zero ow and coil for detecting float position. vices faithfully record the phasic or moment to moment changes in arterial and or venous flow during a cardiac cycle. The differential pressure and pendulum types must be used with heparin and inserted between the cut ends of a vessel, the electromagnetic and sonar flow meters are used to measure blood flow in intact vessels in unanesthetized active animals, and the former has been used in anesthetized humans.

A Differential pressure flow meters By introducing a device between two points in a flowing stream, a pressure difference is created which varies with the velocity of blood flow. The ways of creating the pressure difference are illustrated (fig 18 3a). Of these, only the orifice meter and Pitot tube will be considered.

The orifice meter makes use of the velocity with which blood is flowing. The lateral pressure difference is determined between two regions above and below a region of constriction (the orifice) in a flowing bloodstream, the cross sectional area of which is constant. Because of the higher stream velocity just below the constriction, the downstream lateral pressure is lower. The pressure difference is proportional to the flow.

With the Pitot tube method the difference in pressure is determined in two tubes inserted into a vessel, one directed upstream, the other downstream. In the tube pointed upstream the energy of movement is added to the existing potential energy (pressure on the wall) and a higher pressure is thus recorded in the tube. In the tube pointed downstream, the kinetic energy of movement is deducted from the potential energy (pressure). The pressure difference is entirely a function of the velocity of flow at the two points.

In the past, for these two types of flow meter the pressure difference which is proportional to flow has been optically recorded by a differential manometer. The manometer is a rubber membrane optical pressure manometer except that the rubber is very thin and a chamber filled with saline surrounds the front surface of the membrane for application of the downstream pressure. Membrane excursions are recorded by light passing through a glass window in the outer chamber to a small mirror mounted on the membrane. Recent replacement of the optical differential manometer by an electrical system and amplification has improved the fidelity of differential flow meters.

Until recently most of our information regarding phasic blood flow in the aorta, venae cavae,

FIG 18 2B The Potter electro-turbanometer (After Sarnoff, *Circulation Res*, 1953, 1, 724)

FIG 18 2C Diagram of direct current thermistor flow meter (Gregg *Coronary Circulation in Health and Disease*, Lea & Febiger, Philadelphia, 1950)

and various arteries has come from the use of the two flow meters. Both are quite satisfactory. The orifice meter causes a considerable pressure drop, the Pitot meter does not, hence, the former is adequate for arterial flow, the latter for venous flow. The question has been raised whether the orifice meter, by imposing resistance to flow gives a correct phasic flow curve in an artery such as a

coronary, in which blood temporarily reverses its direction of flow during a portion of the cardiac cycle. However, recent experiments in the author's laboratory have shown that flow curves are similar with the orifice meter and with an electromagnetic flow meter in which no resistance to flow is imposed by the meter.

B. Pendulum flow meters. In principle first de

FIG 183 Phasic blood flow meters *A* Schematic drawing illustrating the principle of the orifice meter and the Pitot tube (after Brecher Venous return Grune & Stratton, Inc., New York 1955) *B* Schematic diagram of the bristle flow meter cannula utilizing a subminiature vacuum tube and flow sensing element (after Brecher, Venous return, Grune & Stratton Inc., New York, 1955) *C* Sonar flow meter principle (Franklin *et al*, Am J Physiol, 1959, 14, 809) *D* Electromagnetic flow meter principle *E* Electromagnetic flow meter probe

scribed in the 15th century, a small pendulum, paddle, reed, wire, or bristle which is introduced into a blood vessel is deviated from its resting position by the flowing blood, the amount of deviation being proportional to the velocity of flow

At least two successful types are in use. In one type, the electromagnetic pendulum flow meter, the pendulum is made of ferro magnetic material which moves in an induction field. The induction changes are then amplified. In a second type, the

bristle flow meter, the blood-stream deviates a small bristle, one end of which is inserted into the blood vessel and the other end is attached to the plate pin of a subminiature vacuum tube (fig 18 3B) When the bristle is deviated by the flowing blood, the electron current from cathode to anode varies in proportion to the distance between them which is determined by the degree of deviation. The electrical signal is amplified. These two types of devices have the advantages of smallness and compactness, good frequency and sensitivity, minimal resistance to flow, low drift and equal response to forward and backward flow. A big drawback is that the pendulum or bristle are very sensitive to position changes (gravity effect) as well as to flow.

C Sonar and electromagnetic flow meters The optimal flow meter for physiological investigation would be made up of a miniature sensing agent which is mounted chronically on the external surface of intact blood vessels. It would record instantaneous flow for extended periods, weeks to months without change in calibration, and would have sufficient sensitivity and frequency response to monitor flow in arteries and venous trunks. Two different types of flowmeter, the sonar and electromagnetic, have been developed in the attempt to satisfy these demands (figs 18 3C and D)

An electrosonic meter has been used to measure flow in the arteries, aorta and vena cava and to measure left ventricular diameter of unanesthetized dogs. Earlier models were developed by Kalmus with some miniaturization by Herrick. In principle, the transit time of sound moving downstream is determined by the velocity of sound in the motionless medium plus the velocity of the medium. The transit time of the sound upstream is determined by the velocity of sound in the motionless medium minus the velocity of the medium. Thus the difference in transit time of the ultrasonic waves upstream and downstream is proportional to the velocity of the medium. In practice, barium titanate crystals are mounted at diagonally opposed positions near the end of a lucite cylinder divided longitudinally and this is clamped about an artery. Bursts of ultrasonic waves (3 megacycles per sec) emitted by one crystal pass through the vessel wall and diagonally through the stream of flowing blood to reach the opposite crystal. Bursts are emitted at about 12,000 per sec with direction reversal at 500 per sec. The difference in transit time of the ultrasonic waves is converted into a direct current

voltage, amplified and recorded. By turning off the ultrasonic pulse generator, the flow beam reaches a position which is the same as that following temporary mechanical occlusion of the vessel. This device appears to be usable on both artery and vein.

The electromagnetic flow meter has been used for pulsatile flow recording in the aorta and arteries of the dog and man. A number of different types have been produced, some commercially. In the author's laboratory, the Kolin type somewhat modified has been used. This was first crudely designed 24 years ago. In principle an electromotive force or voltage is induced in a conductor moving through a magnetic field at right angles to the lines of force. In biological use blood moving within an intact blood vessel serves as the conductor and the induced voltage which is proportional to the blood velocity is picked up by a pair of electrodes positioned against the vessel wall, perpendicular to the magnetic field and to the direction of blood flow. The flow meter which is encased in plastic consists of a miniature electromagnet made up of coils of wire mounted on steel laminations, a slotted plastic tube into which the vessel is inserted, two electrodes and wires for energizing the electromagnet and for leading off the induced voltage (one millionth volt) which is amplified and recorded. In use, the probe is implanted around an intact blood vessel by temporarily decompressing and forcing the vessel through the longitudinal slit in the probe. Its main advantages are its ability to measure mean and phasic flow in unopened large and small vessels of chronic animals, its linearity of calibration and its high frequency of response. The flow beam can be made to approximate the zero flow position by "electronic zeroing" or repeated mechanical flow zeros can be easily obtained even in the exercising dog by temporary (3 to 4 sec) inflation of a rubber pneumatic cuff just distal to the flow meter.

FICK PRINCIPLE Much of our information concerning blood flow, especially the output of the heart is derived from the use of methods based on the Fick principle. To employ the Fick principle to determine blood flow through the whole body or an organ, it is necessary to have a substance that is either removed from or added to the blood during its period of flow through the vessels under study. The amount which is added or removed from the organ by the blood is equal to the difference between the amount brought into the organ and the amount carried away from

the organ. The amount of the substance in the blood is expressed as the volume multiplied by the concentration. Thus $Q = F_i \times C_i - F_o \times C_o$ in which Q = amount of reference substance picked up or released by the organ, F_i = blood flow into organ, F_o = blood flow out of organ, C_i = concentration of reference substance in the inflowing blood, and C_o = concentration of reference substance in outflow blood. Since the inflowing and outflowing volumes are assumed to be the same, the equation becomes

$$F = \frac{Q}{C_o - C_i} = \frac{Q}{\Delta C}$$

A. For cardiac output with oxygen and carbon dioxide. Measurement of the output of blood by the animal or human heart has been calculated from the difference between the oxygen content of the mixed venous blood and that of the arterial blood and the total oxygen consumption. It must be evident that if the quantity of oxygen which a unit of blood delivers to the tissues (or takes up from the lungs) is known, together with the total quantity of oxygen consumed over a given period, then the volume of blood which had been engaged in the carriage of this quantity of gas can be calculated. To take an example. The arterial blood contains about 19 volumes of oxygen per 100 cc. It gives up, let us say, 6 volumes to the tissues, i.e., the mixed venous blood coming to the lungs contains 13 volumes per cent. The arteriovenous (A-V) oxygen difference is, therefore, 6 volumes per cent. If the total quantity of oxygen consumed per minute is found to be 250 cc, then the cardiac output is

(Total O_2 consumption per minute)

$$\frac{250}{19 - 13} \times 100 = \text{(Output per minute)} \\ 416 \text{ liters}$$

(Arteriovenous O_2 difference)

The oxygen consumption must be measured very accurately for several minutes. The arteriovenous oxygen difference should be obtained simultaneously and must be based on blood from any artery and mixed venous blood since the quantity of oxygen contained in venous blood from different regions is grossly different depending upon the vascular bed from which it drains. Even the oxygen content of blood in the superior vena cava differs from that in the inferior vena cava by 1 to 2 volumes per cent. Mixing of the blood occurs in the right ventricle and is generally

complete by the time the blood reaches the pulmonary artery where sampling is made.

The cardiac output can be calculated in a similar way from the total carbon dioxide elimination and the arteriovenous carbon dioxide difference (CO_2 in mixed venous blood less CO_2 in arterial blood). However, the vagaries of cardiac output calculation on this basis are such that the measurement is generally ignored. The unreliability of the Fick method when carbon dioxide is used is related to the fact that small changes in ventilation strongly influence carbon dioxide storage by the body and a steady state is hard to reach.

The direct Fick method was first employed in man in Germany in 1929 by Forssmann, who experimented upon himself, and a little later by Klein, Courmand, and his associates established the safety of the procedure and stimulated widespread utilization of the method. The technique of cardiac catheterization has been described in detail by Courmand, Sosman, and Dexter. A sample of mixed venous blood is drawn from the pulmonary artery by means of a urethral catheter (No. 7 or 8) passed up an appropriate arm vein. The introduction of the catheter is guided by X-ray visualization (fluoroscope). A sample of arterial blood is obtained by arterial puncture. The blood samples can be analyzed for their oxygen contents and after the total oxygen consumption has been determined in the usual way, calculation of the cardiac output is made from the formula already given. The oxygen contents can be measured with the Van Slyke apparatus or for more rapid determination a photoelectric method has been developed which is only slightly less accurate than the Van Slyke (fig. 18.5A). Blood for analysis is drawn through a cuvette which is transilluminated by a constant intensity light source. The light passing through a 628 filter falls upon a photomultiplier tube. This method has a high degree of accuracy and has proved only slightly less accurate than the Van Slyke procedure.

The method presupposes that the oxygen consumption and the A-V oxygen difference are obtained simultaneously and are constant during the time of measurement. Both cardiac and respiratory cycle changes in the concentration difference of oxygen and the flow rate are capable of introducing large errors in cardiac output calculations. These changes do not appear to occur to any significant degree in man under normal circumstances.

A potentially serious error of the Fick applica-

tion arises from storage in, or liberation of, gas from the body including the lungs. This would occur when the relation of aerobic to anaerobic metabolism of the body is altered and, thus, the level of blood oxygen would be altered without relation to blood flow. Thus, the Fick calculation is dubiously related to cardiac output as the organism goes into or comes out of an anoxic state or in the presence of congenital heart disease with cyanotic episodes. In the latter instance, the shunts between the pulmonary and systemic circuits induce rather large errors in calculation of systemic flow. Special formulas have been developed to calculate the volume of blood flow through such shunts.

Cardiac output determined by the Fick method probably has an error of ± 10 per cent when very carefully done. However, it is to be remembered that cardiac catheterization gives rise to considerable apprehension and may in itself abnormally increase the cardiac output values.

B For cardiac output with foreign gases Most of the early figures for cardiac output were based on the Fick principle using a foreign gas. For this, the lungs are used as a gas aeronometer to measure the gas tensions of mixed venous blood and, hence, its gas content. A subject breathes an inert foreign gas (i.e., one which becomes dissolved in plasma but does not combine with hemoglobin, lipid or other constituents of the blood). If the rate of gas absorption by the blood, its alveolar tension and its stability in blood are known, then the quantity of blood which has passed through the lungs can be calculated.

Flow

$$= \frac{\text{rate of gas absorption}}{\text{alveolar concentration of gas} \times \text{blood solubility}}$$

This is the principle upon which a foreign gas method is based. Nitrous oxide (N_2O), ethyl iodide ($\text{C}_2\text{H}_5\text{I}$), and especially acetylene (C_2H_2) have been used in the past. The main difficulty of the method is that equilibrium between alveolar air and the venous blood must be effected before recirculation. Originally, it was felt that the circulation time was 25 to 30 seconds, and hence, that a respiratory mixture could be left in the lungs for that length of time without exposure to recirculated blood. However, the correct figure for circulation time is much shorter, 10 to 18 sec., which is often an insufficient time for equilibrium to be established, hence, the figure for resting cardiac output of 2.2 liters M^2 per

minute established by this method is often lower than the normal figure and, at times, grossly in error. Recently nitrous oxide has been used to estimate not only cardiac output but the instantaneous capillary blood flow since it is so soluble that it is immediately picked up by blood entering the capillary bed of the lungs (fig. 18.4A). If a subject is in an airtight chamber and takes and holds a single breath of N_2O for 8 to 10 sec., the chamber pressure falls at a rate which indicates the rate of absorption of the gas by the blood and, consequently, the rate of pulmonary capillary blood flow or cardiac output. Recirculation is not a problem during this short time. The instantaneous rate of blood flow can be calculated since the rate of N_2O absorption, the alveolar gas tension and its blood solubility are known.

C For regional blood flow Of the methods considered, except for the electromagnetic flow meter and sonar techniques, measurements of volume of blood flow passing through the splanchnic bed or kidney cannot be made directly even in experimental animals without destructive surgical procedures or unphysiological interference with function. The Fick principle has been used to determine mean blood flow in man and animal through the liver, and kidneys as well as the coronary and cerebral circulation. The introduction of venous catheterization has made it possible to obtain blood issuing from the hepatic vein in intact animals and man, thus permitting the development of methods of measuring flow on the basis of the Fick principle. Bromsulphalein (BSP) has proved especially useful here because it is taken up by the liver with remarkable efficiency. Of the total removed from the blood each minute, when the plasma BSP concentration is maintained by constant intravenous infusion below 2 or 3 mg. per cent, no more than 5 per cent can be attributed to escape through extrasplanchnic portals. For practical purposes, therefore, the hepatic removal of BSP equals the rate of infusion as long as the plasma level is constant. The splanchnic blood flow may be calculated by dividing the removal rate by the difference between BSP concentrations in peripheral arterial and hepatic venous blood. The flow value is generally referred to as the estimated hepatic blood flow since sampling is made in only one of several hepatic veins. A number of other substances such as Rose Bengal and I^{131} , have been used in the same way to measure splanchnic blood volume.

Similarly, the blood flow through the human kidney can be determined. Diodrast, when in low

FIG. 184 Left Diagram illustrating the principle of measurement of pulmonary capillary blood flow (DuBois, *J. Clin. Invest.*, 1957, 36, 1566) Right Graph indicating typical nitrous oxide saturation curves obtained in determining coronary flow per 100 grams per left ventricle per minute in dog. Upper curve from carotid artery, lower curve from coronary sinus by catheter (Gregg, *Coronary circulation in health and Disease*, Lea & Febiger, Philadelphia, 1950)

concentration in the plasma, undergoes virtually complete clearance, i.e., it is removed from the plasma in a single passage of blood through the kidney. This substance is excreted largely by the tubules, only a small fraction (about 16 per cent) being filtered through the glomerulus. Knowing the amount excreted in the urine within a time, and the plasma concentration, the quantity of blood that has passed through active renal tissue can be calculated. For example, if 600 mg of diodrast are excreted in the urine per minute, and each milliliter of plasma contains 1 mg, then to deliver 600 mg of diodrast, 600 cc of plasma went through the kidney, or with an hematocrit of 40, about 1,000 ml of blood flow. Diodrast can be used in a similar way to estimate renal blood flow.

Mean blood flow has been successfully determined through the coronary circulation with nitrous oxide inhalation and through the cerebral circulation with nitrous oxide or krypton inhalation. It is the only method available for such studies in man (fig. 184B). In use in the heart or brain, several simultaneous arterial (any artery) and venous (coronary sinus for the heart and the internal jugular vein for the brain) samples are drawn from the beginning of N_2O inhalation (mixture of nitrogen, 64 per cent, N_2O , 15 per cent, O_2 , 21 per cent) to the time of its equilibrium in the bloodstream or during denitrogenation after previous inhalation of the nitrogen

mixture. Continuous simultaneous samples can also be drawn from the artery and vein for analysis. The flow per unit of time through these organs is equal to the amount of the substance taken up by that organ in a given time divided by the difference in concentration of the substance in the arterial blood and venous drainage of the organ in the same time period. The flow is determined by dividing the nitrous oxide uptake by its arteriovenous difference in the brain or left ventricle. The denominator in the Fick equation is found by computing the integrated difference between the concentrations of N_2O in arterial and venous blood during the period of equilibration with a low concentration of N_2O . The concentration of gas in the tissue at the time of equilibration (the numerator in the Fick equation) is unobtainable directly and is assumed to be equal to the product of the venous blood concentration of the gas (after equilibrium is established) and a partition coefficient (1.0 in case of the heart and 1.3 for the brain). When the equation is multiplied by 100, units for blood flow are obtained which are expressed as cubic centimeters of flow per 100 grams of heart or myocardium.

As compared to direct measurement of cerebral and coronary flow with a rotameter, the method shows a reasonable accuracy and, in humans, has furnished almost all of our information regarding the cerebral and coronary blood flows.

INDICATOR DILUTION PRINCIPLE The principle

is based on observation of the rate at which a known quantity of material introduced into a vessel or heart cavity is diluted by blood flow through the vessel or cavity. In the principle as originally applied by Stewart and modified by Hamilton, it has been shown that the average rate of blood flow can be stated

$$F = E / \int_0^{\infty} C dt$$

where F = average rate of flow, E = total quantity injected, C = instantaneous concentration of the injected material. From this relationship, it is possible to determine the average flow rate in almost any cavity or vessel of reasonable size if the amount of injected material is known and if the concentration time function can be accurately determined.

For good quantitation, however, various precautions are necessary. The procedures and indicator substances used must cause little discomfort or injury, minimal volumes of added solution or volume of blood should be removed for analysis. In addition, the indicator should stay inside the blood vessels between the points of injection and sampling (such loss would be calculated as an increment of flow), the indicator should not diffuse into or out of red cells during its passage. Dilution of the indicator in the cavity or vessel can be determined in the same cavity or a small distance downstream in the vessel, or far removed from the injection site. In all cases, and especially the first, the injection must be made almost instantaneously, and in most sites, the injection should be made with special apertures in the catheter tip so that turbulence is induced and mixing is immediately complete and sampling is on an accurate dilution basis. This in itself leads to certain difficulties when the injection is made into the systemic circulation. It has long been known that rapid intra arterial injection is followed by some hemolysis which liberates vasoactive substances. This gives rise to a vasodilation sometimes of considerable magnitude in the organs deriving their blood from the ventricle, aorta or artery in question, so that the quantity to be measured is altered at the very moment it is measured. Thus although the methodology may give correct flows they are too high. This obstacle is difficult to circumvent.

A. Indicator substances. A variety of indicator substances have been used to modify, in a quantitative way, the optical, electrical, thermal, and radioactive characteristics of the passing blood.

(1) The optical density of the blood has been

altered by the injection of plasma and dyes such as brilliant vital red, Evans blue (T 1824), Cardio green and Rio 1743. The latter two dyes are especially useful since they have a high extraction value around the isobestic point of reduced oxyhemoglobin at 805 m μ and, therefore, they do not require constancy of oxygen saturation of the blood as do the other dyes. Thus, with their use the blood flow in cyanotic patients or in the veins of normal subjects can be determined. Of course, constancy of hemoglobin quantity in the light path is required during the registration of each dilution curve. (2) The electrical conductivity of the blood has been changed by injection into it of hypertonic salt solution (fig. 18.5B). It is critically important that calibration of this method be done with exactly the same blood and injection solution whose mixing is actually recorded. Following salt injection the increase in electrical conductivity is due partly to the increase in sodium chloride concentration and partly to red cell dilution. (3) A thermal dilution technique has been employed in which cool (18 to 22° C) sodium chloride or 5 per cent glucose has been injected. One must be very careful of the obvious possibility of heat exchange between the cold injectate and the warm tissues of the central circulation. (4) Changes in radioactivity of the blood have been induced by the injection of radioactive inorganic P³², radioactive iodinated serum albumin, organic radioactive iodine, D₂O, potassium⁴² chloride, Rb⁸⁶ chloride and 4 iodoantipyrine (I¹³¹).

B. Indicator detectors. For recording continuously the different properties of arterial blood which are changed by such injections, four types of detector are used. One type is inserted directly into the bloodstream through the vessel or cavity wall in a needle or catheter. This is used to indicate changes in conductivity (conductivity cell), in temperature (thermistor), and in the optical density of the bloodstream to the right ventricle. A second type of detector encloses a segment of unopened vessel monitoring changes in conductivity or optical density of the bloodstream using a photocell. In a third type the blood is pushed or pulled through an indwelling tube, after which it is discarded or mixed or analyzed or returned to the body by vein or artery (fig. 18.5A). This is the most widely used and follows optical changes and radioactive emanations of the blood. The changes in optical density and radioactivity concentration are detected by having the blood flow continuously, in the first case, by a photocell or photomultiplier tube and, in the second case, by a continuous scanner. Analysis can also be

FIG 185 Left Drawing showing principle of the densitometer used to determine instantaneous cardiac output and continuous blood O_2 saturation Right Principle by which change in blood conductivity in a ventricular cavity is used to determine diastolic ventricular volume and stroke volume

made with the Beckman spectrophotometer and counters on multiple individual samples taken every second. The fourth type, easiest but empirical, is applied to the external intact skin to obtain a curve of radioactivity or transillumination of the pinna of the ear for opacity changes. This type is obviously subject to many uncontrollable difficulties for much unrelated tissue is interposed between the detector and area in which flow is to be measured.

C Uses The various approaches have been used in a variety of situations. In general, the conductivity method has been used for determining cardiac output and diastolic volume of the heart; the thermal, dye, and radioactivity methods for cardiac output and flow in arteries and veins. In addition, the radioactivity method has been applied to the fractional distribution of cardiac output to various organs of very small animals (as well as large animals). For this, simultaneous measurement of the flow fractions to the organs is based on the principle that for a short time (6 to 60 sec.) after a single intravenous injection of any foreign substance, the organ reservoir for its dilution is so large in relation to the inflow rate of the substance that it does not appear in the venous circulation and, consequently, its extraction ratio is 1. The substance is, therefore, distributed in the same manner as the cardiac output. Although sound in principle, the accuracy of the method has not yet been established. It would be expected to furnish only very rough values because of the anesthesia and trauma associated with the determination of the isotope content of the individual organs.

Figure 18 6 illustrates the principle applied to

determination of cardiac output in the unanesthetized human. In this approach a tracer material (Evans Blue dye, T1824) that affixes itself to the albumin of the blood plasma is introduced into the large veins near the superior vena cava and the diluted material that issues from the heart is continuously sampled at a peripheral artery (radial). This blood is drawn at a constant rate through the cuvette of a densitometer which gives a continuous record of the changing optical density of the blood induced by the injected dye. The dye dilution curve is plotted at one second intervals as the logarithm of deflection against time and the straight line down-slope is extrapolated to 1.0 mm. deflection. The average height of this plot, calculated by area per unit of time is then converted to an average concentration of dye in milligrams per cc. by means of the calibration curve and this value is used in the formula for calculating the cardiac output.

Most work with indicators deals with what happens when a "slug" of indicator is introduced as rapidly as possible. A variation of this procedure is to give a constant rate of infusion of the indicator, and to observe its resultant plateau. Experiment and theory demonstrate, however, that such an equilibrium concentration or plateau is a very dubious possibility (fig 18 6). This is because recirculation of the indicator prevents attainment of a plateau, and the curve must begin to rise, because of this, before it has stopped rising toward the equilibrium level. On the other hand, recirculation is easily detected with the "slug" injection technique.

The indicator dilution technique especially dye dilution, is a standard procedure for measuring

Fig 18.6 Concentration curves resulting from continuous infusions of brilliant vital red (BVR) and rapid injection of T1824 (Evans Blue) both started at zero seconds. Short horizontal lines and figures denote the expected concentration plateau levels of the continuous infusion on the basis of instantaneous injection (I) or the measured flow (M) plotted on three logarithmic decades (Hamilton *et al* Am J Physiol 1953 175, 173)

cardiac output. Its accuracy is about the same as that of the Fick procedure. It has the added advantages that cardiac output can be determined from only a few heart beats and it is not neces-

sary to immobilize the subject because of the presence of an intracardiac catheter. cardiac output measurements can be made during violent exercise on a treadmill.

PLETHYSMOGRAPHY This is based upon the principle that if the venous return from an organ is occluded, any change in volume of the part which results during the period of occlusion must represent the amount of blood which has entered the part during that period. This change in volume presumably approximates the normal inflow into the organ if its venous outflow had not been occluded, since the major portion of volume in a vascular bed is on the venous side and because it can take up large volumes of blood with minimal change in pressure. Still, the time during which the vein is compressed and, consequently, the duration of the observation must obviously be brief, for interference with the venous flow will quickly slow the bloodstream and give a fallacious result. In use, an organ with its blood vessels intact is placed in an air tight chamber. At the point where the vessels enter and leave the chamber, a soft material, e.g., sponge or tow packing smeared with vaseline, is used to form a hermetic seal but does not compress the vessels. A tube leads from the interior of the chamber to a tambour and recording apparatus. The excursions of the latter are calibrated to represent cubic centimeters of blood. To estimate the blood flow, the vein is suddenly clamped and the increase in volume of the organ recorded over a short period. This method has been adapted by Hewlett and Van Zwaluwenburg and others, to the estimation of the volume flow in the human hand and forearm. The chamber is filled with air or fluid. A narrow cuff encircling the upper arm is employed to compress the veins (fig. 187). A number of variations of this type of plethysmograph, for the finger, toe and leg, on the same principle have been designed. Recently consider-

able doubt has been thrown on this classical method of measuring inflow by Gaskell and Burton, who found that the very act of collecting blood in the vessels of a part (toe or finger) by distending the veins by change in limb posture, reduced the rate of arterial inflow and this was ascribed to a veno vasomotor reflex from vein to artery. However, Greenfield and Patterson found no evidence for this in the forearm in which inflow was unaltered in the presence of venous back pressure sufficient to increase the resting forearm volume by 2 per cent.

Although no entirely satisfactory method is yet available, ventricular volume in systole and diastole has long been determined by some form of plethysmography. It is not necessary to occlude the inflow or outflow since the heart induces by its contraction change in its own volume (fig. 188). The plethysmograph or cardiometer is applied around both ventricular cavities in the isolated heart, heart lung preparation or the open chest dog. Changes in external volume of the ventricles create small pressure changes within the cardiometer which are recorded and calibrated against ventricular volume. Under special circumstances it is used to determine cyclic changes in right and left ventricular volume separately. The change in volume of the left ventricle alone can be recorded in the open-chest dog by shunting the systemic flow around the right ventricle; similarly, right ventricular volume change can be followed where there is total cardiac bypass using a heart lung oxygenator and in which the only blood supply to the heart is through the coronary arteries which eventually drain into the right ventricle and leave the left ventricle unchanged.

FIG. 187 Diagram showing Hewlett and Van Zwaluwenburg's method for estimating the rate of blood flow in the arm. (After Hewlett and Van Zwaluwenburg.)

QUALITATIVE OR EMPIRIC METHODS There are a number of methods using sound principles but which, because they must be applied in a biological environment rather poor for their operation, give qualitative or directional trends or which achieve their degree of validity from constants derived by comparison with a primary method.

A The ballistocardiographic method This method for determining cardiac output was originated by Henderson many years ago and has been elaborated and modified in recent years by Starr and his colleagues. The cardiac output is calculated from the record made by the recoil of the body caused by oppositely directed movements of the heart and by the impact of the blood during systole. It involves the basic principle that "every reaction has an opposite and equal reaction." The apparatus or ballistocardiograph consists of a table suspended in different ways and braced to prevent any but a horizontal movement in the long axis of the body (fig. 189A). The patient lies supine on the table with his feet braced against a footboard. The movements of the table are opposed by a strong spring and magnified greatly. The normal ballistocardiogram shows three principal waves H, I and J, inscribed during systole. The stroke volume is calculated from the areas of the waves I and J, and by applying the following formula

$$\text{Stroke volume} = 7\sqrt{[I + J] AC / 23}$$

where I and J are the areas of the waves so designated, A is the diameter of the aorta (calculated from age and surface area according to Bazett's data) and C the duration of the cardiac cycle; the minute volume is obtained by multiplying the value of the stroke volume by the pulse rate. Different correction values are needed to apply to such calculations to make them match the accepted cardiac output values obtained simultaneously in normal and disease states.

This method should not be used for cardiac output. Such calculations of cardiac output from ballistic waves must be on an empirical procedure which cannot give valid values since, although the usual ballistocardiogram represents movements along the longitudinal axis of the body, the blood ejected from the two ventricles moves simultaneously in several directions (3 dimensions) after leaving the heart. Since the amplitude of the deflections is influenced by the rate of blood acceleration, variation in pattern should reveal changes in force of ventricular contraction.

It should, therefore, be possible to recognize empirical relationships between different types of cardiac dysfunction and characteristic ballistocardiographic patterns.

B X-ray kymography An indication of possible directional changes in ventricular blood volume has been obtained in various ways. The area of shadow on x-ray film during diastole has been used as a cross section of the whole heart, and a fairly accurate nomographic chart of the relation of this heart shadow to cardiac volume has been worked out for the anesthetized dog. Planimetric measurements of a cross section of either the right or left ventricular cavity during systole and diastole have been made from successive motion picture frames following injection of contrast medium into the right ventricle through a cardiac catheter or into the left ventricle by retrograde catheterization by way of the carotid arteries and the aortic valves. Except in the first instance these methods have never been validated against a direct measurement. Hence interpretation of results with their use should be made with great caution unless the change in size of the cardiac silhouette is very large.

C Pulse pressure From the time of Erlanger and Hooker, a large amount of experimental work has been applied to the development of the possibility that the product of heart rate and the systolic pulse pressure to an organ (and especially in the case of the central aorta to the body as a

FIG. 188 Schematic drawing showing cardiac plethysmograph. A rubber cuff secures the chamber to the base of the heart at the A-V ring. Pressure volume changes are tapped from the small outlet and recorded as in figure 187.

FIG 18-9 *A* Schematic showing the ballistocardiograph and typical ballistocardiogram (Modified after Rushmer *Cardiac Diagnosis* W B Saunders Company, Philadelphia 1955) *B* Principle of Whitney gauge as applied to a ventricle. As the mercury filled rubber tube changes in length its electrical resistance is altered (Whitney *J Physiol* 1953 121, 1) *C* Variable inductance gauge used to measure a ventricular dimension (Rushmer *Circulation Res* 1954 2 14) *D* Sonar principle used to measure a ventricular dimension (Rushmer *Circulation Res* 1956 4, 634)

whole) might quantitatively represent the blood flow through that organ. To do this effectively, one must know the volume of blood required to expand the arterial tree as the pulse wave passes out over the arteries and the volume of blood which drains out of the arterioles during systole. Such pressure-volume curves should be linear, if possible, but at least must be constant among animals or individuals. The distensibility of the four main divisions of the arterial tree (aortic arch, head, viscera and legs) and the effective pressure change in each area brought about by

the pulse wave have been laboriously determined in animals and the arteriolar outflow during systole calculated from Poiseuille's law (see ch 15), on the basis that it is the product of the prevailing pressure and flow, with the assumption that the arterioles do not change in diameter. In dogs the pulse contour method gives results which compare reasonably well with those obtained simultaneously with the Fick dye injection, or rotameter method. However, there are many circumstances in which the values are poor, such as in the presence of high aortic diastolic pres-

sure, and following prolonged venous stasis. Why the distensibility of the arterial system varies spontaneously under circumstances such as these and others, is not known. In humans the attempt has been made to "calibrate" the distensibility of the subject's arteries before an experimental investigation by first making an actual cardiac output measurement with the Fick or dye dilution technique. This is not helpful for it assumes that thereafter arterial distensibility will not change, a highly unlikely assumption.

A Plethysmography Two types of plethysmographs, the electrical impedance and the mercury rubber strain gauge (Whitney gauge, fig 18 9B) have been used successfully for indicating the blood flow through the extremities of man or animal. In principle, the electrical impedance plethysmograph measures the change in electrical conductivity of an extremity induced by the changing number of ions brought to the segment by the heart action, i.e., the electrical impedance is a function of the volume of the part. Without venous occlusion, this represents volume pulsation of the extremity, with occlusion, the inflow of blood. For the Whitney gauge, a delicate rubber tubing is filled with mercury and sealed at each end with insulated wires. It is wrapped around a finger or arm of man, or the aorta, left or right ventricle of the unanesthetized dog. Lengthening of the gauge reduces the cross-sectional area and increases the length of the mercury column producing a corresponding increase in electrical resistance. The gauge forms one arm of a Wheatstone bridge. An index of ventricular cross-sectional area has also been obtained in active unanesthetized dogs by measuring the change in inductance of a variable inductance gauge implanted in a ventricle (fig 18 9C), by the change in transit time of sound waves across the cavity (fig 18 9D), and by the use of an electromagnetic principle.

A third type of plethysmograph utilizes a photocell to detect vascular changes by the absorption of light from transilluminated skin. Light from an illumination source enters the skin and scatters, the resulting variations in the photoelectric current caused by changes in blood flow can be recorded. Blood flow in skin areas, not accessible by other means, can be estimated by this method. The amplitudes of the photoelectrically recorded cutaneous pulses may be calibrated by use of a 'filter' and correlated with finger blood flow measured by other methods. However, the volume pulse depends on the relationship between arterial inflow and venous

outflow and, at best, is only a qualitative measure of actual blood flow.

B Isotope clearance A small amount of radio active ion (Na^{24} or I^{131}) is injected into a tissue such as muscle and the rate of clearance from the area is then followed by a counting device. There is doubt that this measures blood flow since, in some instances, the rate of clearance does not parallel the blood flow simultaneously measured.

C Thermal methods Devices using the principle of heat clearance have been widely used to indicate directional changes in blood flow in a localized area of skin, muscle or internal organ or through part or the whole of an extremity. One type of device consists of a thermocouple or thermistor (connected in series with a reference thermocouple or thermistor) mounted in the end of a hypodermic needle. The needle is inserted a variable distance into the tissue and a constant source of heat is used to raise the temperature of the test thermocouple 2 to 3° C above tissue temperature. The temperature difference between the test and reference junctions is essentially determined by the heat output of the heater and by the carrying away of the heat by the blood flow. The more rapid the blood flow, the smaller will be the junction temperature difference. A variation of this arrangement is to supply a variable amount of heat to the test junction at a rate just sufficient to maintain a small difference in temperature between the heat source and the reference junction. As blood flow through the tissue increases progressively higher rates of delivery of heat will be required to maintain this constant temperature difference between heat source and "heat sink." The "rate of flow" will follow the magnitude of the electric current supplied to the heat source.

A second type of device has been much used in recent years to measure blood flow through part or all of an extremity. It is based on the thesis that when the limb is in a water bath, the blood flow is equal to the amount of heat given out to the water, divided by the temperature difference of arterial and venous blood, times the specific heat of blood. However, the arterial-venous temperature difference is not measurable, and there is no guarantee that the ingoing and outgoing temperature reach water bath temperature. A variation is to circulate the water and to measure the heat exchange from the volume of water flow and temperature difference. As with the thermal needle, an index of blood flow can also be obtained by setting the calorimeter water

temperature below mouth temperature and then measuring the amount of current necessary to keep the bath temperature constant

This approach has been found very useful and has given much valuable information despite the facts that there is no good way of calibrating the deflections against known blood flows, zero flow is difficult if not impossible to obtain, in the case of the needle, the surrounding tissue is not normal and in addition to capillary flow, the device may be affected by flow in nearby veins

D Oxygen electrode When a very small negative voltage is applied to a metallic electrode in a solution containing dissolved oxygen, there is a reduction of the oxygen at the electrode surface resulting in a small flow of current through the electrode. At such a voltage, the oxygen is reduced as quickly as it reaches the electrode surface and a straight line relationship exists between the oxygen concentration and the current that flows. In use, a platinum wire protrudes through a fine glass tip inserted into the skin, mercury makes contact between the platinum and the circuit. It is assumed that the electrode is in contact with a number of capillaries and that as blood flow increases, it will indicate the rising oxygen tension in the tissue. This has been used to indicate blood flow in the skin, skeletal muscle, and myocardium. It is at best a qualitative indication of tissue blood flow and has most of the disadvantages of the thermal methods.

Blood Velocity

Of the two measurements, volume flow of blood in milliliters per minute and the velocity of flow in centimeters per second, the former is probably more important. The major function of the circulation is to supply the metabolic needs of the tissues and volume flow is closely related to this, whereas measurement of velocity of flow alone does not necessarily tell us anything about the blood supply to the tissues. Despite this, knowledge of the flow velocity is highly important to an understanding of hemodynamics of the circulation. Flow velocity measurements have been made under direct vision, by use of the various flow meters that have been described, by observation of movement of injected substances, and finally, by determination of the differential pressure within an unopened and unrestrained vessel.

VISUALIZATION There is a natural tendency to assume that when one actually sees the movement of blood within a vessel, this must supply

the most certain evidence. However, when this is done, one tends to be impressed by the movement of the red cells and not by that of the blood as a whole. Even if this were not so, there is not necessarily any relation between the observed velocity and volume flow. For example, in the presence of local constriction in a vessel without constriction in other areas, flow velocity will increase, but flow will decrease. In the presence of general as well as local constriction, velocity and volume flow will both decrease.

FLOW METERS By insertion into or application on to a blood vessel of almost any of the flow meters described, one automatically measures the velocity of flow since the meter insures a fixed diameter through which the flow occurs. This is because $V = v/\pi r^2$, where V = velocity in millimeters per second, " v " = volume flow of blood in milliliters through the meter per unit of time, and " r " the radius of the vessel. For example, if a large rotameter is used to quantitate aortic flow and the flow is 3,000 ml per min, vessel diameter is 2.4 cm, then the velocity approximates 12 cm per sec.

MOVEMENT OF INJECTED MATERIALS Various noteworthy attempts have been made to follow cyclic changes in velocity in the unopened vessel by recording the movements of various injected foreign materials such as air bubbles, dyes, and x-ray opaque fluid. This is a difficult technique since the moving front of the injected material, i.e., the difference of optical density between blood and the contrasting medium, is often difficult to detect. This is because the velocity is not the same at different points along the radius of the blood column, the flow being much greater in the axial part of the stream than toward the periphery, and also because the flow is not always unidirectional. This gives the mean or average velocity which is derived from the flow indicated by mean flow meters. It, of course, ignores very large fluctuations in velocity which occur during a cardiac cycle. The moment-to-moment or phasic velocity is recorded by those pulsatile flow meters whose frequency of response is sufficiently rapid to follow it.

DIFFERENTIAL PRESSURE VELOCITY The instantaneous blood velocity has been determined in the aorta and arteries from the instantaneous pressure difference between two points located along the axis of flow or along the vessel (ch 15, fig 159). Such pressure gradients have been measured by simultaneous recording of arterial pressure at the two points either with individual pressure manometers or by use of a double lumen

catheter attached to a differential pressure strain gauge. In the double lumen catheter which has been used in the aorta of humans, the lateral opening of one catheter tip opens at a point about 5 cm from the other. From the pressure gradients, velocity curves and flow curves have been calculated which agree well with those directly measured. A consideration of this highly technical approach is beyond the scope of this section.

A rough approximation to mean linear aortic velocity in man can be made from the use of the cardiac output and the cross section of the aorta of a man of this size in a cadaver. The velocity in centimeters per second =

$$\frac{\text{cardiac output}}{\text{cross sectional area}}$$

Circulation Time (C.T.)

By this is meant the shortest time which a particle of blood takes to go from one point in the circulation to another. It is obvious that there are as many circulation times as there are vessels or regions in which to make the measurement. Circulation time is, however, most often determined for a portion of the circulation, such as, from the right to left side of the heart.

The circulation time of a particle of a substance can be accurately determined if it is injected instantaneously into a blood vessel, if it moves at the same rate as the blood stream and if its arrival further down the vessel is accurately detected. Practically, the situation is much more complicated. When a reasonable amount of a substance is injected, its arrival time is so spread out at the downstream detection point that detection is difficult. If the circulation time is made across an organ or a major portion of the circulatory system, the spreadout is even greater. In addition, if all the blood channels between the two points are not approximately uniform in length and diameter, only a part of the blood will pass from point to point at the rate indicated by the measurement. Despite these considerations, measurements of circulation time can be semi quantitative.

The clinical methods for estimating circulation time use injected substances, such as, decholin and ether that signal their arrival by effects on special receptors, such as, the tongue. With decholin, the normal range of arm to tongue (bitter taste) time is 8 to 17 seconds, with ether, the normal arm to lung (patient first smells ether) is from 4 to 8 seconds. For greater precision in

FIG 18 10 Schematic diagram illustrating the relation between circulation time, volume flow, and the volume of the vascular bed

experimental investigations, these classical methods have been superseded by the injection of dyes and radioactive tracers whose arrival is easily and objectively detected by densitometers, conductivity cells and isotope counters. The main technical difficulty is the proper calculation of the average transit time. In a symmetrical curve, the mean (average of all transit times), the mode (time coordinate of the peak), and the median (time coordinate which halves the area) all coincide. But as the curve becomes asymmetrical, and particularly as the terminal portion stretches out more in time than the initial part, the three measures depart more and more from each other. The mean circulation time (MCT) it takes all dye to pass is computed as the center of gravity of the curve (fig 18 6).

The significance of a change in circulation time is debatable. The circulation time between two points in the vascular system is equal to the volume of the vessels between the two points divided by the flow (fig 18 10). The validity of this relationship has been checked in glass models and mathematically. From this, it is obvious that a change in circulation time could be due to a change in volume of the vascular bed between the point of injection and sampling, as well as to change in flow. Since change in flow follows any vasomotor change, and since the resultant redistribution of pressures causes local volume change, both numerator and denominator of the ratio for circulation time (volume over flow) change simultaneously. They generally change in the same direction, and so the circulation time could be a very poor indicator of blood flow, volume of blood or vasomotor change.

Volume of Organ, Vessel, Cavity and Region

Information is not abundant concerning regional blood volume, and the alterations that occur in normal humans and animals. Available

information is based largely on some form of calculation, on the use of some form of plethysmography, and on the use of the dilution technique

CALCULATION For example, the blood volume of a single capillary may be derived from measurement of its length and diameter by microscopic inspection. Calculation of the total cross sectional area of the capillary bed in man is based on the fact that the same volume of blood going through one part of the vascular bed, such as the aorta, goes through the total capillary bed, i.e., cross sectional area of aorta times average velocity in the aorta = cross sectional area of the capillary bed times the average velocity in the capillaries. Since the aortic velocity and cross section and capillary velocity (by inspection) can be determined experimentally, then cross section of capillaries =

$$\frac{\text{cross section of aorta} \times \text{aortic velocity}}{\text{average capillary velocity}}$$

PLETHYSMOGRAPHY The plethysmographs used are those already described to determine volume flow, but they are used without local venous occlusion. These have been used successfully on the heart, liver, spleen and vessels of animals. Dimensional, cross sectional or possibly directional change in volume have been obtained in unanesthetized active dogs with the use of some of the various gauges previously described, for the heart cavities, large arteries and veins, the impedance plethysmograph, sonar cardiometer, strain gauge arch, Whitney gauge and mutual inductance coils have been used, for organs, there are used the sonar cardiometer, impedance plethysmograph and Whitney gauge. Most of these techniques are not applicable to man except under unusual conditions. However, determination of variations in blood distribution in man can be made to some extent using plethysmography. For example, changes in quantity of blood in the lower extremities are determined by measuring the volume of the legs after occlusion of the circulation by applying pressure cuffs to the thighs and inflating them to a pressure greater than arterial. Changes in the quantity of blood in the trunk are determined by recording simultaneously the trunk volume with a plethysmograph and determining any change in pulmonary air volume by a spirometer. Variations in average blood volume in the heart are established by estimating the heart volume by x ray. Values obtained by these techniques are admittedly rough

but are helpful in establishing large directional or qualitative shifts in blood distribution resulting from change of position, fainting, injection of drugs, etc.

The plethysmograph is also used to measure the pressure volume characteristics of the distensible venous system in a limb segment. The pressure in a constricting cuff on the limb proximal to the plethysmograph is increased 30 mm Hg by increments of 5 mm Hg and the corresponding increases in limb volume with each pressure rise are recorded. The effective venous pressure can then be plotted against the volume in a graphic representation of the volume of blood that the venous system will accept with a given change of effective venous pressure. Venous constriction or venodilation would result in lesser or greater distensibility, respectively, of the venous bed. Thus an alteration in venous volume, determined by this method, implies a change in venous tone assuming that the volume of a blood vessel varies directly with the effective intravascular pressure, if other factors are controlled.

DILUTION TECHNIQUE Provided certain conditions are fulfilled, the volume of a vascular compartment (cavity or vessel) can be measured in man and animal by analysis of a dilution curve obtained at the outlet of the compartment after rapid injection of an indicator at the inlet to the compartment. The blood content can be calculated from the following equation $C = Q(60/T)$ where C = the cardiac output per minute, Q , the quantity of blood, and T , the circulation time. Thus, the volume is represented by the product of cardiac output and mean transit time of the indicator particles, both values being automatically available when cardiac output is quantitated with the dilution technique as described earlier in this chapter.

Calculation of a central blood volume from the cardiac output and mean transit time obtained following the injection of the indicator has been used experimentally and clinically for many years. Its accuracy has been established mathematically by perfusion experiments, by model systems, and *in vivo*. In the latter, the above measurement in the anesthetized dog was compared to the determination of the actual amount of blood in the heart and lungs by injecting cells tagged with Cr^{51} and then calculating the local blood volume from the total radioactivity in the blended homogenate of these organs.

This is the only method presently available which can be used to quantitate regional blood

TABLE 18 I
Regional distribution of blood volume

Vascular Compartment	Site of Injection	Site of Sample
1 Systemic venous blood volume and right side of the heart	Femoral vein	Pulmonary valves
2 Right side of the heart	Superior vena cava	Pulmonary valves
3 Systemic venous volume (1 - 2)		
4 Lung and left side of the heart	Pulmonary artery	Aortic valves
5 Pulmonary artery to brachial artery	Pulmonary artery	Brachial artery
6 Left atrium to brachial artery	Left atrium	Brachial artery
7 Pulmonary blood volume (5 - 6)		

distribution in man. In addition to central blood volume, it has been used for cardiac volume, systemic venous volume, and other areas. For example, the systemic venous blood volume can be derived from a dilution curve recorded at the right atrium after injection into the femoral vein, the cardiopulmonary blood volume by injection into the right atrium and sampling at carotid artery or aorta. Since, however, in practice a major precaution is adequate mixing at the sites of sampling and injection, in most instances some what more accurate results are obtained by combinations of volumes in which adequate mixing is reasonably assured. The following table indicates how this may be accomplished.

BLOOD PRESSURE MEASUREMENTS

The development of adequate methods and the overcoming of instrumental obstacles are the essential preliminaries to the solution and consideration of problems dealing with the circulation. One must discuss the various devices and procedures that have been used to study the circulation and to point out their respective merits and shortcomings. Indication will be made of the degree of adequacy and the principles upon which a limited number of these devices operate. Such consideration should reveal the proper basis for the interpretation of the present and subsequent studies of the circulation.

Of the three principal attributes of the circulation, blood pressure, flow and blood volume, the pressure is most easily determined and recorded. Measurements in both man and animal are direct and indirect.

Direct Blood Pressure Measurements

In the direct approach, a catheter or needle is inserted into a vessel or heart cavity and connected to a hydrostatic column of fluid or to a special device. The pressures thus obtained have been quantitated and studied in almost all parts of the cardiovascular system of animal and man. Direct pressure measurements have value in determining certain aspects of function of the circulation. They should not, however, as is pointed out elsewhere, be used as an index of change in flow through or volume of a blood vessel or heart cavity. Whenever a change in volume is empirically deduced from a change in pressure, potentially active changes in caliber are ignored which are known to occur in every vessel except the capillaries.

MEANS OF PRESSURE PICK UP Most of these approaches have been worked out in acute experiments in anesthetized animals, but techniques are now widely used in chronic animal preparations and in humans without anesthesia, and both at rest and during physical activity.

In techniques used only on animals, various regions of the circulatory system are made accessible by a previous operation so that pressures

can be determined atraumatically and repeatedly over many months. These include the carotid loop (exteriorization of a carotid artery in a tube of skin) in the dog and rabbit; cardiopexy in the dog (attachment of the apex of the heart to the chest wall just under the skin to permit easy access to the left ventricle); an indwelling silver tube with one end sutured to the exterior surface of a vessel or cardiac cavity and the other end sutured just under the skin; an indwelling polyvinyl tube filled with heparin with one end penetrating a vessel or cardiac cavity and the other plugged end protruding from the skin. In the last instance, the tube is connected directly to the appropriate pressure transducer, in the others, a needle and/or catheter connected to a pressure transducer penetrates the vessel or cavity.

A number of techniques are also applicable to both normal man and animal without previous preparation. Needles and catheters can be passed into many accessible veins and arteries. For the right side of the circulation one procedure is to float a polyvinyl catheter with a balloon tip down the jugular vein into the right ventricle or pulmonary artery without benefit of fluoroscopy. The standard procedure, however, is to pass a catheter under fluoroscopy via the jugular vein (dog), or an arm or leg vein (human), into the venae cavae and their venous tributaries from the liver and kidney, or into the right atrium, right ventricle or pulmonary artery.

Various techniques have been used in man as well as in animals for direct measurement of pressures in the left heart which is not normally accessible. A catheter passed by the right heart and impacted in a branch of the pulmonary artery, is presumed by some, to give an approximation to the pressure in the venous end of the pulmonary capillaries. Other approaches include transbronchoscopic and transesophageal entrance for pressure recording from the left atrium, left ventricle and aorta, a percutaneous needle approach through the anterior chest wall for left ventricular pressure, retrograde femoral artery catheterization of the left ventricle through the aortic valves,

transeptal left atrial puncture. In the latter technique, the left atrium is punctured by a retractable needle introduced through a cardiac catheter passed up a leg vein, the tip of which is positioned against the interatrial septum.

MEASUREMENT OF NONOSCILLATORY OR NEARLY NONOSCILLATORY PRESSURES A vertical column of fluid with attached millimeter scale, and with some form of anticoagulant between it and the vessel whose pressure is being tapped is the only device needed to determine the pressure in most intravascular pressure regions. To measure the pressure, the column is filled from a side tube, and the column is then allowed to seek its own level by drainage into the vessel (fig 191). For the low pressure regions such as the venous system, atrium and pulmonary artery, the column is saline solution; for higher pressure as in the arteries, the column is filled with mercury to keep it short. This is generally in the form of a "U" tube. To minimize the pressure fluctuations the tubing between the mercury manometer and the vessel is constricted to dampen the oscillations. By placing a float with a writing point on top of the saline or mercury, the venous or arterial blood pressure can be continuously recorded. Such a

fluid manometer is the basic instrument for pressure recording and most complicated pressure devices are calibrated against such pressure indicators. Very often, complicated pressure devices are used when this simple arrangement would suffice. For measuring intravascular pressure in arterioles, capillaries and venules, cerebrospinal fluid and extravascular pressure in the tissue space in skin, muscle, kidney, subcutaneous tissue, etc., water or saline manometers are used in which little or no fluid enters or leaves the tissue space. This is very important for the addition or removal of even small volumes of fluid may grossly affect the absolute pressure level obtained. This consists of a small hypodermic needle attached to a horizontal glass capillary tube partially filled with sterile saline to a reference line. Except for the water manometer, the rest of the system is filled with air. Upon insertion into the tissue, the pneumatic bulb is compressed, and the meniscus is returned to the reference line when the pressure in the manometer equals the tissue pressure. A correction must be made for the capillarity of the system. This system may also, of course, be used to determine venous pressure.

Since the pressures in veins and extravascular spaces change slowly, they can be accurately indicated usually with these two simple fluid manometer systems. When the mercury filled manometer is applied to an artery, a pressure is recorded which is a rough mean of the existing intramural pressure but which does not normally exist as such. To accurately measure the widely fluctuating pressures during systole and diastole, in the arteries and in the ventricular cavities, or to continuously record electrically or photographically these, as well as nonoscillating pressures more complicated and sophisticated instrumentation is necessary.

MEASUREMENT OF PRESSURE PULSES The pattern of variation of pressure occurring with each heart beat (but not the pressure values) can be recorded from the surface of the accessible large arteries and veins without interference with them. In arteries, a crude representation of the pulse can be made by applying the principle that the relatively minute natural excursions of an artery are increased by applying a button with such a tension that the extra arterial approximates the intra arterial pressure. This amplified excursion of the vessel wall is further magnified by mechanical levers. In arteries, a more precise indication of the pressure pulse pattern is obtained by following the volumetric change in diameter of the

FIG 191 Method for measuring pressure in a superficial vein using a vertical column of saline

artery by means of a cup system placed over it. An open cup or receiver is firmly pressed to the skin over an artery such as the carotid and connected by tubing to a highly sensitive pressure recorder. For registration of the venous pulse, the patient is placed in the recumbent position to neutralize the effects of gravity, and a cup receiver is applied snugly over the right supraclavicular fossa or over the internal jugular bulb at the margin of the sternocleidomastoid muscle, or over the supra-sternal notch. In turn, this is connected by an air system to a sensitive pressure manometer.

Apparatus and requisite techniques for registering pressure curves in a proper manner have improved rapidly in the last few years because of increasing interest in cardiac catheterizations, chief improvements lie in the use of expedients for giving greater amplification, flexibility and ease of operation. The simple principles involved, however, are unchanged, and the classical curves of Wiggers and others, using older optical manometers, have not been improved upon.

Basically, all types of pressure apparatus involve measurement of the displacement of some type of elastic membrane which is moved by generation of pressure in a vessel or cavity. In one group of manometers, an essentially nondis-

tensible conduit (needle, lead tube, cannula or catheter) is filled with fluid and connected to the membrane outside the body, this, in turn, is connected to a form of amplification and recording. In the other, a micromanometer membrane or its equivalent is mounted in a catheter tip at the pressure source, and the catheter serves only as a conduit for wires to the amplifying and recording assembly (fig 19.2). The detection and transmission of the movements of the membrane can take place by mechanical, optical or electrical means, or by a combination of these principles. Owing to their technical imperfections, purely mechanical systems are now only of historical interest. Pretty much in the same category are manometers which combine optical and electrical systems.

Manometers with fluid filled conduit. *A. Optical manometers (fig 19.2).* In the case of the optical type of manometer (which was largely used until recently), the entire system consists of a stiff rubber or metal membrane of minimum diameter connected to a fluid filled conduit of high elasticity and of minimal volume, and which is inserted into the source of pressure variation. Movements of the membrane induced by pressure change are recorded by reflecting from an

FIG 19.2 Externally recording pressure gauges. *Left* principle of the classical optical method for determining biological pressures. A flexible short, nondistensible lead tube offering little damping effect, connects to the pressure source. *Center left*, capacitance transducer, *center right*, strain gauge transducer, and *right*, catheter mounted inductance transducer.

attached mirror a weightless beam of light as a lever to give rapid response with adequate sensitivity. A number of different forms of such manometers have been developed and widely used.

B. Electrical transducers The common feature of the methods dependent on electrical principles is that the movement of the manometer membrane is transformed into electrical energy which is then transferred to a recorder. In practice, the transformation of the pressure impulse is effected by a piezo-electric effect, or by a change in capacitance, resistance and inductance. The piezo-electric principle which depends on the difference in potential occurring in certain crystals exposed to mechanical pressure, is little used since stationary difference of crystal potential cannot be maintained and constant pressures cannot be accurately measured.

For most present day determinations of biological pressures, the pressure fluctuations in a cavity or vessel are transmitted as in the optical manometer through a long nondistensible catheter filled with fluid. This activates an electronic pressure transducer in which movements of a stiff membrane with minimal fluid displacement and high frequency produces a change in capacitance, resistance or inductance.

One of the first of the electronic pressure transducers was devised by Lilly (1942), in which a stiff metal membrane separated from an electrode by a very small air gap, formed a condenser. Movements of the membrane relative to the electrode vary the capacitance which is measured by a radio frequency circuit. This device is rather temperature sensitive and has considerable zero pressure drift (fig. 192).

The electronic transducer in most common use today is the resistance wire strain gauge. Strain sensitive wire responds to a change in pressure with a change in the resistance to flow of an electric current. A membrane is displaced by increased pressure in a chamber attached to the pressure source (fig. 192).

MANOMETERS MOUNTED IN AN EMPTY CATHETER TIP In this type of gauge, the pressure sensitive element is mounted in the catheter tip, the catheter contains no fluid, serving only as a conduit for wires leading to an amplifier. Inductance pressure gauges of this type are coming into use in which the variable mutual inductance between a pair of coils can be altered by changing the position of an iron core within its magnetic field. If the iron core connected to the center of an elastic membrane is mounted between two coils, move-

ment of the membrane moves the core within the coils, changing their inductance. Change in inductance, monitored by an appropriate bridge circuit indicates the extent of membrane displacement (fig. 192). This instrument was first devised by Wetterer and has been considerably modified and improved by others. The strain gauge principle has also been applied to a micromanometer mounted in the end of a catheter. In this, a strain wire wrapped around a metal reed with multiple longitudinal slits is stretched by the pressure source.

Both the inductance and strain gauge type of micromanometer faithfully record the pressure pattern but are difficult and expensive to build. Inductance gauges have been used in animals and, at times, in humans, but their use has been limited because it has not been possible to determine accurately the zero pressure with the Wetterer type. Although the strain gauge type does not have this disadvantage and has been used with some patients, its initial expense is more, and it has the added drawback that no way has been found to disconnect it from its catheter which wears out first.

AMPLIFICATION AND RECORDING The signal from the various pressure transducers (except the optical manometer) is amplified electronically to drive a high frequency galvanometer or oscilloscope. The devices used to record the pressure pulses are the optical manometer with camera, the direct pen writing galvanometer, the optical galvanometer, and the cathode ray oscilloscopic camera. Many types of pressure transducer amplifier combinations are available commercially. In terms of ascending order of frequency of response, the systems may be graded as follows: the direct writing galvanometer, the optical manometer, the optical galvanometer, and the oscilloscope. However, no ideal system exists at present. For any specific application the combination of transducer, recorder, and amplifier, is a compromise of sensitivity, stability, convenience of use, and frequency of response.

FREQUENCY OF MANOMETER SYSTEMS The accuracy with which a manometer system records change of pressure without lag and with correct phase relations depends on its natural frequency. Reasonably good reproduction of a wave form can be recorded by such a system which has uniform response to the tenth harmonic of its fundamental frequency. With a heart rate of 240 beats per minute, the pulse frequency is 4 per second, and its tenth harmonic is 40 cycles per second.

With such a frequency, rapid changes in pressure are fairly well recorded

The frequency response characteristics of the entire system of transducer, amplifier, and galvanometer must be determined rather than that of a component part, since the net frequency is limited by the lowest component of the system. The frequency of a manometer with a fluid filled conduit is governed by its effective mass and the elasticity of its membrane, i.e., frequency is increased by a decrease in the mass to be moved by the pressure and by a decrease in the size and distensibility of the membrane. In the case of the optical manometer, this is the sole determinant of frequency response since the rest of the system is a weightless light beam which does not affect the frequency. The normal frequency of such manometers is 120 to 160 double vibrations per second. In the case of the other types of manometer with a fluid filled conduit, the frequency is often limited as well by the type of recorder used and may vary from 5 to 100 cycles per sec. In the manometer in which the catheter is used only as a conduit for wires, the basic frequency is generally higher than in the other types and is determined solely by the characteristics of the membrane at the catheter tip since there is no fluid space central to the membrane.

The fact that a recording manometer system has an adequate frequency and sensitivity does not insure that the recorded pressures are free of artefacts. Impact of a cardiac cavity or vessel on the side or tip of the catheter very often leads to very large artefacts in the recorded pressure curve, which invalidates a goodly portion of records taken in catheterization laboratories for diagnostic purposes. In the manometer with a fluid filled catheter, this type of artefact is maximal and, despite all precautions, it is very often impossible to obtain technically perfect records. The response characteristics of such curves can be somewhat improved by "critical damping" through mechanically constricting the conduit system. However, this is not to be recommended since it is almost impossible to maintain a fixed degree of damping and slight increases in it completely deform the pressure curve. In the pressure manometers in which the membrane is mounted in the catheter tip, the phasic pressure patterns invariably are excellent and artefacts are almost nonexistent. This is the pressure manometer of the future.

STANDARD ZERO REFERENCE PLANE FOR PRESSURE MEASUREMENTS The numerical value obtained from pressure measurements in the cardio-

vascular system depends, of course, upon the horizontal plane to which zero pressure is referred. Most commonly, this has reference to the assumed level of the center of the atrium. The exact level is easy to establish in the open-chest animal or human, by adjusting the needle or catheter end attached to the recording manometer to the level of the midpoint of the atrium. This is zero pressure. When the chest is closed it is difficult to determine precisely the proper zero point of reference and to obtain comparable figures in different subjects or in a series of measurements. It is not surprising, therefore, that many different reference planes or levels have been used. Possibly, the one closest to the truth is that described by Winsor and Burch. The reference level or heart level used is an axis running transversely through the thorax at the point of junction of a plane passing cross sectionally through the fourth intercostal space adjacent to the sternum with a frontal plane passing midway between the posterior surface of the body and the xiphoid process of the sternum. Horizontal planes passing through this axis are the zero pressure reference levels to be used for that particular position of the patient.

This, however, measures the intravascular pressure against the atmospheric pressure as a reference. Most vessels are imbedded in tissues which have a significant tissue pressure that is either lower (in the thorax) or higher (in the abdomen and skeletal muscle) than the atmospheric pressure. For precise quantitation, the intravascular pressure should be measured against the extravascular or tissue pressure which is around the vessel. The terms, effective, transmural or net pressure, have been introduced to indicate the pressure difference between the intravascular and extravascular pressure. Precise determination of extravascular pressure is unreliable and the artefacts are especially large in measuring tissue pressure in solid organs, especially the heart, and least in recording pressure surrounding the great vessels and the heart. Intrathoracic pressure is taken as an approximation for the latter, but even here, calculation of transmural pressure must be made on the basis of the immediately contiguous intrathoracic pressure since regional intrathoracic pressure is quite variable.

Indirect Blood Pressure Measurements

Human

Although the blood pressure can be determined in man by the insertion of a hollow, wide bore needle into an artery and connecting it with a

suitable manometer such a method is usually reserved for human cardiopulmonary diagnostic work. Convenience and safety demand that any method for general clinical use must be indirect. The principle employed consists in balancing air pressure against the pressure of the blood in the brachial artery and then estimating the former by means of a mercury or an aneroid manometer.

The instrument used for this purpose includes a flat rubber bag covered by an undistensible envelope of cotton fabric. The cavity of the bag is connected by a length of rubber tubing with the manometer and by another tube with a hand bulb or small pump. By this means the bag can be inflated to any desired pressure. A small valve between the bulb or pump and the bag permits the escape of air and the reduction of the pressure as required. The uninflated rubber bag (usually referred to as the cuff or armlet) which should be at least 12 cm. wide is wrapped snugly around the upper arm just above the elbow. The bag is then inflated until the air pressure within it overcomes the arterial pressure and obliterates the arterial lumen. The pressure is increased a little beyond this point and is then cautiously reduced again by the release of the valve until the arterial pressure just overcomes the air pressure and blood escapes beyond the cuff into the peripheral section of the artery. At this instant the pressure in the bag is read from the manometer. Since the air pressure practically balances the systolic arterial pressure the manometer reading must indicate the value of the latter. It is essential in the method that the manometer reading be taken at the instant when the blood escapes beneath the cuff.

One of the three methods, the *palpatory oscillatory* or *auscultatory*, may be employed to determine the latter. In all three procedures the value for the lateral pressure in the brachial artery is obtained, whereas direct methods which entail the introduction of a straight unbranched cannula or a large bore needle into an artery measure the end pressure. The latter is greater because it includes not only the lateral pressure on the elastic arterial wall but also that derived from the conversion of the kinetic energy of the moving blood column as it meets the obstruction as well as an increment of pressure caused by the reflected wave from the obstruction.

A The palpatory method. In this method the examiner takes the moment that the pulse is felt

at the wrist as the index of the systolic pressure. This method is now rarely used since it lacks accuracy. It assumes that the first escape of blood beneath the cuff will cause pulsation in the peripheral artery but there is no evidence that the amount of blood which escapes beneath the cuff when the artery first opens is sufficient to produce a pulse wave detectable by the finger. Definite pulsation may not occur until the cuff pressure has been lowered 5 to 10 mm. below the point when the artery first becomes pervious. This method therefore gives readings that are too low. Another disadvantage of the palpatory method is that the diastolic pressure cannot be measured satisfactorily.

B The oscillatory method. In this method a tambour or capsule covered with a very delicate membrane or a second bag connected with the cuff is used to pick up and magnify the pulsations transmitted from the artery to the upper edge of the latter. The pulsations are made to appear as oscillations of the indicator needle on the clock face dial of an aneroid manometer. Pressures are marked by figures on the dial as the cuff is inflated or deflated; the needle moves to indicate the applied pressure at the moment. At pressures exceeding systolic the oscillations are minimal but as the pressure is gradually lowered and the pulsations pass beneath the cuff a sudden increase in their amplitude and duration occurs. This is the criterion of systolic pressure. The oscillations show little change in magnitude as the cuff is deflated further until the pressure has fallen to the diastolic level at which they suddenly become smaller. At this instant the figure on the dial to which the needle points is noted.

C The auscultatory method. This procedure is the one generally employed clinically. It was introduced in 1905 by the Russian physician Korotkow. Certain sounds heard during auscultation of the brachial artery below the cuff are taken as the criteria for the systolic and diastolic pressures. Under ordinary circumstances if a stethoscope is placed upon the brachial or any other artery no sound can be heard; the flow of blood along the arterial channels being inaudible. If however the artery is compressed by the manometer cuff so as to completely arrest the flow of blood for a moment a sharp light tapping sound in rhythm with the heart beat will be heard when the pressure in the cuff is again released and falls just sufficiently to permit the arterial lumen to open and allow a jet of blood to pass beyond. As the pressure in the cuff is progressively lowered the sound undergoes a series of changes in quality and intensity.

Four phases of the sound, each having its distinctive character, may be heard in succession in the normal individual as the pressure is gradually reduced from about 120 to 80 mm. of mercury or less. These are given below with the average pressures at which they are normally heard.

¹ Should deflation be carried out too rapidly the mercurial type of clinical manometer shows a considerable lag due to the time required for the air above the mercury column to reach atmospheric pressure. The rate of deflation should not exceed from 2 to 3 mm. Hg per second.

Sounds of Korotkow

- Phase I Sudden appearance of a clear, but often faint, tapping sound growing louder during the succeeding 10 mm Hg fall in pressure
- Phase II The sound takes on a murmurish quality during the next 15 mm fall in pressure
- Phase III Sound changes little in quality but becomes clearer and louder during the next 15 mm fall in pressure
- Phase IV Muffled quality lasting throughout the next 5 to 6 mm Hg fall. After this all sound disappears

The beginning of the first sound is taken as the index of systolic pressure. As it is quite faint at its commencement it may not be caught at this time by the ear of the inexperienced, or if the observer's hearing is distracted by other sounds. The sound then will not be picked up until the pressure has dropped below the level at which it could be heard in quiet surroundings, and the reading of the systolic pressure will be too low.

The pressure at the time of complete disappearance of the fourth sound is taken as the index of the diastolic pressure. This sound coincides with the moment that the blood escapes beneath the armlet in a continuous stream rather than intermittently.

It should be clearly understood that arterial blood pressure cannot be measured with precision by means of sphygmomanometers. It is attended by inaccuracies dependent upon the presence of normal arrhythmia and respiration and the resistance of the tissues of the part. To compensate for the latter, a rule of thumb is that the inflatable arm bag should be approximately 20 per cent wider than the arm diameter, or approximately 12 cm for adults, 8 cm for children less than 8 years, 5 cm for children less than 4 years, 2½ cm for children less than 1 year. Despite use of such cuffs, a mean error of ± 8 mm Hg may be expected in individual readings of systolic and diastolic pressures. In the arms of people with much fat tissue the error is further exaggerated in subjects with well defined arrhythmias, deep breathing, or with an abnormal arterial wall, the errors are still larger. Variations in the resistance of the arterial wall in different individuals, as a result of sclerotic changes or simple hypertonus of the muscular coat, give readings that are too high. Repeated compression and decompression just before the actual determination is made may soften the artery or remove any spasm of its walls sufficiently to reduce this source of inaccuracy. Though lower readings as a rule are not obtained in a normal individual by repeated readings in others with apparently normal arteries the reading obtained after the third or fourth trial may, as a result of

the reduction in tone of the vessel wall be lower than the initial observation by several millimeters.

Animals

These involve placing a cuff around a carotid loop in the dog (Van Leerum), or around the tail or foot of the rat and detecting the onset of blood flow under the cuff as its pressure is lowered. In the dog this is done with the auscultatory method, in the rat, the volume of blood passing into the tail or foot when the cuff pressure drops below systolic, is insufficient to cause an audible sound. The first blood flow under the cuff and, hence the volume change, is detected in the tail by noting the onset of volume change in a small water filled plethysmograph just beyond the cuff, or by having the expanding tail press on a carbon button causing a change in tone pitch in ear phones. In the foot, the increase in volume with the lowering of cuff pressure is indicated by the sudden decrease in current flow from a photocell which receives light through the foot.

Use of Simultaneous Measurements of Pressure, Flow, and Volume

In addition to the direct information supplied by blood pressure measurements, knowledge of its association with other phenomena in the circulation, such as blood volume and blood flow, has contributed greatly to advancement in this field. Some reference has already been made to this relationship in chapters 15 and 18. As has been pointed out here, differential pressure measurements in the aorta have enabled calculation of the patterns of flow velocity even in the aorta of man, and the use of such a principle when the pressure pick-up is mounted in a rigid sleeve or vessel, has permitted, in animals, not only patterns of flow velocity but also absolute values for phase and mean flow. Pressure determination has been particularly useful in estimating the contractility of the heart muscle and the distensibility of the ventricles, arteries and veins. Because of its extreme importance, consideration of this subject will also be found in chapters 14 and 20.

THE HEART AS A PUMP

Functional Anatomy

Knowledge of the functional anatomy of cardiac contraction is essential for an understanding of cardiac action. Actually, the two ventricles have different anatomical and functional characteristics. The energy released during systole of the heart represents the combined effects of various bundles of myocardial fibers. The contribution of each bundle depends not only on its contractile power but also on its anatomical orientation within the cardiac walls.

STRUCTURE Four valve rings of dense connective tissue join to form a fibrous skeleton of the heart. The atria and arterial trunks are attached to the superior surface of this fibrous skeleton, to its inferior aspect are fastened the arteriovenous (A V) valves and ventricular chambers. The atrial musculature is thin and arranged as bands radiating from the sulcus terminalis. The atria have two muscular systems, one common to both atria and encircling them, the other arranged at right angles and independent for each atrium. From a functional point of view, the ventricular musculature has two groups of myocardial bundles, the spiral muscles and the deep constrictor muscles (fig. 20-1). The superficial spiral muscles which arise from the mitral and tricuspid rings cover very thinly almost the entire surface of both ventricles to a depth of about 1 mm. They course diagonally around the surface of both ventricles to converge at the apex where they are strongly twisted and where they make up the full wall thickness. They penetrate to the interior of both ventricles to form there its inner thin layer of spiral muscle and the lower third of the inter-ventricular septum. They spiral upward in reverse directions to form the papillary muscles from which fibrous tendons (chordae tendineae) attach to the valve leaflets (A V valves). The inner and outer spiral muscles follow oblique directions about 90° apart since they spiral in opposite directions. As they contract, the oblique traction by the outer layer is opposed by tension in the opposite direction by the inner layer. The

net result of their action is a shortening of the ventricular cavities longitudinally rather than a rotation of the ventricles. Interposed between the thin exterior and interior spiral muscles are the heavy constrictor muscles which make up the basal two thirds of the septum and lateral wall of the left ventricle. In the right ventricle these deep circular fibers form a thin middle layer but its contribution to thickness is small compared to that of the inner and outer spiral layers. Because the left ventricular wall contains a large mass of circularly arranged constrictor fibers its contraction would be expected to result predominantly in a reduced ventricular diameter with minimal shortening from apex to base whereas in the right ventricle with its dominance of spiral muscle the ventricle should shorten with little movement of its lateral wall.

ROLE OF THE PERICARDIUM The pericardium is a double-walled sac containing a few cubic centimeters of serous fluid which gives a smooth lubricated surface for the heart's movements. Although its potential volume is larger than that occupied by the normal heart in diastole, still after moderate enlargement of the contained heart, the interpericardial sac pressure rises greatly with small volume influence. Thus, in case of left ventricular stress and enlargement such as occur in hypertension, the pericardium restrains diastolic expansion especially of the right ventricle, and therefore, limits right ventricular work. This protects the left ventricle from overload and the pulmonary circulation from congestion. The pericardium also protects against tricuspid or mitral valve regurgitation at high ventricular filling pressures. However, congenital lack of a pericardium is not uncommon in animals and humans who live to a ripe old age without evidence of cardiac distress.

ATRIAL AND VENTRICULAR BLOOD VOLUME Io man the atrial capacities are slightly greater than those of the corresponding ventricles, thus assuring the presence of sufficient blood to fill the ventricular cavities completely. In the dead hu-

man heart, the right atrium has 163 cc the right ventricle 137 cc the left atrium 140 cc the left ventricle 120 cc

Such *in vitro* measurements are of limited interest and do not give information as to the diastolic volume of the ventricles during life or the portion of the diastolic volume which is expelled nor the portion which remains in the ventricle at the end of each heart beat. It is now well-established that the heart is not completely emptied of blood during ventricular contraction i.e., a residual ventricular volume of blood remains at the

end of ejection. Nylin was the first to demonstrate that the diastolic volume of the human heart under working conditions is about 540 cc, of which about 140 cc is ejected by the two ventricles. The difference, 400 cc, is an estimate of the volume of blood which is normally available at the end of systole for refilling the two ventricles. However, what fraction of this is in the atria and what fraction is in the ventricles is not known. Observations in dogs indicate that the right ventricle and left ventricle both empty in a fractionate manner, ejecting 40 to 45 per cent of

their end diastolic volume with each stroke and retaining a residual volume of 55 to 60 per cent. The stroke volume in the resting untrained human approximates 60 cc. On the basis of the dog, this would give a diastolic volume of 130 cc in the human ventricle. As yet, precise observations have not been made in humans although attempts have been made to do so for the right ventricle, and it does appear that this volume is increased in congestive heart failure.

PATTERNS OF VENTRICULAR EMPTYING Traditional concept has it that the ventricles eject blood primarily by shortening of the longitudinal axis accompanied by a rotational action comparable to a wringing out of a wet rag. Direct measurements, however, of changing ventricle dimensions in unanesthetized dogs by cinefluorographic techniques with contrast media, by intraventricular gauges and by external resistance gauges, indicate that the left ventricle resembles a cylinder with a conoid apical segment. The cylindrical portion is made of a strong cuff of deep fibers between thin layers of spiral muscle. The conoid section is made primarily of closely woven spiral muscle entering and leaving "the vortex." Left ventricular contraction involves primarily a reduction in transverse diameter. This action accounts for most of the power and volume of the ejection since the contained volume decreases with the square of the radius in a cylinder. There is relatively little rotation or shortening of the longitudinal axis. All this would be expected since the bulk of the fibers is circularly arranged.

By contrast, right ventricular ejection of blood can be effected by three means. (1) Longitudinal shortening of the chamber, i.e. base moving toward apex is the most obvious movement. This might be expected since the inner and outer layers of spiral muscle making up most of the right ventricle are oriented at about 90° from each other. Hence, simultaneous contraction of the two layers of spiral muscle produces shortening along the longitudinal axis of the right ventricle chamber. (2) The right ventricular chamber is roughly triangular in shape being bounded by a convex septal wall and a concave free or lateral wall which enclose a crescent shaped area between them. The free wall of the right ventricle moves toward the convex surface of the septum. This movement although slight could be extremely effective in moving blood, and it would operate like a bellows used to kindle a fire, i.e., since the sides of the ventricle or bellows are large compared to their enclosed space, slight movement toward each

other should cause displacement of a large volume of blood. (3) Contraction of the left ventricle must produce a greater curvature of the septum, and thus, since this is attached to the right ventricular lateral wall, traction on it will add to the bellows action. The action of this or the other factors has not been quantitated. That it can be a potent mechanism, however, is borne out by the observation that right ventricular ejection can be maintained when the free wall of the right ventricle has been almost completely destroyed by cautery in the dog or by coronary occlusion in man.

The reduction in diameter and circumference necessary to eject the stroke volume is different in the two ventricles because of their shape and manner of contraction but they are small in both cases. With present methodology, it is not possible to quantitate the extent of myocardial fiber shortening associated with ventricular ejection of blood. However, some rough estimates are instructive. Under normal circumstances the ventricles function at relatively large diastolic and systolic dimensions since possibly half their contained volume is not ejected with each contraction. If the left ventricle is regarded roughly as a cylinder which ejects approximately half its contained volume of 130 cc, then the diameter can decrease from 5.2 cm. to 3.0 cm., and the circumference from 16.5 cm. to 12.1 cm.

The right ventricle has some resemblance to a segment of a sphere, and a small shortening of its fibers will eject a large blood volume. If its volume is also 130 cc., and half is ejected, the diameter will decrease from 6.3 cm. to 5.1 cm., and the circumference from 19.8 cm. to 16.0 cm. The average shortening of the right and left ventricle walls might be estimated as 20 per cent and 25 per cent of the diastolic size. The extent of myocardial shortening also varies greatly for the same volume of ejection depending on the size of the cavity or the fiber length before ejection takes place. It takes a much smaller reduction in fiber length of a larger sphere or cylinder to eject the same volume. For example if in a heart enlarged by congestive failure of the circulation the right ventricle contains 500 cc. blood, then ejection of 60 cc. will decrease the diameter from 9.8 cm. to 9.4 cm., or by 0.4 cm., and the circumference from 30.8 cm. to 29.5 cm.

It would be expected that the shortening of muscle fibers of the lateral wall of the right ventricle at different depths would be similar since the wall is so thin. In the left ventricle, however, the circumferentially arranged deep constrictor fibers form a cuff of muscle making up most of

the muscle wall which is so thick that the inner layers near the endocardium have a much smaller radius and circumference than the outer layers near the epicardium. With the onset of contraction, the inner layers must shorten more than the outer layers in ejecting a particular volume. Thus, presumably, no two layers of the myocardial fibers shorten to the same extent during ejection.

Pressure and Volume Events of a Cardiac Cycle

It is important to consider the means by which the heart cavities are able to pump the necessary volume of blood from the systemic veins to the arteries and to impart to it a pressure sufficient to cause a continuous flow of blood through the capillaries. The sequence of events can be considered in terms of atrial, ventricular, and arterial pressures, and of variations in the volume of and means of emptying the cardiac cavities. The events of the cardiac cycle for both left and right hearts are depicted in figure 20.2. Terminology and symbols given to the various phases of the cardiac cycle by Wiggers are used. The curves are synthesized in part from records obtained in dogs. In the main, however, pressure values and temporal relations are based upon pressure pulses obtained from all four cardiac chambers, pulmonary artery and aorta, by direct needle puncture at the time of thoracotomy in human subjects clinically free of cardiovascular disease. The schematized volume curve is based on recordings of volume of both ventricles in which a cardiometer has been placed around the ventricles up to their A-V junction in the open chest dog. No adequate recordings of moment to moment changes in volume of a ventricular cavity during a cardiac cycle are yet available.

SEQUENCE OF EVENTS Ventricular contraction begins at "1", and almost instantly closure of the mitral valve occurs as the ventricular pressure curve exceeds the left atrial pressure curve. The "c" wave in the atrial curve begins at this time and is due to the rising pressure in the ventricle which is transmitted through the closed A-V valves which bulge into the atrium. It marks the onset of the left ventricular isometric contraction period which consists of a slow and then a rapid phase of pressure rise. The isometric contraction period in which the ventricle is a closed cavity, ends at "2" the moment at which the ventricular pressure exceeds the aortic pressure. The aortic valves are forced open as indicated by the onset of the pressure rise in the aorta, and blood is discharged from the ventricular cavity

From the moment that the aortic valves open at "2", until they close at "4", ventricle and aorta are common cavities and, consequently, their pressure pulses have a similar contour. Ventricular volume starts now to decrease. The period of maximum ejection lasts until the peak of the aortic pressure pulse and is followed by a period of reduced ejection which is completed at the beginning of the incisura (3), a point which is often difficult to identify on the records. This is the end of ejection of blood and of ventricular systole. The ventricular cavity still retains more than half its original diastolic volume. During protodiastole (3 to 4), the pressure within the ventricle continues to decline and this phase ends at the moment of aortic valve closure (4), i.e., at the bottom of the incisura of the aortic pressure curve. Isometric relaxation (4 to 5) then follows. At this time, the atrium and ventricle are relaxed and the left ventricular cavity is completely closed off from the atrium and aorta and only partially filled.

During the preceding ventricular contraction, the left atrial pressure undergoes a temporary abrupt decline as a result of an artefact imposed by cardiac movement. As blood, however, pours into the cavity of the left atrium from the pulmonary veins, the atrial pressure rises continuously to the end of the isometric relaxation period forming the "V" wave. This atrial blood which has accumulated during the previous ventricular contraction is now transferred to the ventricle. Ventricular filling begins at the time the intra-ventricular pressure drops below the intra-atrial pressure and the A-V valves reopen (5).

The period of rapid ventricular filling, i.e. the early diastolic inflow period is marked by a continuous decline in ventricular pressure and in the "V" wave of the atrial pressure curve. Inflow into a ventricular cavity is regulated by mechanisms operating in both its systole and diastole. Since no blood enters the ventricles until it has passed through the atria, it is important to know their means of filling. It is not possible to measure flow into the atria, but since they are continuous with the venae cavae without intervening valves, venacaval flow should indicate atrial flow. Caval flow into the atria shows three phases. It is reduced nearly to zero during atrial contraction. During ventricular diastole inflow is considerable but the volume of atrial inflow is greater during ventricular systole when the A-V valves are closed and no blood can enter the ventricle, than during ventricular diastole when A-V valves are open and atria and ventricles form a common cavity.

FIG 20.2 Schematic representation of the sequential cardiac events relating pressure volume changes to the phono and electrocardiograms. *upper tracings*, right and left heart pressures, *middle tracings*, phono cardiogram and ventricular volume, and *bottom tracings*, electrocardiogram. Vertical lines correspond temporally to the following: 1, onset of isometric ventricular contraction and closure of A V valves, 2, end of isometric contraction and opening of semilunar valves, 3, incisura or end of ventricular ejection and ventricular systole, 4, closure of semilunar valves and onset of isometric ventricular relaxation, 5, opening of A V valves and onset of rapid ventricular filling, and 6 and 7, slow ventricular filling or diastasis, ending with atrial contraction.

Atrial inflow during ventricular contraction is particularly effective in the presence of tachycardia in which the time available for diastolic inflow is shortened. The pistonlike downward movement of the atrioventricular junction during ventricular systole enlarges the atria and vena cava and attracts blood to them. The filling of the atria during ventricular systole depends on the quantity and pressure of blood available in the venous reservoir and the vigor with which ventricular systole moves the A-V junction. Thus, ventricular myocardial contraction is a very important means of actively filling the atria during systole and, therefore, in determining the extent of ventricular filling during the rapid filling phase.

Finally, attention is directed to the dashed and abruptly dipping line representing an alternate decline of the ventricular pressure and which, at times, indicates a negative intraventricular pressure has developed. Such a dip in the pressure curve of ventricular relaxation, although recorded for many years and considered an artefact, is now given more credence since (1) it can be recorded with a micromanometer (which is supposedly immune to artefacts), (2) recent experimental evidence indicates that the relaxing ventricle can develop suction under certain artificial experimental conditions. For example, in the beating mammalian heart, a moderate volume of fluid can be drawn into the ventricular cavity in the absence of a positive ventricular filling pressure and in the presence of an empty ventricle or one with some systolic residual volume. The time available during which suction could act is approximately 0.1 sec, i.e., the earlier part of the rapid inflow period. The quantitative contribution of the ventricle to ventricular filling under normal conditions is still unknown and, hence, the physiological significance of diastolic suction for the return of blood to the heart cannot be evaluated. Wiggers, in summarizing the problem, states "crucial evidence is still required that the small remnant of elastic recoil still operative at the end of relaxation can create sufficient suction to be of significance in filling the normally beating heart. Dynamically it must be shown that the concordant declines of atrial and ventricular pressures are due to a more rapid rate of ventricular relaxation than of filling from the atrium."

Diastasis, or the period of slowed ventricular filling, begins when the atrial pressure begins to rise during diastole (6). The end of diastasis (7) is marked by the onset of atrial contraction ("a" wave) which is reflected in the ventricle since the atrial and ventricular cavities are now continuous

The dynamic interval of atrial systole lasts until the peak of the atrial contraction wave while the inflow phase that follows ends at the onset of ventricular isometric contraction and completes the cardiac cycle.

ATRIAL CONTRACTION The dynamic importance of atrial contraction on ventricular filling has been much debated. The older view that the chief function of the atria is filling the ventricles is not now acceptable since it is known that such filling occurs chiefly during the earlier portion of diastole when the difference between atrial and ventricular pressure is maximal. However, in hearts slowed by vagal stimulation to separate atrial and ventricular contraction and in hearts with 2:1 or more block, it can be demonstrated that atrial contraction has a small but significant effect on the ventricular volume curve obtained with a cardiometer.

PRESSURE AND TIME VALUES OF DYNAMIC AND ELECTRIC EVENTS AND THEIR TEMPORAL RELATIONSHIP IN THE LEFT AND RIGHT HEART For full details original articles should be consulted. However, certain features are obvious. The following table gives the approximate figures for the duration of the chief phases of the cardiac cycle of the left heart when the heart rate approximates 70 per minute in the human.

	Seconds
Atrial systole	0.11
Atrial diastole	0.71
Ventricular systole (total)	0.27
Isometric contraction period	0.06 (right ventricle, 0.02)
Ejection period	0.21
Ventricular diastole (total)	0.56
Protodiastolic period	0.02
Isometric relaxation period	0.05 (right ventricle, 0.02)
Rapid inflow period	0.16
Diastasis	0.23
Atrial systole	0.10

A Pressure pulse values Aortic pressure throughout the cardiac cycle is uniformly higher than in the pulmonary artery. The peak aortic pressure during systole of 120 mm Hg is approximately five times that of 25 mm Hg in the pulmonary artery, the relative end diastolic pressures are 80 mm Hg versus 10 mm Hg, the relative pulse pressures are 40 mm Hg versus 15 mm Hg. The diastolic pressure in both cavities is

quite low with a small pressure gradient from the left ventricle (5 mm Hg) to the right ventricle (2 to 3 mm Hg). The atrial pressure values are only a few mm Hg and are uniformly somewhat higher in the left atrium than in the right atrial curve.

B Asynchronisms of pressure pulses While dynamic events on the two sides of the heart are generally similar, there is considerable asynchronism and some difference in duration of parts of the cardiac cycle. The onset of contraction of the right atrium precedes that of the left atrium while the onset of contraction of the right ventricle follows that of the left ventricle. Right ventricular ejection begins earlier and is completed later than left ventricular ejection.

C Electrocardiogram versus onset of pressure events In man the interval between the onset of electrical and mechanical activity in the left atrium (rise of P wave versus onset of rise of atrial A wave) is of the order of 0.06 sec., for the right atrium, the interval approximates 0.08 sec. For the left ventricle, the interval between the onset of ventricular depolarization (Q wave) and onset of left ventricular contraction (onset of pressure rise) approximates 0.04 sec., for the right ventricle, the interval is about 0.05 sec. The T wave has a variable relation to the end of systole but terminates usually before the incisura of the aortic pressure curve.

The Movements of the Heart Valves

The chief factor concerned in the opening and closing of the valves is, as already indicated (p. 242), the difference in pressure upon their opposite surfaces. Some additional features of the valvular mechanisms must now be considered.

THE ATRIOVENTRICULAR VALVES (TRICUSPID AND MITRAL) The valve leaflets or cusps, three in number on the right and two on the left side, are attached by their bases to the fibrous rings surrounding the atrioventricular openings. Their free margins are connected through delicate tendons (chordae tendineae) to the papillary muscles which prevent inversion of the valves into the auricle during ventricular systole. The chordae tendineae are tightened at the commencement of systole by the contraction of the papillary muscles. The leaflets are composed mainly of a double layer of the endothelial lining of the heart, strengthened by a few connective tissue fibers. Their attached bases are thicker and contain more connective tissue, small blood vessels and delicate strands of smooth muscle. The latter, however, play no part in valve closure

which is effected, as mentioned above, in a passive manner.

A The mechanism of valve closure According to traditional concept, an advancing gush of blood thrusts the A-V valves widely open during early ventricular diastole. During atrial systole the leaflets do not lie back against the ventricular wall but occupy a midposition as a result of two opposing currents. The inflowing blood pressing upon their atrial surfaces keeps them open, while eddies reflected in the reverse direction from the ventricular walls strike their ventricular surfaces and tend to close them. Thus they float in a position of delicate balance. When as a result of the fall in intra-atrial pressure at the end of atrial systole, the incoming jet is diminished in force and finally ceases, the back eddies persisting for a brief space and being unopposed, approximate the valves or bring them gently into apposition (fig. 203). The fact that the first heart sound has been found to be significantly delayed in the absence of atrial systole supports this view that normally the atrioventricular valves are closed or nearly so, before ventricular systole. They are not, however, firmly closed. This is effected by the rise in pressure in the ventricle when it contracts. Dean has shown by attaching a hair to the septal leaf of the valve and recording its movements that if ventricular systole does not follow almost instantly upon the cessation of the flow of blood from the atrium the valves start to reopen. In instances therefore in which ventricular systole is delayed, that is when the A-V interval is prolonged, the reopening of the valves proceeds for an appreciable time. Then, when ventricular contraction occurs a small amount of blood regurgitates into the atrium before the valves are swung closed by the

FIG. 203 Two diagrams showing mechanisms concerned in valve closure. A, showing relations of papillary muscles and chordae tendineae to valve flaps. B, partial closure due to eddy formation (after Wiggers, 1934).

rising intraventricular pressure. The backward flow of blood through the orifice may then give rise to a murmur just preceding the first heart sound (presystolic murmur).

These concepts have been derived mainly from observations and direct photography of valve action in isolated hearts and from correlation of heart sound with mechanical and electrical events of the cardiac cycle. However, cinefluorographic observations of the motions of the mitral valve cusps by means of attached radiopaque markers in intact anesthetized dogs, showed the edges of the valve cusps to be only slightly separated during ventricular filling. Since in both instances, it is not possible to rule out certain experimental artefacts, at present no choice can be made between the concept of wide valve excursion in isolated hearts and restricted valve movements in intact animals.

THE SEMILUNAR VALVES The dynamics of aortic and pulmonary closure are essentially the same in principle as those described for the A-V valves. The valves form three small pockets open toward the arterial lumen. Back eddies which are set up during the ejection phase of systole prevent the contact of the valves with the arterial wall. When ejection ceases the centripetal currents carry the valves into apposition and firm closure is effected by the higher pressure at this time upon their arterial surfaces.

Heart Sounds

METHODOLOGY The sounds produced by the heart during a cardiac cycle consist of waves of greatly varying frequency. To pick these up a simple form of stethoscope is used in which a

small bell or disk placed over the chest conducts the sound waves through rubber tubes to ear pieces. Because of the intervening tissue, the intensity of the sounds is generally decreased and some components are accentuated and others depressed. The stethoscope itself does not amplify sounds accurately or conduct them accurately to the ear, the size and shape of the end pieces and the pressure exerted affecting the auditory characteristics of the sounds. Despite this the sounds heard thus by ear give more practical information than is obtained by any other approach. The heart sounds have also been picked up by a microphone applied to the chest wall over the heart, amplified, and the frequency selectively filtered before it reaches the ear or is conducted to a loudspeaker. This is didactically helpful since many can listen simultaneously, but it does not give a better appreciation of the sounds as they actually occur.

Graphic registration of the heart sounds has been used to give a permanent record for study and to permit precise relations to be established between them and the events of the cardiac cycle, as recorded by other graphic methods such as the electrocardiogram and intracardiac and intravascular pressure curves. As already mentioned this provides an accurate method of measuring the duration of ventricular systole. In the classical direct method heart sounds at the chest level are conducted by a stethoscopic bell by means of a short rubber tube to a sound recorder the coarsest vibrations being allowed to escape through a lateral opening. The recorder consists of a very fine rubber membrane with attached mirror whose movements are recorded on photographic paper. Einthoven introduced an indirect method in which the sounds picked up by a stethoscope fastened to the chest were transmitted to a microphone the movements of the disk of which produced changes in a simple electric circuit recordable by a string galvanometer (fig. 20-4). With the development of crystal microphones and proper vacuum tube amplification, a number of devices are available commercially in which the heart sounds are converted at the chest level into electrical variations which are amplified and recorded by high frequency oscillographs. In this electronic apparatus, the lower frequencies have generally been severely attenuated or filtered to resemble the effect of the human hearing mechanism with a stethoscope. The records are used to increase the acumen of clinical auscultation, the advantage is mainly in appreciating the timing and relation to each other

FIG. 20-4 Schematic diagram illustrating the recording of heart sounds. The signal from the microphone goes through an amplifier to give it the necessary amplitude to drive a recorder.

of heart sounds and murmurs. But in the matter of increase in perception of faint murmurs, phonocardiography does not compare with the remarkable sensitivity and selectivity of the human ear.

For obvious reasons, sounds picked up from the surface of the thorax are not a true representation of the actual vibrations of the cardiac valves and walls. Thus, attempts have been made to move the pick up device closer to the source of sound by placing microphones in the esophagus, by suturing microphones to the myocardium in experimental animals, by applying suction microphones directly to the surface of the human heart, and finally, by introducing the microphone into the cardiac chambers themselves. The latter technique aids in locating the site of production of normal heart sounds and serves as a valuable diagnostic tool in diverse states in locating the origin of abnormal sounds and murmurs. However, use of data obtained thereby must be tempered by knowledge of the fact the catheter mounted device may itself, through the motion imparted to it in the cardiac cavities, produce sounds which are recorded as naturally occurring.

CHARACTERISTICS OF HEART SOUNDS Two distinct sounds are heard by direct auscultation and occasionally a third is also audible during a cardiac cycle. A fourth sound is revealed by graphic methods. The first two sounds occur mainly during ventricular systole, the other two sounds take place during ventricular diastole (fig. 20-2).

A. Origin of heart sounds and time relations These vibrations arising in the heart are fundamentally the result of sudden displacement of blood (acceleration) or abrupt stoppage of blood (deceleration).

The temporal relations of human heart sounds to central hemodynamic events are illustrated schematically in figure 20-2. The large vibrations of the first sound begin with the rapid rise in intraventricular tension and by the beginning of ejection they have already reached a maximum. The beginning of the second sound coincides with the trough of the incisura of the aortic pressure. The third sound occurs near the end of the rapid inflow phase of diastole of the ventricles. The fourth sound begins near the middle of the atrial pressure wave and extends to the isometric phase of ventricular contraction.

B. First heart sound The first sound is of relatively long duration, soft in quality and low in pitch. The second sound is shorter, sharper and of higher pitch. These characteristics are best imitated vocally by the syllables "lub" and "dup" separated by a brief pause. The two heart sounds

mark the beginning and end of ventricular systole and the determination of the interval between their commencements (as determined by the phonocardiogram) is a reliable method for arriving at the length of ventricular systole in man. The pause between the end of the second sound and the beginning of the first coincides with ventricular diastole.

The first sound is heard most clearly and at maximum intensity over the 5th left intercostal space, i.e., with an area centered over the "apex beat." Here the mitral element of the sound predominates. Any abnormal sound produced at the tricuspid valve is detected by listening over the lower end of the sternum.

The principal factors entering into the production of the first sound are (1) the closure of the atrioventricular valves and the tension set up in the valve leaflets and chordae tendineae as the intraventricular pressure rises (valvular element), (2) the rush of blood from the ventricles and the shock transmitted to the walls of the aorta and pulmonary artery (vascular element), and (3) contraction of the ventricular muscle. Vibrations set up by the atrial muscle at the end of its systole may sometimes contribute to this sound.

The vibration of the valves is the most important element of the first sound. Some have claimed that the first sound is not prolonged into the ejection period, and therefore, the impact of the blood upon the walls of the large vessels cannot contribute to the sound. But the observations of Straub and of Oras and Braun Menendez indicate that the first sound does extend beyond the isometric period and that the vascular element is an important component. Of the three, the muscular element appears to add least to the sound. Dock has questioned whether the ventricular muscle produces a sound at all. He recorded the sound vibrations by means of a phonocardiograph applied to the surface of the heart and reported that no sound was produced when the empty heart contracted, valve action being abolished. Although he concluded from this that the normal first sound contained no muscular element, evidence from other sources is strongly opposed to such a conception. Wiggers and Dean previously had recorded sound vibrations from an isolated strip of myocardium. It has also been shown that when free movement of the valves of the beating heart is prevented, the booming character of the first sound still persists.

Phonocardiographic records from the chest over the heart show, as a rule, no vibrations before the onset of ventricular contraction thus indicating

that the presystolic apposition of the valves is silent. The sound commences 0.008 second before the peak of the R wave of the electrocardiogram. Its duration is about 0.18 sec. Sometimes, however, the phonocardiogram records a few small presystolic vibrations which are attributed to auricular systole, occasionally a faint sound is heard at this time.

The record of the first sound is composed chiefly of a series of from 9 to 13 vibrations, and has a duration of from 0.9 to 0.16 sec. These are of small amplitude to start with but rise to a "crescendo" which reaches its maximum at the end of the isometric period and is followed by a "diminuendo" of about the same duration. This main series of vibrations is sometimes, as mentioned above, preceded by a couple of small introductory vibrations which occur before the ventricular pressure rise. These are possibly of atrial origin. The main series is also followed by a few final vibrations, variable in number. The vibrations are in general irregular, which places the sounds in the category of noises rather than of musical tones. The frequency is low varying from 33 to 110 per sec.

C The second sound results from the vibrations set up in the blood column and arterial walls as the aortic and pulmonary valves are placed under tension following their closure. The duration of the second sound is about 0.10 sec. It commences about 0.09 sec. after the summit of the T wave of the electrocardiogram. The average frequency is about 50 per sec. It is heard best over the pulmonary and aortic areas—the upper part of the sternum adjacent to the 2nd left intercostal space, and the 2nd right costosternal junction respectively.

D The third heart sound Sometimes a faint third sound is heard in normal hearts which follows the second sound by about 0.08 sec. and lasts for about 0.04 sec. It is heard at the apex and is commonly found in young adults. Thayer found it present in 65 per cent of normal individuals. It may be made to appear or is intensified by procedures which increase the venous flow into the atria, e.g., exercise, recumbent position, etc. The sound was first described by Gibson and independently by Herschfelder, several explanations have since been given to account for it. (1) Some have considered it to be due to the asynchronous closure of the aortic and semilunar valves, but the interval between it and the second sound is too great for the acceptance of this explanation. (2) White considers that it is due most probably to the opening snap of the A-V valves

or to the vibration of the ventricular walls as the blood rushes into the ventricle. (3) Another view is that the sound is simply due to prolonged after vibrations of the aortic valves which have become separated from the earlier vibrations as a silent interval. None of these explanations is entirely satisfactory in all instances.

E Variations in the intensity of the heart sounds It is the general belief that the first sound varies in intensity with the force of ventricular systole and the loudness of the second sound with the height of the arterial blood pressure. The experiments of Wiggers bear this out. The sounds were recorded graphically and correlated with the intraventricular and aortic pressure curves. It was found that the vibrations of the first sound were increased in amplitude and number when the tension developed by the cardiac muscle was increased. The intensity of the first sound is directly related to the rate of the pressure rise within the ventricle during the isometric period. The intensity of this sound is not dependent upon the volume of the systolic discharge but rather upon the diastolic pressures in the pulmonary and systemic circuits. Wiggers found that when the heart was slowed and the systolic discharge consequently increased but the diastolic pressure lowered, the intensity of the first heart sound was reduced while acceleration of the heart (reduced systolic discharge with raised diastolic pressure) increased its intensity. These experiments together with the observations that the first heart sound is believed to be largely on a valvular basis and is intensified with prolongation of the P-R interval strongly suggest that the intensity of the sound is ultimately conditioned by the position of the A-V valves at the onset of ventricular systole.

The intensity of the second sound in the aortic or pulmonary area is increased by an elevation in the systemic or pulmonary pressures, respectively. Among the cardiovascular conditions associated with intensification of the second sound are, mitral stenosis and failure of the left ventricle which raise the pulmonary arterial pressure, and arterial hypertension which raises the aortic pressure.

REGULATION OF PRESSURE AND FLOW IN THE SYSTEMIC AND PULMONARY CIRCULATION

If all the vascular beds of the body were to open simultaneously to their full capacities, the total peripheral resistance would disappear and the cardiac output and blood pressure would be reduced to zero. In order, therefore, to permit the circulation pumps and vessels to carry out their functions, most blood vessels must be partially constricted much of the time. To effect this, vascular constriction must be precisely balanced against vascular dilation so as to permit the requisite cardiac output for tissue needs.

Body economy requires that blood flow through some organs or regions be dictated by their local function. In some tissues with a high metabolic rate, such as active skeletal muscle and the myocardium, the volume of blood flow is very high and the arteriovenous (A-V) oxygen difference may be 70 per cent or more. In other tissues, such as skin, kidney, and the brain, blood flow is not determined by local metabolic demands. Here, with rather low metabolic requirements, the blood flow is high with a small A-V oxygen difference, because the specialized functions of temperature regulation, urinary secretion and neural activity require a very large blood flow beyond their oxygen requirements.

The size of vessels can be varied passively because of their content of elastic and collagenous tissue, and of smooth muscle, each of which can be stretched by an intravascular pressure. The walls of most vessels such as the aorta, arteries, arterioles, venules and veins, contain involuntary muscle fibers arranged in circular fashion. The walls of the arterioles are composed almost exclusively of this smooth muscle. Vascular contractility is dependent only on these smooth muscle cells. Such contractility is based on their local "tone" and on their response to blood borne substances. In addition, like the cardiac muscle, the musculature of these vessels is supplied by two types of nerve fibers—inhibitory and excitatory. Those which cause contraction of the mus-

culature are called vasoconstrictor, those which inhibit, and in consequence, cause relaxation of the muscle rings, are termed vasodilator. Both sets together are referred to as vasomotor nerves.

Since, according to Poiseuille's law, pressure, flow and resistance are intimately associated it is necessary for proper study, as pointed out in chapter 15 to be able to measure the blood flow in the presence of a constant perfusion pressure, or to measure the blood pressure change in the presence of a constant blood flow. In no other way can one determine whether a change in peripheral resistance arises through a change in blood flow from a primary change in heart action or through a change in state of vasomotion of peripheral vessels induced by local mechanisms, or by nervous and humoral mechanisms operating locally. Ever since Poiseuille introduced the mercury manometer, in 1828, and later Ludwig added a float and a writing point, it has been easy to make pressure measurements, whereas, because of the slowness in development of methodology, flow measurements have not been too plentiful. However, enough information is at hand to consider the subject briefly.

Local Control of Vascular Smooth Muscle

The smallest blood vessels have an inherent, myogenic automaticity or basal degree of contraction of their contained smooth muscle which is independent of blood borne substances or nervous influences, but which can be altered by stimulation of nerve fibers, local electrical stimulation, or by changing the physical and chemical environment. The mechanism of this inherent vasomotion is unknown. Presumably, it arises from locally produced metabolites whose effects can be complex. Locally, in the arterioles, pre-capillaries and capillaries, there are normally released 5 hydroxytryptamine, noradrenaline, acetylcholine, histamine, CO_2 , lactic acid, products of nuclear metabolism and presumably many

other substances, each of which could act differently on these vessels. The extent of such basal vasomotion has been evaluated in sympathectomized, vascular areas where neurohumoral, circulatory, constrictor influences are eliminated. Although large quantitative differences exist in different parts of the vascular tree, generally speaking, there is an inverse relation between the local, inherent activity of smooth muscle cells and the extent of neurohumoral control in any given vascular bed. The cutaneous arteriovenous anastomoses, such as in the paw of the cat, which are strongly controlled from the hypothalamic heat loss center, are maximally dilated when neurohumoral agents are eliminated, while elimination of the vasomotor nerves serving vitally important metabolic areas, such as the brain and myocardium, has scarcely any effect on the local blood flow. In areas such as skeletal muscle, neural elimination still leaves a very strong vessel tone in the dog and man, which is increased with time. Indeed, some investigators have expressed the belief that in skeletal muscle, blood flow is mainly under local control by metabolites, and not nerves, since sympathectomized people do as well running (athletes and normals) before and after sympathectomy. This difference may apply in the same vascular bed, for evidence suggests that reactivity to local metabolic effects is stronger in the metarterioles and precapillary sphincters, whereas constrictor fibers predominantly affect the arterioles. Presumably, in all beds there is some locally produced vasodilation which counteracts the centrally induced reduction in blood flow by constrictor nerves and protects the tissue against ischemia.

The Sympathetic Vasoconstrictor Fibers

DISTRIBUTION These were discovered in 1852 by Claude Bernard, who stimulated the cervical sympathetic nerve in the rabbit and observed constriction of the vessels of the ear. They belong to the thoracolumbar (sympathetic) division of the involuntary nervous system. The constrictor fibers arise from groups of nerve cells situated in the lateral horns of the spinal gray matter, extending in man from the 1st thoracic to the 2nd or 3rd lumbar segment, inclusive. All the arterioles of the body wherever situated are supplied with filaments whose ultimate source is in this relatively limited region of the central nervous system. They are distributed to the periphery in the manner elsewhere described for the thoracolumbar outflow in general (see also ch 71).

The vascular nerves of the limbs, as shown by Todd and Kramer and by Woollard, are distributed by two distinct modes. (1) A *proximal* innervation which arises in the case of the vessels of the upper limb directly from the cervical part of the sympathetic chain—middle and inferior cervical ganglia. The fibers pass to the subclavian artery and are conveyed in a plexiform manner along the outer coat of this vessel and its branches, and into the arm along the axillary artery. The corresponding supply to the vessels of the lower limb is derived by extension from the aortic plexus in the abdomen. The fibers follow the common and external iliac arteries into the thigh. The sympathetic fibers derived in the manner just described do not extend beyond the larger vessels of the limbs—proximal portions of the brachial and femoral. (2) A *distal* innervation which is carried to the peripheral vessels via the spinal nerve trunks. These reach the arteries at different levels and, penetrating the vascular wall, form a nerve net surrounding the muscular coat, the highest level of this type of innervation probably overlaps the region innervated by the proximal group of fibers mentioned above. The lowest levels supply the arterioles and capillaries. It is solely through such sympathetic fibers traveling with somatic nerve trunks that constrictor impulses are conveyed to the minute vessels of the limbs. Ganglion cells are absent from the vessels of the limbs. Section of a peripheral nerve, therefore, causes complete degeneration of vasoconstrictor fibers in the area of its distribution.

Vasoconstrictor fibers to the head and neck are conveyed from the sympathetic chain through plexuses investing the blood vessels but also via peripheral nerve trunks (cervical and certain cranial nerves). The vessels of the abdomen and pelvis are supplied with fibers which pass along the vascular walls from plexuses surrounding the aorta and its branches. The sympathetic fibers to the heart arise chiefly in 5 upper dorsal segments of the cord, pass to the stellate ganglia and upper dorsal ganglia as white rami, and proceed to the heart by a complex plexus. There is no certainty that these fibers should be included here. They are included, however, because with their stimulation noradrenaline is released in the heart, but no good evidence exists to prove that stimulation *per se* causes dilation since each stimulation is overshadowed by a massive metabolic response and associated dilation.

SITE AND MODE OF ACTION These nerve fibers

constitute a group of powerful vasoconstrictor mechanisms which are available and in constant function. The physiological discharge rate of the vasoconstrictor fibers is 1 to 2 per sec to maintain normal vessel tone and reaches 10 impulses per sec, with maximal physiological excitation. The chemical transmitter released at the smooth muscle cell is probably norepinephrine, since almost all pure norepinephrine is released into the blood stream on intense sympathetic stimulation. However, such an overflow does not usually occur at physiological discharge rates. These constrictor fibers exert control over the resistance vessels (arterioles and adjacent smaller blood vessels) where the main drop in blood pressure occurs. This can be observed by noting the marked increase in blood flow in a limb of man or animal with sympathetic block to that area. Predominantly, the true arterioles are controlled by constrictor fibers while the capillaries are mainly regulated by local factors.

In addition, these fibers exert strong control over the heart size and the capacity vessels, mainly the veins, which can alter greatly the venous return to the heart and, thus, markedly influence cardiac output. To establish this capacitance action, pressure changes occurring in functionally isolated parts of the superficial and deep venous system of dog and man were used to indicate changes in venous constriction, and evidence of a reflex constriction to a variety of stimuli was obtained. Isolated venous segments in the intact forearm constrict after reflex sympathetic stimulation by cold, excitement, etc. Venospasm in the forearm occurs in response to pooling of blood in the leg. Similar observations have been made on the capacity vessels of the splanchnic area. These effects are abolished by constrictor fiber blockade by hexamethonium. Possibly the most clear-cut experiments in dogs on the quantitative importance of the sympathetic system in adjusting total vascular volume, and hence, venous return and cardiac output, are those in which a pump, with output which remained constant under marked variations of peripheral resistance, was substituted for the left ventricle of a dog. The pulmonary drainage of blood was carried to a reservoir by means of a plastic tube in the left aortic arch. The blood was pumped from the reservoir through a T tube in the descending thoracic aorta. Under equilibrium conditions (reservoir level remaining constant), if norepinephrine (which simulates sympathetic vasoconstriction in physiological dosages) was injected into the dog, there was not

only an increase in vascular pressures but also approximately 250 cc (3% of the dog's blood volume) was forced into the pulmonary drainage reservoir feeding the mechanical left ventricle. This could only come from the venous system and the right heart. When hexamethonium (simulating a functional sympathectomy) was injected instead of norepinephrine, the pressures fell and the dog took up 200 to 300 cc of blood from the reservoir. Further work has extended these findings to man. In normal man, removal of large amounts of blood in 50 cc increments produces little change in vascular pressure or hemodynamics. But if done following inhibition of sympathetic vasoconstrictor reflexes with hexamethonium, then with each 50 cc of blood withdrawn, there is a perceptible decline in blood pressure. After removal of only 350 to 500 cc of blood, the arterial pressure falls, by decrements, to collapse levels. During reinfusion, the process is reversed. Thus, sympathetic vasoconstrictor inhibition has converted the vasculature into a static system. In addition, using the pressure-volume apparatus of Litter and associates, which can be applied to the extremities of man, it is calculated that infused epinephrine and norepinephrine can shift as much as 500 ml of blood from the veins of dependent limbs in a short period of time.

These effects of constrictor fibers on venous volume can considerably change venous return by very small changes in vein caliber. For example, if the veins contain 60 per cent of blood volume of which 1 to 2 per cent make up the stroke volume of the ventricles, a 1 to 2 per cent shortening of venous vascular smooth muscle would be estimated to double diastolic inflow to the heart, thus same amount of constriction of the resistance vessels would only insignificantly increase the peripheral resistance.

Excitation of sympathetic vasoconstrictor fibers affects somewhat the aortic smooth muscle cells and possibly other arteries. Presumably, the effect is mainly a change of vascular distensibility and, only secondarily, on mild pressure changes along the arterial tree (see also ch. 26). In general, however, the effect is small. In vessels from the root of the aorta down to arteries of 1 mm, induced changes in diameter are probably less than 5 per cent of total diameter even with marked vasoconstriction or vasodilation. Even a 30 to 50 per cent change of intravascular pressure will only alter diameter within 5 per cent.

FUNCTIONAL SIGNIFICANCE Experimental evi-

dence now indicates that these vasoconstrictor fibers are responsible for blood pressure homeostasis (vascular adjustments derived from the baro and chemoreceptors), and for the regulation of heat loss by the skin blood flow. Thus, the commonest type of centrally induced vasodilation is caused simply by an inhibition of vascular tone. In fulfilling their role as the main neurogenic adjusters of the peripheral circulation, they may show a generalized, strictly segmental or regional function, depending upon the type of stimulus.

CENTRAL CONTROL. The control of the degree and sites of vasoconstriction depends predominantly on the influence of hormonal action and on the action of the central nervous system. In discussing the central control of the cardiovascular system, it should be emphasized that, in the past, relatively little work has been done in this field. This has been true ever since the discovery and location of the medullary vasomotor centers by Oswjannikow and by Dittman in 1873. It was not until 1916 that Ransom and Billingsley published further significant work. Practically all the work in the field has been done by neurophysiologists with the result that generally only blood pressure and heart rate have been measured. More recently, circulatory physiologists have become interested in the problems, and with teams of neuro and circulatory physiologists in operation, regional blood flows and direct effects on the heart have been studied with some progress.

However, at times, interpretation of results is difficult because of the types of central nervous changes that are necessarily induced experimentally. For such studies these include stimulation of outlying nerve fibers, ganglionic blockade, electrical exploration of the central nervous system, ablation of areas and chronic implantation of stimulating electrodes. Each has its drawbacks in a physiological system. Ganglionic blockade is a pharmacological test used to identify vasomotor activity. Its action may be incomplete or not entirely selective. An electric shock is an artificial stimulus and its frequency and intensity may bear no relation to a physiological stimulus. Such stimulation experiments, in general, demonstrate what can happen in nerve fibers, and that in the central nervous system there are excitable areas in the region of the electrodes which, in turn, have synaptic continuity with the cardiovascular outflows. They do not necessarily indicate what role the excitable areas play in the intact human or animal. Ablation experiments

obviate some of these difficulties but there is no surety that the cardiovascular changes induced by ablation are not in part due to injury to surrounding areas. Attempts have recently been made with the use of chronically implanted electrodes to simulate the hemodynamic responses normally occurring in excitement and exercise and then to show, by ablation of such areas, that the cardiovascular response disappears. This approach has considerable promise.

A. The spinal cord. The preganglionic sympathetic nervous may, under some circumstances, exhibit spontaneous activity independent of an excitatory drive from afferent fibers or central levels. This spontaneous discharge may arise from a changed oxygen and CO_2 tension which is prone to occur in a spinal preparation in which neuronal respiration and blood supply are without doubt considerably altered.

Various afferent impulses are able to call forth spinal vasomotor reflexes when the vasoconstrictor neurons form the efferent link. Pain or cold stimulation in the skin induces a segmentally arranged constriction of the intestinal vessels in such spinal animals. Vasodilation occurs when the skin is moderately heated. More intense and widespread effects are seen in human beings with chronic transverse lesions of the spinal cord. Guttman and Whitledge showed the existence of powerful reflexes, in the spinal man, arising from the hollow viscera. In patients with high spinal transection, distension of the bladder would raise the blood pressure from normal levels to 300/140 mm Hg. This is ascribed to the action of reflexes initiated by the tension in the bladder wall and mediated by the isolated spinal cord and the sympathetic outflow. There could also be demonstrated vasoconstriction in the hand and a fall in calf blood flow. These phenomena are consistent with a very widespread vasoconstriction as a result of afferent impulses which spread to an unusual extent in the isolated spinal cord.

the hypothalamus and in the cerebral cortex. In the intact mammal, complicated afferent influences integrated in the cerebral cortex and hypothalamus modify and control the action of the vasomotor center.

The state of activity of the medullary vasomotor center depends upon afferent nerve impulses received from various organs and regions of the body, as well as from other nervous centers, respiratory centers, etc., and upon the chemical composition of the body. In turn, the contractility of the heart, the relative peripheral resistance and, hence, the cardiac output, with its distribution to the various organs, are all mainly controlled by the medulla oblongata responding to impulses from all tissues of the body, including the spinal cord and other portions of the brain itself.

The vasomotor center exhibits inherent automaticity, since its continuous discharge goes on even after elimination of all incoming nerve influences. Section of the brain stem above the medulla does not affect blood pressure, indicating that upper areas do not dominate vasomotor outflow from the sympathetic nervous system. However, such control may be demonstrated by sectioning the cord in the lower cervical region. This interrupts the stream of vasoconstrictor impulses passing from the medullary to the spinal centers, the vessels dilate and the blood pressure falls. After a time, however, the blood pressure rises again, the spinal centers exhibit their inherent power of autonomous action, and assuming the duties hitherto exercised by the medullary centers, restore the vessels to their previous state of tonic constriction. The time required for the vessels to regain their tone after section of the cord varies considerably in different species.

The high degree of vasoconstrictor tone which is normally maintained is shown by the fact that section of the splanchnics doubles the flow in the vessels of the denervated area (Burton Ogitz). After the tone resulting from cord section has been restored it falls again if the splanchnics are sectioned, but after a time a certain degree of tone is regained. This resides in the vascular muscle itself—*peripheral tone*. Apparently, a long period is required for the development of the intrinsic arteriolar tone.

C The hypothalamus In the hypothalamus, electrical stimulation shows the existence of both excitatory and inhibitory neurons which presumably, have much to do with blood pressure regulation. It must be remembered that drastic

redistribution of blood flow following extensive changes in the discharge of the constrictor fibers to some areas, is often concealed behind slight blood pressure changes and, hence, blood pressure change alone is not a reliable guide. Recently, the hypothalamic area has been explored for structures from which a pure inhibition of sympathetic activity could be induced. Such a structure, of very restricted dimensions, has been localized in the anterior part of the hypothalamus, only a few millimeters from the relay station of the sympathetic vasodilator fibers (see next section). From this area topical stimulation induces a generalized, often very marked inhibition of sympathetic discharge affecting both resistance and capacitance vessels.

An immediate and persistent lowering of blood pressure in both normotensive and renal hypertensive dogs occurs following large bilateral coagulations involving the hypothalamic area. This lowering of blood pressure is small in magnitude but is as marked as that resulting permanently from bilateral sympathectomy and low cervical transection. Whether this lowering in blood pressure has a neural or an endocrine basis has not been determined. It is not due to the absence of the neurohypophyseal antidiuretic principle because precipitation of a maximal diabetes insipidus (functional neurohypophysectomy) has been accomplished without affecting blood pressure. It is believed not to be due to a neighboring adenohypophyseal hypofunction because the lowering of pressure following adenohypophysectomy is delayed rather than immediate as is the case following hypothalamectomy. It is perhaps associated with the immediate and marked decrease in basal energy metabolism which supervenes following appropriate hypothalamectomies.

In addition, there is a "heat loss center" in the anterior parts of the hypothalamus which controls the discharge to the vasoconstrictor fibers of the skin and blood vessels, and, thus, plays an important role in adjusting blood pressure. Electrical stimulation or local cooling of this area brings about a fall in blood pressure while direct warming of this region produces a rise in blood pressure. The cutaneous arterioles and precapillary vessels, and especially, the arteriovenous anastomoses (shunts), are the vessels most sensitively engaged in the control of heat loss. However, Keller has marshalled evidence to indicate that vasoconstrictor impulses responsible for the maintained contraction of cutaneous blood vessels do not take origin from the hypo-

thalamus as evidenced by the following experiments. An asymmetry in the ear vessels and in skin temperature (Horner's syndrome) does not follow unilateral lesions in the hypothalamus or hemisection of the brainstem at a midbrain, pontile or upper medullary level, nor does a complete transection of the midbrain or pons result in generalized cutaneous vasodilation. Ipsilateral vasodilation does occur following hemisection of the lower medulla and this approximates in magnitude and duration that which follows hemisection of the cervical cord.

D Cerebral cortex Quite a number of studies of cortical vasoconstrictor fiber control are available but relatively little is known about the circulatory adjustments. Stimulation of the motor and premotor cerebral cortex results in marked elevation of blood pressure with constriction of the cutaneous, splanchnic and renal vessels, and, at the same time, a considerable vasodilation in the skeletal muscle. It is believed that these higher centers play significant roles in blood pressure response to pain and anxiety.

The Vasodilator Fibers

Dilator impulses emerge from the central nervous system by (1) the thoracicolumbar outflow, (2) the cranial outflow of the parasympathetic division reaching the periphery by way of the chorda tympani, glossopharyngeal and vagus nerves, (3) the sacral outflow of the pelvic nerve, and (4) the posterior spinal nerve roots—autonomic impulses.

THE SYMPATHETIC VASODILATOR FIBERS The question of dilator fibers in the sympathetic system has been much debated. About 10 years ago, it was generally believed that they took an active part in regulation of vascular tone, their activity being governed by the medulla, and that such fibers were distributed to the skeletal muscles, the facial muscles, the buccal mucosa, the coronaries, the intestines, and to certain skin areas, such as the ear. These findings were based on direct stimulation of sympathetic fibers and the recording of blood flow by plethysmography. The advent of direct measurement of blood flow (volume changes by plethysmography do not always mean change in blood flow), and location of an area of central control has led to considerable clarification. The control of the degree of vasodilation of blood vessels is, indeed, supplemented by a system of efferent dilator nerves transmitting from the central nervous system, but this seems to be distributed only to skeletal muscle. Electrical stimulation of the sympathetic

fibers usually brings about vasoconstriction in the innervated area, since the action of the vasoconstrictor influence usually predominates over that of vasodilation. But, if the vasoconstrictor response is first blocked by ergotamine, then if the sympathetic outflow contains vasodilator fibers electrical stimulation produces vasodilation. The existence of a sympathetic vasodilator innervation to skeletal muscle of the dog and cat has been established by this technique. The vasodilator nerves may also be activated by topical stimulation in the brain (hypothalamus), using the Horsley Clarke technique with the result that venous outflow from skeletal muscle of the hind leg of the dog may increase 4 to 5 times (as does the local lactic acid production), but the oxygen usage may decrease suggesting that shunts are being utilized. In addition such stimulation results in release of norepinephrine from the adrenal glands. This increased rate of blood flow approximates maximum dilation achieved by other means, such as acetylcholine injection. This may be a potent means of dilation in the human, since blood flow in the human forearm increases during fainting. Also since the blood pressure falls and the blood flow is greater in the normal forearm than in a nerve-blocked forearm during syncope, this might be explained by active vasodilation in the normal forearm excited by sympathetic fibers to the muscles. The transmitter is believed to be acetylcholine and the fibers are exclusively cholinergic, i.e., they are blocked by small amounts of atropine. They take their origin in the motor cortex, pass to the hypothalamus as a thin bundle in the ventrolateral portion of the medulla oblongata and down to the lateral horn of the spinal medulla where they are relayed to lower motor neurons. This pathway is anatomically and functionally separate from the medullary vasomotor center which mediates vasoconstrictor activity. Their functional significance is unknown, but it has been suggested that they are activated in response to cerebral activity, presumably in association with, or in anticipation of skeletal muscle activity.

PARASYMPATHETIC VASODILATOR FIBERS The parasympathetic vasodilator fibers run to restricted cranial and sacral areas such as the cerebral vessels, tongue, salivary glands, external genitalia and, possibly, to the bladder and rectum. These fibers are probably not concerned with baro and chemoreceptor control of blood vessels, nor are they tonically active. It is generally believed that these fibers are cholinergic,

although their vasodilator effect is very resistant to atropine. Their distribution to a few areas with highly specialized functions makes it probable that their function is associated with the special tissue in which they are located.

ANTIDROMIC VASODILATOR IMPULSES Stricker, many years ago, reported that stimulation of the peripheral segments of the cut posterior roots of the sacral nerves caused dilation of the vessels of the dog paw. This observation was at variance with the Bell-Magendie law which states that the posterior roots convey only centripetal impulses. However, in subsequent years the former view has been fairly well documented since such fibers do not convey the induced impulses to the central nervous system but rather the vasodilator impulses are conveyed along the fibers in a direction opposite to that in which ordinary sensory impulses travel; they are called antidromic.

The effective stimulus leading to vessel dilation may arise in or around dorsal root ganglia, or it may arise in the skin to be conveyed antidromically to superficial blood vessels. The latter are sometimes called axon reflexes but they are obviously not true reflexes since no nerve cell is involved. The efferent and afferent limbs of the axon reflex are formed by the branching of a single nerve fiber. A stimulus applied to one branch sets up an impulse which travels centrally to the point of division where it is reflected down the other branch to an effector organ. The most familiar type of axon reflex is that which involves a sensory nerve fiber and through which vasodilator effects are effected.

Dorsal dilation is of significance only in tissues with a relatively rich distribution of pain fibers, such as the skin and mucous membranes. Various substances have been indicated as the transmitter—a histamine-like substance, acetylcholine, and adenosine triphosphate. This local axon reflex in the skin is induced by any factor which causes damage to surface tissues—trauma, cooling, heating, frostbite. Thus, this local mechanism contributes to local defense and repair in surface tissues by creating an increase of local blood flow in response to the majority of harmful stimuli.

Adrenal Medulla versus Neural Control of Blood Vessels

Aside from direct neurogenic connections to the blood vessels, the presence in the blood stream of circulating catecholamines raises the question of their role in controlling the circulation. Presum-

ably they appear through some form of hypothalamic stimulation. It has been widely assumed, but never proved, that the hormones secreted from the adrenal medulla markedly contribute to the vasomotor control of the blood vessels. Using a method that allowed a direct comparison of the individual actions of the hormone and vasomotor fiber on peripheral resistance in representative vascular bed, it has been found that the blood vessel are completely dominated by their vasoconstrictor fibers—the contribution by the adrenal secretion being negligible, except in skeletal muscle, in which small physiological concentrations of epinephrine caused almost maximal vasodilation. On the basis of adrenal catecholamine secretion following maximal excitation of the vasomotor center it is estimated that the maximal secretion is 2 to 3 μ per g per kg per min. Such concentrations of epinephrine and norepinephrine (probably 10 times the normal concentration) when injected intravenously, dilate the vessels of the skeletal muscles and probably those of the liver, but have insignificant vasoconstrictor effects in other regions when compared with the constrictor fibers.

The importance of the catechol hormones for the motor control of the blood vessels is next to insignificant as compared with direct vasomotor innervation. However, a moderate secretion of epinephrine may induce extensive metabolic effects in skeletal muscle and liver cells which lack direct sympathetic innervation. Norepinephrine secretion from the adrenal gland has relatively little influence on the blood vessel, either directly or indirectly, through metabolic dilation.

The vasomotor system of nerves discussed above is the main adjuster of the peripheral circulation, whereby the blood pumped by the heart is distributed throughout the body according to the needs of each individual tissue and of the organism as a whole. This vital role is accomplished by constant, moment-to-moment adjustments of the resistance in the local vascular bed, and it is mediated and regulated by the central nervous system through various reflex mechanisms (Fig. 21-1).

Our knowledge and understanding of these reflex mechanisms is far from complete. The function of some of them is fairly well established, the existence of others is known without any certainty regarding their function, and it is safe to assume that there exist still others, totally unknown to us at the present time. Inevitably, in the ensuing parts, the lengthiest considerations will be given to the most completely studied

FIG 21 1 Diagrammatic representation of cardiovascular reflex mechanisms

mechanisms, but it should be clear that this is not necessarily proportional to their respective physiological importance.

Vasomotor reflexes can be elicited by the stimulation of practically any afferent nerve—somatic or visceral.

Vascular Reflexes Resulting from the Stimulation of Somatic Nerves

Historically, these are among the earliest vascular reflex mechanisms known, although their importance in overall circulatory regulation is relatively minor.

Stimulation of the central end of a nerve, such as the sciatic, the median or a sensory cranial nerve, may result in either a rise or a fall in the arterial blood pressure according to the strength and type of the stimulus employed. The components of the reflex arc upon which the responses depend are, (1) afferent fibers in the peripheral nerve, (2) the vasomotor centers, and (3) the efferent vascular nerves, i.e., the vasoconstrictors, or vasodilators. In order to elicit a pressor reflex, a stimulus much stronger than that necessary to provoke a depressor response must, as a rule, be applied, that is, one which would elicit pain in a conscious animal. In the elicitation of either reflex, the magnitude of the response is apparently dependent upon the number of afferent fibers involved. For example, stimulation of various nerves of the brachial or lumbar plexus causes practically equivalent depressions or elevations in the blood pressure when the number of afferent fibers in the respective nerves is taken into account.

It must be re-emphasized that not all the pressor or depressor impulses ascend to the medulla but that reflex arcs exist which have their centers within the cord, both vasoconstrictor and vasodilator reflexes can be elicited in an animal whose cord has been divided in the lower cervical region a short time previously.

From the results of experiments upon animals, it is to be expected that in the human subject a painful stimulus applied to a somatic nerve will be followed by a pressor response. The excitation of psychic centers and, also, the liberation of adrenaline are additional factors which play an important part in the pressor response resulting from painful stimuli. On the other hand, there are numerous afferent fibers in the hollow viscera which respond to stretch and result in a decreased blood pressure. Stimulation of the mesentery, peritoneum and abdominal viscera or of certain regions such as the anus, vagina, and spermatic cord may be followed by a fall in blood

pressure. Finally, there may be obvious reflex effects which may or may not be associated with blood pressure changes. For example, in normal persons with bladder distention, there may be facial flushing but with evidence of widespread venous constriction. Following inflation of balloons placed in the esophagus, rectum or in an ileostomy, regional venoconstriction also can be demonstrated.

The Pressor or Baroreceptors

Experiments have shown that the fundamental regulations of systemic blood pressure is reflexly controlled by the action of the arterial pressure itself on pressure sensitive receptors located in the vascular walls, especially of the aortic arch and carotid sinus areas.

THE AORTIC OR CARDIAC DEPRESSOR NERVE. The branch of the vagus which is known as the aortic or cardiac depressor nerve was first described by Cyon and Ludwig (1866). It is purely afferent and depressor in function, when sectioned, and its central (cerebral) end stimulated, a pronounced fall in pressure occurs (fig. 21.2), excitation of the cardiac end, on the other hand, causes no effect. Two factors are involved in the depressor response following stimulation of the depressor fibers: (1) *Slowing of the heart rate and increased force of the ventricular contraction.* The efferent fibers of the vagus of the same and of the opposite side constitute the efferent limb of the reflex arc through which this response is chiefly brought about, for its full elicitation at least one vagus must, therefore, remain intact. (2) *Vasodilation.* The vasomotor pathways constitute the efferent limb of this reflex. Vasoconstrictor tone is reduced and vasodilator tone increased. The reflex effect upon the vessels cannot, therefore, be elicited if

FIG. 21.2 Fall in arterial blood pressure resulting from stimulation of the central end of the cardiac depressor (aortic) nerve. The drum was stopped in the middle of the curve and the excitation maintained for 17 minutes. The line of zero pressure should be 30 mm. lower than here shown. (From Bayliss.)

FIG 21 3 Innervation of the carotid sinus and arch of aorta, 1, Heart, 2 arch of aorta, 3, common carotid, 4, carotid sinus, 5, external carotid, 6, internal carotid, 7, carotid bodies, 8, cardiac depressor nerve, 9, ganglion of vagus, 10, sinus nerve, branch of the glossopharyngeal nerve, 11, nerve branch connecting the carotid sinus with the vagus ganglion, 12, glossopharyngeal nerve, 13, vagus nerve (After Heymans)

FIG 21 4 The upper curve in each record represents the arterial blood pressure registered by a membrane manometer, the lower curve of each record shows the electrical discharge from a single fiber of the carotid sinus nerve of the rabbit. In the upper record (A) the mean arterial pressure was 55 mm Hg, even at this low level a discharge of 4 impulses accompanied each ventricular systole. In the lower record (B) the mean arterial pressure was 135 mm Hg, in this instance there was a more rapid and more continuous discharge from the end organ. (Bronk and Stella)

ter section of the spinal cord in the lower cervical region

The receptors of the reflex (the terminals of the aortic nerve) are situated in the aortic arch and upper part of the thoracic aorta, in the ventricles and possibly also, according to Daly and Verney, in the coronary and pulmonary vessels (see fig 21 3)

The fall in pressure is due mainly to dilation of the splanchnic vessels. The dilation is not, however, confined to these vessels but includes those of the skin and muscles. Cardiac slowing plays a minor role in the production of the fall in blood pressure, for almost as great an effect can be obtained after both vagi have been cut. The depressor reflex can be elicited by mechanical or electrical stimulation of the aortic wall wherein the special proprioceptors are located, stretching is an especially effective type of stimulus. It was shown that action currents ascend the nerve synchronously with the heart beats (fig 21 4). The normal stimulus is, therefore, quite evidently the pulsatile expansion of the aortic wall, a rise in general blood pressure increasing the intensity of the stimulus, a fall in pressure causing the reverse effect.

THE CAROTID SINUS MECHANISM The carotid sinus is the term applied to the slight enlargement of the common carotid artery where it bifurcates into the internal and external carotids (fig 21 3). The carotid sinus was shown by Hering in 1923 to play an important role in the regulation of the cardiac rate and arterial blood pressure. Compression of the carotid at its bifurcation (so as to raise the pressure within the sinus) causes a marked slowing of the heart rate, vasodilation and a fall in blood pressure; these effects result even though mechanical stimulation of the vagus is carefully avoided. Electrical stimulation of the sinus wall produces similar effects. Pressure upon the common carotid some distance below the sinus (so as to reduce the blood pressure within the sinus itself) causes cardiac acceleration, vasoconstriction and a rise in arterial pressure together with, as shown by Heymans, the liberation of adrenaline. The carotid sinus therefore constitutes a mechanism whereby both pressor and depressor effects are mediated. The effects are brought about through the following neural mechanism.

THE SINUS REFLEX ARC The afferent fibers of the reflex arc are contained in the *sinus nerve*, a branch of the glossopharyngeal. This delicate filament descends between the internal and external carotids to the sinus where its fibers terminate in

sensory organs (proprioceptors) situated between the connective tissue fibers in the adventitia of the sinus wall. Centrally the fibers of the sinus nerve make connections with the cardio-inhibitory and vasomotor centers. The efferent limb of the cardiac part of the reflex is, of course, the vagus. The efferent limbs of the vasodilator and vasoconstrictor reflexes are apparently sympathetic fibers, for these reflexes are abolished by complete removal of the sympathetic chains.

Study of the action currents passing along the sinus nerve shows that ordinary arterial pressures impulses are discharged throughout the cardiac cycle, their frequency increasing during systole and decreasing during diastole. A rise in general blood pressure increases the rate of impulse discharge as well as the number of sense organs excited. The latter show slow adaptation so that though the stimulus (distension of the arterial wall) persists the impulse discharge shows little reduction in frequency, and when the pressure is very high, they extend with little reduction in rate throughout diastole. At low pressures, impulses are discharged only during systole.

The sinus reflexes have been studied exhaustively by Heymans and his associates. They carried out cross-circulation experiments which speak conclusively for the physiological importance of these reflexes in cardiovascular regulation (see fig. 21.5). The sinus of one dog (B) was isolated from the general circulation and perfused with the blood of another animal (A) in the manner shown in the figure. The nerve supply to the sinus was left intact. When the arterial pressure of dog A was raised, that of dog B, recorded in the femoral artery, fell. Conversely, a reduction in blood pressure of dog A caused a rise in the blood pressure of dog B. In the latter instance, adrenaline liberation also occurred which was a contributory factor in the blood pressure elevation as indicated by its pressor effect upon the circulation of dog C, connected to the suprarenal vein of B. These effects could not be obtained after denervation of the sinus.

The sinus and aortic nerves, or so-called 'buffer' nerves, constitute a mechanism of the utmost importance in controlling the arterial blood pressure and in maintaining the circulation to the brain. The rise in diastolic pressure and the increase in heart rate which occur when the body changes from the recumbent to the sitting position or from the sitting to the standing position, are apparently brought about through these nerves; they therefore play an essential part in

FIG. 21.5 Scheme of perfusion of the isolated carotid sinus of dog B by dog A and an anastomosis between the suprarenal vein of B and the jugular vein of dog C. 1 left carotid artery of dog A, 2 right carotid artery of B anastomosed with carotid of A, 3 left external jugular vein of A, 4 isolated right carotid sinus of B, 5 lingual artery of B anastomosed with jugular vein of dog A, 6 nerve supply to carotid sinus of B. The blood from dog A flows through the carotid sinus of dog B and back to A via the lingual artery of B and the external jugular of A, 7 internal carotid, 8 facial and maxillary arteries, 9 common carotid, 10, 11, 12 and 17, femoral arteries to manometers, 13 adrenal gland, 14 and 15 suprarenal jugular anastomosis, 16 decapsulated spleen in plethysmograph, 18 piston recorder for plethysmograph (After Heymans).

compensating for the effect of gravity upon the circulation.

An underfilled state of the vessels, as may result from hemorrhage or shock, or any other condition which tends to cause a fall in blood pressure, will call these mechanisms into play. A generalized vasoconstriction results to adjust the vascular capacity to the reduced blood volume and thus maintain the blood pressure. Excessive elevation of the blood pressure, on the other hand, is countered by a depressor reflex (see diagram fig. 21.1). The great importance of these reflex mechanisms in hemorrhage is shown by the fact that in an animal in which all four buffer nerves have been sectioned the rapid loss of only about 35% of the blood volume proves fatal whereas usually a reduction in blood volume of from 35 to 45 per cent is required to cause death. Mayerson found that tilting anesthetized dogs from the horizontal to the upright position caused a sharp drop in blood pressure followed within 10 sec

FIG 21.6 Bilateral carotid artery compression in supine man producing carotid sinus hypotension, reflexly causes a rise in systemic pressure, a tachycardia and an increase in peripheral flow with concomitant decrease in peripheral resistance

by a compensatory rise. After section of both sets of buffer nerves the compensatory rise did not, as a rule, occur.

Several (European) workers have reported the occurrence of permanent hypertension in animals following bilateral section of the sinus aortic nerves. Pressures as high as 200 mm Hg lasting over a period of 3 years have been reported. Other investigators who have carried out similar experiments find that the hypertension so produced is not permanent in the majority of animals, but tends to return to normal after a variable period. Such a result may be due to the regeneration of the sectioned nerves or to the reflex control of the circulation being assumed by some other mechanism.

MECHANISM OF ACTION The mechanism of action of the blood pressure on the baroreceptors is complex and only partially understood. If deformation of the baroreceptive arterial walls from a raised arterial pressure is prevented, the baroreceptors no longer respond to the pressure change. Local application of drugs, such as epinephrine or norepinephrine, increases the smooth muscle tension in the arterial wall of the isolated carotid sinus preparation which, in turn, is

associated with a large increase in impulse traffic along the baroreceptor fibers through out the cardiac cycle, and a resetting of the baroreceptive mechanisms at a higher level, with resultant blood pressure adjustment. Sodium nitrite, which relaxes smooth muscle, reduces the intramural tension in these sensitive regions, decreases the impulse traffic and resets the blood pressure regulation at a lower level. These experiments indicate that under normal conditions, the response of the baroreceptor area and the level of blood pressure maintained depend not only on the level of arterial pressure, but, possibly, even more so on the resistance of the baroreceptive arterial walls to deformation by the intravascular pressure.

Possible Other Arterial Baroreceptors

Possible additional arterial baroreceptor types have been studied in the common carotid artery, the thoracic, and mesenteric arteries. Experiments in which a sudden rise in intracranial pressure causes systemic hypertension, and sudden reduction in intracranial pressure leads to systemic hypotension, suggest, but do not prove, that pressure sensitive receptors are present in the cranial cavity. Such responses could be due to asphyxia of the medullary centers. However, the fact that chronic constriction (flow effect not known) of the internal carotid arteries by plastic clamps above the sinus area in dogs causes chronic systemic hypertension enduring up to four years, is not so easily explained. Impulse output in the mesenteric baroreceptors exists throughout the cardiac cycle, and, if pressure is changed in the mesenteric artery or the artery is clamped, vasomotor reflexes are induced. These reflexes do affect the systemic blood pressure even when the sino aortic nerves are cut. It is a segmental, reflex adaptation of the circulation and vasomotor state related to pressure changes in a given area. It apparently exists in the cat but not in the dog. Reflex responses can also be obtained in the innervated perfused hind leg of the open chest dog, when the descending aorta between the left subclavian artery and the diaphragm is isolated and perfused at varying pulsatile pressures, or when adrenaline is added.

The importance of these afferent mechanisms in control of the circulation is not known.

Balanced and Reciprocal Vascular Reactions

In the intact animal the height of the blood pressure at any moment, insofar as the nervous control of the peripheral vessels is concerned, is

apparently the algebraic sum of the effects of afferent impulses impinging upon the vasomotor centers. Under ordinary circumstances impulses arising from the carotid sinus and aortic arch play the most prominent roles, but impulses from skin, muscles and viscera and from higher nervous centers also exert an important influence. That pronounced effects upon the peripheral vessels can be produced by the irradiation of impulses from higher centers is evidenced by such phenomena as blushing, pallor, erection and certain types of syncope (fainting). Similar vascular changes can be observed in the mucosa of the extenuated colon of the dog when the animal is excited and in splenic volume. Even very mild excitation of psychic centers exerts an influence upon the vascular mechanisms. The psychogalvanic reflex (due to changes in the electrical resistance of the skin) has a vascular basis. A reciprocal relationship also exists between splanchnic and cutaneous vascular areas on the one hand and the vessels of the muscles on the other. Adrenaline for example, causes dilation of the latter vessels accompanied by vasoconstriction in the skin and abdominal viscera. Stimulation of the wall of a large vein or distension of the duodenum causes reflex constriction of the cutaneous vessels and stimulation of the skin results in an increase of the blood in the liver and in the renal cortex. Furthermore, the muscular and cutaneous tissues may show opposite vascular reactions. Thus, in the dog, cooling of the body causes constriction of the skin vessels and vasodilation in the muscles.

A mechanism also exists in the experimental animal whereby afferent impulses arising within an organ although leading to generalized vasoconstriction result locally in dilation and increased blood flow.

An interesting example of the complex nature of the reflex vascular adjustments has been described. An electrical record obtained from a nerve twig coming from a Pacinian corpuscle in the mesentery during perfusion of the mesenteric vessels showed an increase in the frequency of the afferent impulses when the perfusion pressure was raised. The impulse frequency was reduced by bleeding the animal and increased again when the blood was reintroduced into the body. It is suggested that the Pacinian corpuscles which lie in close relation to the vessels are stimulated when the latter dilate. Messages pass to the vasomotor center which then discharges vasoconstrictor impulses to the vessels of the area from which the afferent impulses arose. Thus undue distention of the vessels and pooling of blood in the splan-

chnic region is prevented. It has also been shown that stimulation of the peripheral end of the splanchnic nerve causes a much greater rise in blood pressure than usual if the carotid sinuses have been excluded from the circulation (by clamping the carotids). This observation indicates that ordinarily the pressor effect of splanchnic stimulation is largely counteracted by a depressor reflex initiated from the sinus.

The Extraresistance (Cardiac) Effects of the Baroreceptor Reflexes

Too much attention has been paid in the past to the effects of baroreceptor reflexes on the level of blood pressure itself. The action of the baroreceptors is not confined to effects on arteriolar resistance. Much of the preoccupation with peripheral resistance has stemmed from the difficulty in measuring capacity and total flow of the vascular system, a situation which is now being alleviated. The ease of measurement of arterial blood pressure and the dramatic effects thereon from stimulation of the baroreceptor afferents have resulted in identifying circulation changes in terms of blood pressure and hence, in terms of alterations of peripheral resistance. If vasoconstriction of arterioles were the sole result of baroreceptor stimulation, it is debatable whether any benefit would be conferred on the circulation as a whole. The last few years have seen considerable development in flow methodology and evidence, thus far, from such studies indicates that we have been too prone to describe changes in the circulation to blood pressure and arteriolar resistance alterations. The most important changes during reflex systemic hypertension of sinusortic origin are those of venoconstriction (effects on the capacity vessels) and direct sympathetic stimulation of the heart. Occlusion of the common carotid arteries causes systemic hypertension with resultant decrease in the plethysmographic volume of spleen, limb, kidney, and other parts of the circulation. If the systemic hypertension is ascribed to widespread arteriolar vasoconstriction, cardiac output would be expected to fall or, at least, not to increase. However, total pulmonary, muscle and kidney blood flow have been shown to increase during carotid occlusion. There is always some increase in peripheral resistance but it is of less quantitative significance, since the cardiac output increases.

There is evidence that the sympathetics (from the stellates), and parasympathetics (vagal) to the heart, can significantly alter the atrial and

ventricular contractility and that this occurs naturally by way of reflexes. In the open chest dog, stimulation of the cardiac nerve fibers previously isolated from the left stellate ganglion, increased systolic blood pressure, cardiac output and stroke volume with a decrease in heart size. The heart rate did not necessarily change. Since stellate stimulation largely elevated arterial blood pressure and cardiac output in the presence of a constant heart rate, after all known connections to the peripheral vasculature had been severed, it follows that the rise of blood pressure was caused by the augmented force of contraction giving an increased cardiac output and not by increased peripheral resistance. These results with cardiac fiber stimulation are similar to those obtained with carotid sinus hypotension. In the open chest dog, when both carotid sinuses were independently perfused under controlled conditions, in the presence of a high, but constant, heart rate, and the mean perfusion pressure and pulse pressure were greatly decreased, the arterial blood pressure, cardiac output and stroke volume rose appreciably. The calculated stroke work increased about 10 times, while the peripheral resistance was only about doubled. This indicates that the circulatory response to carotid sinus baroreceptor stimulation can be, dominantly, an increased cardiac action and, secondarily, an increase in peripheral resistance. Repetitive stimulation at different levels of carotid sinus hypotension produced a shift of the ventricular function curve to the left (more external work at a lower filling pressure). The reverse is also true, i. e., carotid hypertension reduces arterial blood pressure, cardiac output, stroke volume, and shifts the ventricular function curve to the right. The effector portion of this reflex appears to be the sympathetic fibers from the stellate ganglia to the heart, since, following their section these effects disappeared or could not again be induced.

In the open chest dog with an electrically driven heart (and, therefore, at a constant high heart rate), distal stimulation of the cut vagi decreased mean atrial pressure, arterial pressure, cardiac output and stroke volume, while the ventricular function curve was shifted to the right. Carotid sinus hypertension (produced by the method described in the previous paragraph) gave similar findings. Carotid sinus hypotension enhanced the atrial pressure, arterial pressure, cardiac output and stroke volume. All responses were abolished by atropine. The change in response of atrial contractility is presumed to be

reflexly induced, while the ventricular changes arise secondary to the changing, atrial contribution to ventricular end diastolic pressure and fiber length.

Finally, observations in man are instructive. Pressures within the carotid sinus regions were directly measured with indwelling catheters in conscious, supine man while the internal pressure was lowered by central, bilateral, carotid artery compression. As the carotid sinus pressure dropped from a mean of 100 to 40 mm Hg, the arterial blood pressure and heart rate increased only mildly. There is no evidence that the pressor response is secondary to reduction in caliber of the limb and skeletal muscle vessels. The resistance to flow which they offer is actually slightly less than in the control state as the result of a mild increase in systemic blood pressure and in blood flow through the limbs. Simultaneous measurement of cardiac output would have been helpful here, since the increase in arterial blood pressure could arise from the increased cardiac output or from increased vessel resistance in another area.

Cardiovascular Reflexes of Chemoreceptor Origin

Just as the receptors in the root of the aorta and in the carotid sinus serve as outposts of the brain, testing the blood for its pressure level so that the vasomotor center may be advised, so, in similar fashion, the adjacent carotid and aortic bodies contain epitheloid cells and nerve endings sensitive to the chemical composition of the arterial blood. The fibers of the aortic body run in the vagus while the fibers of the carotid body are branches of the glossopharyngeal nerves. The aortic body is connected with a branch of a fine artery arising from the aorta beyond its arch. The carotid body (glomus carotidum) is a small structure situated upon a branch of the occipital artery or upon a small vessel arising directly from the external carotid just above the bifurcation of the common carotid. It is composed of rounded clumps of polyhedral cells, and possesses a rich network of capillaries of sinusoidal character. These chemoreceptors sample the blood for its pO_2 , pCO_2 , pH, and possibly for other qualities. Blood flow through the carotid body appears to be by far the largest for any body tissue. Calculations based on direct flow measurements indicate a flow of 2,000 ml per 100 g per min (left ventricle = 80 to 100 ml per 100 g per min) while the oxygen usage of 9 ml per 100 g per min, compares with that of the left ventricle. This flow can be cut to 35 by stimulation of the cervical

sympathetics Reflex vasomotor effects evoked by chemoreceptor stimulation have been extensively studied In general the chemoreceptors are stimulated by anoxia, hypercapnia, and acidosis The mechanism by which changes in blood chemical composition effect a response in these two structures is not clearly understood nor has the chemoreceptor intermediate that stimulates the nerve endings been identified, but it has been shown that electroneurographic evidence of chemoreceptor activity exists at CO_2 tensions above 30 mm Hg and O_2 tensions approximately 90 mm Hg or less With increasing CO_2 and decreasing pO_2 , discharge of the chemoreceptors is diffuse, but the discharge with increasing CO_2 tension is rarely as great as that from anoxia According to Heymans, "it is doubtful that chemoreceptors exert any significant effects on the circulation at rest" However, acute hypoxia (inhalation of low oxygen mixtures or of nitrogen) causes systemic hypertension and increased vasoconstriction (decreased blood flow) in the limbs and intestine, but responses are abolished if the chemoreceptor areas are blocked It is unlikely that chemoreflexes cause systemic hypertension only by inducing an increase in arteriolar resistance, but there are no studies of the reflex effects of such stimulation on cardiac output or on the capacitance vessels It is certain, however, that they contribute to the maintenance of the circulation following depletion of the blood volume The latter can be shown in an animal in which, following massive hemorrhage the blood pressure decreased to 70 mm Hg There was intense firing of the chemoreceptors which could be stopped by raising the oxygen tension while resection of the sinus nerves caused a further fall of blood pressure The latter can only be due to withdrawal of chemoreceptor reflex vasoconstriction since the baroreceptors are not operative at this blood pressure level Presumably the capacitance vessels (veins) are involved here as well as the resistance vessels, but this remains to be determined

The Vascular Effects of Normal Variations in Blood Oxygen, Carbon Dioxide and pH

The positive cardiovascular effects of large changes in blood pO_2 and pCO_2 and in temperature, have been discussed in chapter 21 It is generally stated that both CO_2 and oxygen have dual effects Although CO_2 may have a minor reflex effect through the aortic and carotid body chemoreceptors, it may also have a large direct central effect on the medullary centers which

leads to peripheral vasoconstriction with rising blood CO_2 concentrations, while with decreasing blood CO_2 the center will ultimately cease giving out its normal tonic influence It also may have a large direct peripheral vessel effect, an increasing blood CO_2 causing peripheral dilation and a decreasing peripheral CO_2 leading to local vasoconstriction Similarly the central effects of oxygen lack are supposedly largely through the sinus and aortic bodies, a decrease in oxygen leading to reflex peripheral vasoconstriction, while in the periphery, local hypoxia has the effect of vasodilation While these statements based on experimental data have been perpetuated, it is very difficult to make such a functional separation and yet retain some reasonable degree of normalcy in the experimental approach to the problem Aside from the effects mediated through the chemoreceptors it is doubtful that it is known what the relative effects are of variations in blood gases and pH, within a physiological range, on the vasomotor centers and the general peripheral circulation However, for some individual organs or regions one can distinguish between the local effects of chemical changes in the blood on the state of peripheral vessels as compared to their central neural effects at physiological levels of stress and under normal conditions For example, the main body of evidence indicates that small increases in carbon dioxide have a direct vasodilating action on cerebral and skin vessels in animals and in humans

The complexity of the problem, even in individual regions, is indicated when one compares the effect of carbon dioxide on the vasomotor state in the extremities of an abnormal and normal preparation The hindlimb of an animal perfused with blood from a heart lung preparation shows vasodilation (greater blood flow at the same perfusion pressure) when the lungs are ventilated by air containing a small amount of carbon dioxide, or by air with some reduction in its oxygen content These reactions must result from local chemical reactions However, in human subjects with hypercapnia alone induced from breathing a small concentration of carbon dioxide in the inspired air, the forearm's vascular resistance (mainly muscle) is greatly increased, for systemic blood pressure is increased with little or no change in local blood flow In the same subjects in whom hypoxia was produced by breathing 5 to 10 per cent oxygen in nitrogen forearm blood flow increases 100 per cent in the presence of a constant systemic arterial and venous pressure so that vascular resistance in the forearm is

considerably reduced. Since the same results are observed in the nerve blocked arm, the local change in vasomotor state is due to a humoral mechanism and not to a nervous mechanism. When the increased elimination of CO_2 during hypoxia is prevented by adding enough CO_2 to the oxygen poor gas mixture to maintain the alveolar pCO_2 constant, vascular resistance in the forearm is not significantly changed. This indicates that marked hypoxia does not affect local overall vessel resistance. Thus, in man, a humoral vasoconstriction occurs with hypercapnia, and a humoral vasodilation occurs with hypoxia in the muscles of the forearm which is due more to the hypocapnia resulting from the hypoxia than directly to the lack of oxygen. But the exact mechanism is not clear. The CO_2 or altered pH could have had a local effect, but it is just as probable that a rapid change in arterial pCO_2 evoked biochemical changes in the blood which caused local vasoconstriction or dilation. Of several possible humoral vasodilators which are known, the lowered pCO_2 might have led to the release of adrenaline which is known to cause vasodilation in skeletal muscle.

In the past, it has been debatable whether the circulatory effects observed with respiratory or metabolic acidosis come from the elevated pCO_2 , the fall in pH, or a combination of both. This has been because there has not been any good way of separating these effects. However, with the use of the organic buffer Tris (hydroxymethyl) amino methane, reasonable experimental separation has been performed with the finding that the cardiovascular effects arise from the decrease in pH and not from the associated change in blood PaCO_2 (fig. 21.7). To make this study, the effects of metabolic acidosis were observed in dogs under apneic oxygenation with and without Tris injection. Apneic oxygenation is a condition of ventilatory arrest during which oxygenation of the blood is maintained while acute hypercapnia develops. This condition is produced by ventilating the dog with 100 per cent oxygen in an open circuit for one hour. During this time, oxygen replaces nitrogen throughout the body. After this period of denitrogenation, apnea is induced by succinylcholine, and the lungs are left connected to a reservoir of oxygen. Thus, the blood is maintained in full oxygen saturation, but blood CO_2 accumulates slowly. Without the presence of Tris in such dogs, there is a rise in CO_2 , arterial, pulmonary artery and central venous blood pressures, PaCO_2 , and plasma norepinephrine and epinephrine, the blood pH drops precipitously,

the heart rate mildly. In similar dogs treated with intravenous drip of Tris, all these physiological variables remain close to their control values except PaCO_2 which rises from 38 to 82 mm Hg. Since such a pCO_2 increase in the intact animal does produce the above circulatory changes when it is accompanied by a parallel fall in pH, the H^+ concentration increase during hypercapnia seems to be a determinant factor in the stimulation of the cardiovascular system. This type of experiment, however, still does not clearly separate the effects of CO_2 and pH, for the latter does change (7.45 to 7.31), and the vascular system may be very sensitive to it.

Reflexes from the Heart and Lungs

Despite considerable lacks in our knowledge concerning their functions, the carotid and aortic baroreceptor and chemoreceptor reflexes are the most completely studied and understood of vasomotor regulatory reflex mechanisms.

From various intrathoracic vessels (including the chambers of the heart) arise other reflexes affecting vasomotor tone. Although their importance in the regulation of the circulation may possibly be comparable to that of the previously mentioned reflexes, much less is known about their function. As a matter of fact, our present state of knowledge permits little more than an enumeration of various cardiopulmonary reflexes discovered up to date.

It is much more difficult to investigate cardiopulmonary reflexes than those related to the baroreceptors in the systemic circuit. This is because the operative procedures necessary to make interpretable experiments are so extensive and traumatic, and it is almost impossible to denervate the heart and/or lungs. Despite this, the usual technique so successful in other vascular beds, of eliciting reflexes by change of perfusion pressure in an isolated vascular bed, has been used with some success to indicate qualitatively, if not quantitatively, cardiopulmonary reflexes.

RIGHT HEART REFLEXES

Observations have shown conclusively that in the walls of the atria and great veins there are receptors which have fairly large afferent nerve fibers and which respond to change of pressure in the atria by firing during atrial contraction (Type A), and during passive distention during atrial diastole (Type B). These afferent fibers are in the vagi.

The existence of a right atrial reflex has been

FIG 21.7 Comparative changes in pH, pCO₂, blood pressure and catecholamine levels during apnoeic oxygenation with and without TRIS administration (Nahas, Am J Physiol, 1959, 197, 1308)

shown as follows. Blood returning through both venae cavae was collected and pumped into the right atrium, whence it passed through the right ventricle to the pulmonary artery, where it was collected and pumped into a donor dog's veins for oxygenation and returned by a pump to the recipient's left atrium. Increase of perfusion pressure in the right heart gave bradycardia and systemic hypotension which were abolished after vagotomy. Since atropine prevented the bradycardia resulting from the perfusion pressure elevation but did not affect the associated hypotension, a reflex peripheral dilation had occurred. The receptors were found to be in the atrium and not in the ventricle.

In 1915, Bainbridge showed that the intra-venous injection of saline or blood produced tachycardia in the anesthetized dog and that this was abolished only by bilateral vagotomy. This is the one reflex which is known to most medical students. Yet, he left unanswered the question of the nature of the effective stimulus to the receptors and their location in the great veins or right side of the heart. Many subsequent investigators using more refined techniques have tried to pin point the receptors involved and their location. Many are of the opinion that the receptors are in the right atrium; others that no such reflex exists. The answer must await the use of better techniques.

PULMONARY VESSEL REFLEXES

Most investigators now admit that the pulmonary blood vessels have tone and, therefore, the possibility that this tone can be altered. Daly has found evidence in the anesthetized dog that the pulmonary vascular resistance can be altered by extrinsic vasomotor nerves. Both vasoconstrictor and vasodilator responses have been demonstrated. Recently, direct evidence has been produced that stimulation of the carotid body chemoreceptors by perfusion with venous blood decreases pulmonary vascular resistance. This response was abolished by cutting the carotid sinus nerve or cervico vagosympathetic trunks, or by injection of atropine. However, localization of the vascular area involved in the dilation was not possible.

A Pulmonary depressor reflex. In perfusion experiments, blood is pumped from the right atrium

FIG 218 Experimental device to show presence of left ventricular pressure (stretch) receptors by aortic compression *S*, clamp, *AK* and *VK*, aortic and left atrial pressure manometers, respectively, *W*, constant pressure buffering chamber, *R*, systemic flow meter, *P*, pump (Douthett and Kramer, *Pflüger's Arch ges Physiol*, 1950, 269, 114)

of a donor dog through the cannulated left pulmonary artery of a recipient, the outflow from the recipient's left pulmonary vein (thus excluding the left atrium) being returned to the jugular vein of the donor. Marked elevation of the perfusion pressure at times decreases the systemic blood pressure and heart rate which effect is removed by cutting the vagi. In addition, injection of certain drugs into the pulmonary artery also causes a fall in systemic blood pressure and heart rate which is prevented by previous vagal section. This suggests a pulmonary depressor chemoreflex. The receptors concerned are believed to lie in the pulmonary veins.

B Reflexes from the smaller pulmonary vessels. Despite a tremendous amount of investigation, it is problematic whether reflexes are initiated from the smaller vessels of the pulmonary circuit—arterioles, capillaries and venules. Embolization by clots, starch grain, glass and plastic beads, have not led to conclusive experiments as to whether the results have a mechanical or a reflex explanation. From the work of Daly it is known that the sympathetic innervation of the vessels is largely vasoconstrictor and that stimulation of the stellates may, at times, reduce lung blood flow by as much as 30 per cent. Despite this there is no knowledge that pulmonary vasoconstriction can be elicited from stimulation of pulmonary vascular receptors.

LEFT HEART REFLEXES

A Left ventricle. Daly and Verney were first to show that pressor receptors existed in the left heart. In an innervated heart lung preparation in which the aortic pressure was kept constant, an increased pressure in the left side of the heart caused cardiac slowing. More recently, it has been shown that when the pressure is elevated in a vascularly isolated left heart, reflex bradycardia, systemic hypotension, and vasodilation of the leg vessels result. Since left atrial pressure elevation alone was ineffective, it is concluded the receptors were in the left ventricle. Upon vagal blockage the effect disappeared. These effects may also arise from pressoreceptors of the aortic arch which are known to extend into the left side of the heart. Informative experiments are those of Douthett and Kramer, who varied the left ventricular stretch and pressure by an adjustable clamp on the aorta, while the systemic flow was metered, and its perfusion pressure was maintained constant during aortic constriction by a very large pressure buffering chamber attached to the aorta. It can be observed (fig 218) that within 4 sec after elevation

of left ventricular pressure by mechanical constriction, the aortic flow starts to rise and is almost doubled, indicating massive peripheral dilation arising in the beginning of the aorta or in the left heart. The afferent pathway for this reflex was demonstrated to be the vagus nerve, for following its cervical section, the effect disappeared. To what extent this reflex is invoked under normal conditions is problematic, since a rather large increase in ventricular pressure (and presumably, therefore, stretch) is necessary to elicit a systemic flow response.

B Coronary chemoreflex (Bezold-Jarisch reflex)
In the dog or cat, the peripheral ends of the major coronary artery branches have been separately connected to systemic arteries. Injection of veratrine peripherally into the left circumflex artery causes a fall in blood pressure and heart rate. The systemic hypotension was shown to be independent of the bradycardia, being due to reflex vaso-dilation. This does not occur if the vagi are first cut. This does not occur upon injection into the right coronary artery or into the coronary artery branches supplying the atrial appendages. Thus, there are receptors in the left ventricular wall supplied by the left circumflex artery.

C Left atrial receptors Recent work has shown that left atrial vagal receptors (and also possibly in the pulmonary veins) may be the sensory endings of a reflex which controls blood volume. It was first shown that negative pressure breathing causes diuresis. This was then related to the congestion of the thoracic blood vessels which arise from this procedure. Since the effect was removed by vagotomy, it was reasoned that pulmonary or cardiac vessel receptors of vagal origin exist which are responsive to stretch or pressure. Experimentally, it was shown that procedures which lead to an increase of the intrathoracic blood volume (negative pressure breathing), congestion of the pulmonary vascular bed by mitral stenosis through snares, embolization of the pulmonary capillary bed, or an inflated balloon in the left atrium, all cause marked diuresis which, in the balloon experiments, is prevented by previous cooling of the vagus nerves. However, in general the physiological purpose and quantitative effects remain unknown.

RESPIRATORY REFLEXES

A Vasoconstriction in the finger Vasoconstriction occurs in a finger after voluntary deep inspiration or passive deep inflation of the chest with air under positive pressure. The vasoconstriction was determined by a finger plethysmo-

graph in which a blood flow decrease was noted with inspiration which bore no relation to the respiratory fluctuations of systemic blood pressure. The receptors and afferent pathways of this reflex are unknown except that without doubt, they arise within the lungs.

B Respiratory arrhythmias Changes in heart rate caused by respiration can be demonstrated. Most investigations show that mild inflation causes cardiac acceleration and that this can be abolished by vagal section. It is believed, therefore, that the lungs are a constant source of impulses which exert an inhibitory influence on the cardiac vagal center, this influence being maximal during lung inflation and minimal during lung deflation. Presumably, the respiratory arrhythmia of the pulse has also a central initiating mechanism since increase of the carbon dioxide tension in the cerebral vessels augments the heart rate during each period of inspiratory discharge. But it has not been established whether this central arrhythmia is due to diminution of vagal activity during inspiration, or augmentation of sympathetic accelerator activity.

PERIPHERAL VASCULATURE REFLEXES

Although little is known, recent interest has been aroused in sensory mechanisms that may lie in the peripheral vasculature. Haddy and Gilbert, using anesthetized dogs in which pressures were measured in the brachial artery, cephalic vein, small artery and small veins of the paw, and with maintenance of a constant brachial artery flow by a pump, found that elevation of cephalic vein pressure, although the arteries and veins dilated, was completely compensated for by constriction in the small vessel segment. However, after procaine nerve block the vessels did respond like a passive elastic system. Therefore, the observed small vessel constriction must have been of venous origin. However, this local veno-veno motor reflex has not been confirmed by Greenfield and Patterson using the plethysmograph.

LOW PRESSORECEPTORS IN MAN

Most of the previously described intrathoracic vascular reflexes were studied exclusively in experimental animals and their significance in the human remains to be confirmed. It is, therefore, of interest to mention recent experiments in man which have functionally implicated low pressoreceptors in the thoracic portion of the central blood pool in adjustments of the circulation (fig. 21-9). When the legs of a recumbent man are passively raised, the blood flow through the skele-

REGULATION OF PRESSURE AND FLOW IN THE SYSTEMIC AND PULMONARY CIRCULATION

Arterial Blood Pressure

The first determination of arterial blood pressure was in 1733 when the Reverend Stephen Hales inserted a brass cannula into the central end of the femoral artery of a horse, connected it to a long vertical glass tube, and observed that a column of blood filled the tube to a height of 8 ft, 3 in (185 mm Hg)

SPECIES DIFFERENCES The arterial blood pressure varies moderately between different warm blooded species, and there is little or no relation ship between the size of an animal and the height of its blood pressure. The blood pressure, in general, is higher in birds than in mammals, whereas that of cold blooded animals is only about one third as great. The carotid blood pressure (mean) of the unanesthetized, basal dog approximates 110 mm Hg. The domestic cow has a mean blood pressure of about 135 mm Hg. The following systolic pressures (mm Hg) have been reported: mouse, 113, rat, 130, canary, 220, robin, 118, frog, 43, turtle, 44, and carp, 43. Of considerable interest is the arterial pressure in the carotid artery of the giraffe, because of the very long, vertical distance from heart to brain. In experiments performed on 4 standing, unanesthetized giraffes, the carotid pressure, corrected to heart level, ranged from 280/150 to 344/194 mm Hg. The walls of the giraffe's left ventricle and the aorta are extraordinarily thick

ARTERIAL BLOOD PRESSURE IN MAN

A Normal values The average systolic pressure of young male adults at mental and physical rest in the sitting position (as usually measured in a routine medical examination) is usually given as 120 mm Hg, the diastolic as 80, the mean pressure as 100, and the pulse pressure as 40. However, the range of normal blood pressures may be from 90 to 120 mm Hg systolic, and 60 to 80 mm Hg diastolic. Slight diurnal variations in blood pressure of from 5 to 10 mm Hg systolic

occur, the peak being in the afternoon and the lowest level in the early hours of the morning.

B Age, sex and build Age exerts a definite influence upon the blood pressure level. At birth the systolic pressure measures from 20 to 60 mm with an average of 40 mm. It rises rapidly, however, and has an average value of about 70 mm at the end of a fortnight and 80 mm at the end of a month. A slow steady rise takes place from this time until about the 12th year when it averages 105 mm. With the onset of puberty, a more sudden rise occurs which in boys reaches 120 mm at about the age of 17. A steady though not great rise in blood pressure, from adolescence to old age, is the rule in health, the averages for the age of 60 being given as about 140 systolic pressure and 87 diastolic. In women up to the time of the menopause, the systolic pressure is from 4 to 5 mm lower than for men of the same age. At the menopause, however, there is a somewhat abrupt rise, and the pressure remains a little above the male average from then on (table 22.1).

Comparing groups of markedly obese and normal persons, the former have a rather pronounced increase of systolic pressure. The incidence of abnormally high blood pressure (hypertension) is also definitely greater in overweight persons.

C The effects of digestion, emotion, exercise and posture The systolic pressure is influenced to a small but definite extent by meals. A rise of from 6 to 8 mm is the usual effect, and this lasts for an hour or so. There is little change in the diastolic pressure, if anything, it is reduced, presumably as a result of vasodilation in the digestive organs and skin.

Quiet, restful sleep may be accompanied by a fall of from 15 to 30 mm in the systolic pressure. The fall is most marked during the first hours rising gradually again after this until the time of waking. If the sleep is disturbed and accompanied by imaginary motor activities, there may be no depression of the pressure, but rather an elevation, in some instances to as high as 200 mm systolic and 105 mm diastolic. Excitement, fear

worry, etc., markedly affect the arterial blood pressure, especially the systolic. The effects are brought about through increased cardiac action and changes in the state of the vessels through impulses playing upon the cardiac and vasomotor centers in the medulla. The liberation of adrenaline into the blood stream may also be a factor.

Of all physiological conditions, exercise, if of a strenuous nature, has the most powerful effect upon the arterial blood pressure. During the muscular effort or even immediately before, i.e., at the instant that the exertion is contemplated, the systolic pressure commences to rise and may reach a height of 180 or 200 mm. Hg. Except in well trained persons or athletes, this is invariably associated with a large increase in heart rate to 150 or 180 per minute. In the trained individual, the blood pressure rise may be quite mild. The diastolic pressure shows a less pronounced rise (100 to 110) so that the pulse pressure is increased. In light exercise the diastolic pressure may remain at the normal level while the systolic rises several millimeters. Immediately after the exercise the pressure drops momentarily to normal or even slightly below. It then mounts rapidly to its previous high level from which it gradually declines again, and in a healthy person reaches the normal within from 1 to 4½ minutes. The evanescent drop in pressure is explained as being due to the sudden relaxation of the abdominal muscles. The blood is drained into the venous reservoirs. These when deprived of their support (abdominal muscles) have their capacity increased and the blood flow into the right heart is temporarily curtailed. It is not until an appreciable time has elapsed to enable the increased venous capacity to become filled again by blood pouring in from the recently active muscles that an adequate flow into the right heart is restored.

The diastolic pressure is somewhat higher in the standing than in the sitting position and lowest in recumbency. This change is found to occur whether the postural change is brought about actively or passively and is evidently an overcompensation for the gravity effect. The systolic pressure usually rises but to a less extent than the diastolic, so the pulse pressure is reduced. Pressures, however, taken at as short an interval as 10 seconds after the erect position has been assumed show that the initial effect is a fall of from 6 to 22 mm. Hg in the systolic pressure. This is sufficient to stimulate the carotid sinus and aortic mechanisms and cause increased vascular tone with a consequent compensatory rise in pressure. Compensation is usually complete

TABLE 22 1

The average variations of blood pressure (after Hunter a compilation of observations on a quarter million healthy Americans)

(After Gager)

Age	Systolic Pressure	Diastolic Pressure	Pulse Pressure
10	103	70	33
15	113	75	38
20	120	80	40
25	122	81	41
30	123	82	41
35	124	83	41
40	126	84	42
45	128	85	43
50	130	86	44
55	132	87	45
60	135	89	46

within 30 seconds. Reverting from the standing to the sitting or recumbent position has the reverse effect, fall in diastolic pressure and rise in pulse pressure. In persons with an abnormally and habitually low blood pressure, the systolic pressure may actually rise in the lying-down position and fall when the subject stands. The diastolic, on the other hand, is always lowered in recumbency and raised in the erect posture.

THE SYSTOLIC, DIASTOLIC, MEAN AND PULSE PRESSURES. Hales, in describing his experiment, speaks of the blood column after it had ceased to rise further in the tube, oscillating above and below a mean level. To quote his own words, "When it (the blood) was at its full height, it would rise and fall at, and after, each pulse, 2, 3 or 4 inches." By recording with an adequate pressure manometric system, these fluctuations are seen as waves synchronous with the heart beats (see fig. 22 4). The crest of the wave represents the maximal pressure, corresponding to the contraction or systole of the ventricle, and is called the systolic pressure. The trough of the wave, i.e., the point of minimal pressure, coincides with the end of the resting phase or diastole of the cardiac cycle, and is called the diastolic pressure. The mean pressure is usually given as half the sum of the values for the systolic and diastolic pressures. This would be strictly accurate only if the pulse wave inscribed a perfect triangle which however, is not the case. The average pressure throughout the cardiac cycle, i.e., the true or geometric mean, is generally somewhat lower than this lying nearer the diastolic than the systolic pressure. This can be obtained by integration of the curve.

The difference between the diastolic and systolic pressures is the pulse pressure. This is caused by the ejection of blood into the aorta during systole. Its magnitude, other things being equal, will vary with the quantity of blood ejected by the heart at each beat.

The systolic pressure reflects mainly the distensibility characteristics of the arterial system as it receives blood from the left ventricle. It would be expected to undergo wider variations under the stresses of every day life than the diastolic pressure. The latter represents the constant load which the arterial walls are called upon to bear and the resistance which the ventricular contraction must overcome to throw open the aortic valves. It shows a steady but slight decline from the larger to the medium sized vessels. The systolic pressure shows a fall between the larger and the smaller arteries which, though not great, is much more pronounced than that which occurs in the diastolic. On this account, the two pressures tend to become more nearly equal toward the periphery, the pulse pressure being reduced. Since the pulse pressure is the difference between the systolic and diastolic pressures, it may be reduced by an alteration in one or other of these. A rise in the systolic or a fall in the diastolic, will cause the pulse pressure to increase, while a fall in the systolic or a rise in the diastolic will lower the pulse pressure. If both systolic and diastolic pressures rise or fall to an equal extent, the pulse pressure remains unchanged. The mean pressure will rise as a result of a rise in either the diastolic or systolic pressure, or of both together, and will fall when a reduction of either or of both of these pressures occurs.

DETERMINANTS OF NORMAL ARTERIAL BLOOD PRESSURE

Several factors combine to maintain normal arterial blood pressure. They are, (a) the pumping action of the heart, (b) the peripheral resistance, (c) the quantity of blood in the arterial system, (d) the viscosity of the blood, (e) the elasticity of the arterial walls.

A The pumping action of the heart The means by which the cardiac contraction exerts its effect upon the arterial blood pressure is, obviously, through the quantity of blood which it is capable of discharging into the aorta in a unit period of time, i.e., upon the output of the heart per minute or stroke volume times heart rate. When more blood is forced into the already filled arterial system, it cannot escape at once from the system in

the same amount as it is thrown into the aorta, so the arterial walls become stretched. The pressure rises until the velocity of flow through the arterioles is great enough to balance again the outflow from the system with the inflow. Hales grasped this fundamental fact when he wrote, "the real force (pressure) of the blood in the arteries depends on the proportion which the quantity of blood thrown out of the left ventricle in a given time bears to the quantity which can pass through the capillary arteries (arterioles) into the veins at that time."

B The peripheral resistance The peripheral resistance is dependent upon the caliber of the small vessels, mainly of the arterioles and, to a less extent, of the capillaries, and upon the viscosity of the blood. It has also been demonstrated by Haddy, that the macroscopic vessels (smaller arteries and veins) contribute significantly to resistance across systemic vascular beds. By far the greater part of the peripheral resistance of the circulatory system is constituted by the minute vessels of the muscles and of the abdominal structures. The importance in this connection of the latter—the so called splanchnic area—can be demonstrated by tying off all branches of the aortic arch, except the carotids, and the abdominal aorta below the inferior mesenteric branch, when little or no change in peripheral resistance results, whereas an increase in the latter at once occurs when the blood supply to the splanchnic area is reduced by ligating the superior mesenteric artery. Stimulation of the great splanchnic nerve, which innervates the rings of muscle fibers in the walls of these vessels causes their constriction, and consequently a reduction in the outflow from the arterial system. The pressure will continue to rise until inflow and outflow are again balanced. In the absence of compensatory changes in the other factors concerned in the maintenance of the pressure this remains at the higher level so long as the constriction persists. Dilatation of the vessels, i.e., reduction in peripheral resistance, will of course be followed by the opposite effect. When the vessels of the splanchnic area are fully dilated they are capable of accommodating almost all the blood in the body, in such an event the blood pressure would fall to zero. The peripheral resistance might be compared to a dam in a river. If the dam is raised or lowered, and no change occurs in the supply of water flowing down the river to the dam, the water continues to rise or fall respectively (and its pressure in consequence increases or diminishes) until it reaches the new

level. From then on the quantity of water which overflows in a given time is the same as it was at the original level.

The total peripheral resistance in animals or in man can be calculated from the mean blood pressure (M) and the cardiac output (I), since all blood entering the aorta must, of course, pass through the peripheral vessels. This can be derived for the whole body from the simultaneously measured arterial pressure and cardiac output, and for an organ or region from the local arterial pressure and flow, but interpretation is valid only under strictly controlled conditions which have already been discussed. In general, in isolated organs, either pressure or flow should be kept constant while the other is varied. For total circulation either this arrangement or possibly a complete pressure-volume curve for the systemic circulation can be used before and after a test stimulus with subsequent comparison of the two curves. There is a curvilinear relationship between pressure and flow in the aorta (fig. 22.1). This is also true in separate vascular beds where pressure and flow have been measured but the shape of the curves may be quite different.

Various terminologies have been used to define peripheral resistance. Green has used a unit of peripheral resistance (PRU) as equal to 1 mm Hg/1 ml/min. Many authors take such a ratio and by expressing P in dynes per square centimeter and F as milliliters per second the peripheral resistance can be given in absolute units of force. Thus

$$\text{Peripheral resistance (R)} = \frac{M(\text{mm Hg}) \times 1332}{F(\text{ml/sec})}$$

$$R = \frac{\text{dynes/cm}^2}{\text{cm}^3/\text{sec}}$$

$$R = \frac{\text{dyne sec}}{\text{cm}^3}$$

1332 is a figure for the conversion of pressure to dynes.

The peripheral resistance so calculated is found to vary inversely with the size of the animal, i.e., directly with the surface area. It amounts normally to from about 600 to 2,000 absolute units in man but may be over 5,000 in arterial hypertension in which F shows little change. The values for the dog and rabbit range from 2,000 to 9,000 and from 11,500 to 12,000 respectively. This means that the minute vessels in a large animal offer less resistance than do the fewer number in a smaller animal even though the

FIG. 22.1 Relationship between mean arterial pressure in millimeters of mercury (abscissa) and cardiac output in liters per minute (ordinate) in a typical experiment. Solid circles represent values observed with buffer nerves intact; open circles values obtained after bilateral vagotomy and while a constant pressure of 210 mm Hg was exerted upon the isolated innervated carotid sinuses (From Levy *Circulation Res.* 1954 2: 372).

vessels of both are constricted to the same degree. This is due to the fact that the rate of flow in the smaller animal is greater in relation to the size of its vascular bed (cardiac output bearing a constant relationship to surface area which varies inversely with body weight).

C. The quantity of blood in the arterial system. In any closed system of rigid tubes fluid must fill it to capacity in order that a pressure can be developed within it. The arterial walls are distensible and elastic and a certain degree of stretching of these must occur before any considerable pressure is created. The arterial system must be actually overfilled and the greater the extent of the overfilling the greater will be the blood pressure. Loss of blood either of all its elements as in hemorrhage or of the fluid portion alone if not compensated for sufficiently by readjustment of the other factors concerned in blood pressure maintenance must inevitably result in a fall of pressure. Increasing the total amount of circulating fluid artificially as by the transfusion of blood or blood substitute will elevate the pressure again. In animals the blood pressure may be lowered by hemorrhage to half

FIG 222 Description in text

its normal value and restored again to its original level by re-introducing into the circulation the blood which has been removed or by the infusion of an effective blood substitute

D The viscosity of the blood The greater the viscosity or "thickness" of any liquid the greater is the pressure required to force it along a length of narrow tube in a given time, or if the pressure remains constant the longer will be the time required for the liquid to traverse the tube. The frictional resistance which is developed between the parts of the liquid itself, that is, the internal friction is greater when the viscosity is high than when it is low. Viscosity depends upon the degree to which the molecules or particles of a fluid cohere. Blood is some 5 times more viscous than water.¹ With regard to the influence of viscosity upon the blood pressure, it is again a matter of outflow through the arterioles. If the driving force remains constant and the caliber of the vessels is unchanged, then the greater the viscosity the greater will be the frictional resistance developed in this region and the less will be the quantity of fluid that will pass through in a unit of time.

The blood owes its viscosity to its colloids (plasma proteins) and to an even greater extent its suspended corpuscles; friction is developed between the surfaces of the latter and the surrounding fluid. Changes in the concentration of the blood as a result of changes in its protein content or in the number of its corpuscles will therefore alter its viscosity; venesection by removing a quantity of blood and causing dilution of the remainder causes a fall in viscosity which may materially relieve the work of the heart. For these reasons the viscosity is low in anemia and high in polycythemia, leukemia and anhydremia. Also changes in its chemical composition or in its gas content may alter the viscosity of the blood. Carbon dioxide increases the viscosity, oxygen lowers it; venous blood is, in consequence, more viscous than arterial, and high blood viscosity is usual in congestive heart failure with cyanosis. Chloro-

form anesthesia and narcotization with morphine are said to increase the blood viscosity. It is also raised in hyperglycemia, hypercalcemia and in acidosis.

The viscosity of most liquids is reduced by a rise of temperature—hot syrup flows more freely than cold. In muscular exercise and in fever the blood temperature is raised, the viscosity of the blood is lowered, and the work which the heart is called upon to do in overcoming the frictional resistance in the smaller vessels is thereby appreciably reduced. Blood concentration, however, which occurs to some extent under these circumstances, tends to offset the effect of temperature.

E The elasticity of the vessel walls This is concerned mainly with the origin and maintenance of the diastolic pressure and with sustaining the mean pressure at a higher level than would be possible in a rigid system under otherwise identical conditions.

The elasticity of arterial tissue does not come into play to any notable extent with a pressure below from 30 to 40 mm. of mercury. Below this level there would be little stretching of the walls of the arteries which would then behave like a system of rigid tubes. At the usual diastolic pressure that exists, however, the walls are stretched and by virtue of their elasticity tend to recoil against the distending force. We have seen that the flow of blood is pulsatile in the arteries. Beyond the arterioles, *i.e.*, in the capillaries and veins, the flow is continuous. The conversion of the pulsatile flow to a uniform one depends upon the existence of a diastolic pressure. The physical principles involved in the maintenance of the diastolic pressure and the disappearance of the pulse beyond the arterioles may be best illustrated by a simple artificial model similar in principle to one devised by Borelli for the same purpose some 300 or more years ago.

In figure 222 is represented a bulb syringe, S, valved at A, and having a short tube, B, which dips into a basin of water. Leading from the opposite pole of the bulb is a longer tube, C. When the bulb is alternately compressed and released fluid is drawn from the basin and discharged from the mouth of the tube. If the walls of the latter are composed of some rigid material (fig 222, 1), it will be found that when the pump is worked the fluid issues from the tube in spurts or jets synchronous with each stroke, but no flow occurs between the strokes. An increase in the frequency or force of the strokes does not alter the intermittent character of the flow nor does lengthening the tubing. If the peripheral re-

¹ This is an average figure. Values obtained by different observers for the viscosity of blood, taking distilled water as unity, vary considerably but the majority range between 4.5 and 5.5.

sistance of the vascular system be imitated by attaching a nipple of small bore to the mouth of the delivery tube so as to increase the resistance to the outflow of fluid the issuing stream is finer and its velocity is increased but it still remains intermittent (fig 22.2, 2) Let the elasticity of the arterial wall now be imitated by replacing the rigid tube by one of rubber, yet let the mouth of the tube be left free and not constricted in any way (fig 22.2, 3) The intermittent character of the stream is unaffected However, if the small bored nipple representing the peripheral resistance be fixed into the mouth of the elastic tubing the stream will be found to have lost its pulsatile character and to have become continuous (fig 22.2 4) Two factors are therefore necessary to produce this result, (a) *resistance to the outflow* and (b) *elastic tubing* The reasons for this are clear If the fluid has free egress from the tube most of that which enters it from the pump is discharged from the open end before the next beat occurs, the pressure, in consequence, does not rise to a sufficient height to distend the rubber wall i.e. elasticity is not called into play, over filling of the tube does not occur and in consequence the latter acts simply as though it were composed of rigid material

The foregoing facts apply directly to the arterial system The elasticity of the vascular walls and the peripheral resistance are both essential for the maintenance of the diastolic pressure As the contents of the ventricle are thrown into the already over filled system during systole the added pressure which is then exerted upon the vascular walls causes their further distension After the completion of systole the elastic walls rebound and pressing upon the blood within their embrace, force it onwards through the peripheral vessels In other words, the arterial lumen returns to its previous diameter and the energy that had been stored up during the stretching of the elastic tissue is in this way gradually expended during diastole

The elastic recoil of the arterial wall thus acts in a sense as a subsidiary pump to drive the blood onwards in a continuous stream between the heart beats Otherwise the pressure would fall to zero after each systole

It is clear then that any increase in the elasticity of the arteries other factors remaining unchanged will tend toward a lowering of the diastolic pressure If the aorta and its larger branches are stiffened (as a result of sclerotic changes), they cannot expand to the same degree as can healthy, resilient vessels, and therefore do

not so readily accommodate the blood (60-100 cc) ejected from the heart during systole Such a state will lead to a rise in the systolic pressure Normally, however, the cross sectional area of the aorta increases considerably with age so that it needs to expand much less to accommodate the systolic discharge

THE INFLUENCE WHICH VARIATIONS IN SOME OF THE FOREGOING FACTORS EXERT UPON THE DIFFERENT PHASES OF THE ARTERIAL PRESSURE

A Change in heart rate unaccompanied by an alteration in any of the other factors e.g. output of heart per minute peripheral resistance etc will cause a change in the diastolic pressure but relatively little change in the systolic thus giving a smaller pulse rate During cardiac acceleration for example the diastolic period is shortened and less time is therefore allowed for the energy stored in the elastic walls during systole to become converted into energy of flow during diastole In other words the fall in pressure during diastole is halted at a higher level by the earlier arrival of the next beat A decrease in heart rate will have the opposite effect with the longer diastole the slope of pressure is enabled to reach a lower level Since the quantity of blood entering the arteries per minute remains constant the quantity entering at each beat must vary inversely with the change in rate which accounts for the relatively small change in the systolic pressure

B Alterations in the quantity of blood discharged per minute by the ventricle If little change should occur in the heart rate and other factors remain unaltered increase in the output per beat of the heart causes a rise chiefly of the systolic pressure The diastolic pressure is raised less noticeably consequently the pulse pressure is increased The explanation for the less pronounced rise in the diastolic pressure is that as a result of the high pressure at the end of the ejection period the pressure gradient throughout diastole is steeper and more energy is expended in giving velocity to the blood of the blood pumped into the arterial system during systole a larger proportion than ordinarily will therefore have passed through the arterioles by the end of diastole

C Changes in the peripheral resistance while other factors remain constant Though these affect both systolic and diastolic pressures they show their influence predominantly upon the latter phase The diastolic period is considerably longer even in a rapidly beating heart than the ejection period of systole and as we have seen the peripheral resistance is an important factor in the maintenance of the diastolic pressure It follows therefore that any increase or decrease in the outflow from the arterial system will affect this pressure to a greater degree than the systolic The mean pres

sure and pulse pressure vary accordingly. Aortic regurgitation produces an effect upon diastolic pressure similar to that caused by a reduction in the peripheral resistance but greater in degree. The mechanical principles involved are similar, an increased quantity of blood passes from the arterial system during diastole as a result of leakage through the incompetent aortic valves. The peripheral vessels are also usually dilated which combined with the high pulse pressure may cause the appearance of a pulse in the capillaries especially if their emptying be aided by holding the arm above the heart level. Slight pressure upon a superficial capillary area such as at the base of the finger nail may then show alternate blanching and flushing synchronous with the heart beat. In aortic regurgitation the pulse pressure attains a magnitude seen in no other condition (80 or 110 mm Hg) for not only is the diastolic pressure much reduced but the systolic pressure is raised as well owing to the greater volume of blood ejected at each heart beat—that which has regurgitated through the aortic valves plus that received from the auricle. For these reasons the carotids throb visibly. The pulse is of the collapsing type (water hammer or Corrigan's pulse). An arteriovenous aneurysm produces somewhat similar effects upon the arterial system.

D A rise or a fall in blood viscosity. Other factors remaining unchanged tend to affect the diastolic pressure in a manner similar to changes in the calibers of the peripheral vessels.

E Increase in blood volume will raise both pressures as a result of the overfilling of the arterial system and greater stretching of the elastic walls.

F Increase in elasticity of the arterial walls. Obviously a condition such as arteriosclerosis which renders arteries less resilient and more like rigid tubes will tend toward a lowering of diastolic pressure. Yet as a matter of fact, in arteriosclerosis the diastolic pressure may be raised rather than lowered, since there is frequently an associated narrowing of the peripheral vessels which more than offsets the hardening of the walls of the larger arteries. When, however, the sclerosis is confined to the larger vessels and their branches while the peripheral vessels are free from proliferative changes which narrow their lumens the diastolic pressure is lowered. Diminished distensibility of the walls of the aorta and the larger arteries tends to increase the systolic pressure.

In the foregoing paragraphs variations in the several blood pressure factors and their effects have each been considered as being the only variable in a particular instance. The object of this was to disclose the value of each and the manner in which it acted. Yet it must be remembered that such a description is more or less artificial and that in health and even to a large extent

under pathological conditions the various factors interact with one another—there is a give and take among them. When a change in the value of one factor occurs, readjustments of others take place to regulate the blood pressure and keep it within the normal limits. For instance, dilation of the vessels in one area may be accompanied by vasoconstriction in another. Reduction in blood volume as by hemorrhage, is followed by constriction of the peripheral vessels, while increased blood volume or a rise in viscosity will likely be followed by the opposite effect upon the vessels.

THE ARTERIAL PRESSURE PULSE. Pressure waves in the heart cavities, the aorta and almost any of its branches and in the systemic venous system, can be readily recorded in the experimental animal and in humans by use of appropriate combinations of catheters or needles with pressure manometers of adequate frequency (see ch. 19). The form or pattern of the pressure curves can also be recorded from superficial vessels such as the radial artery, subclavian artery and vein, carotid artery, jugular vein, etc., by overlying cup tambour arrangements or microphones (for details see ch. 19, and Wiggers).

A Velocity. The pulse is the pressure change created by the ejection of blood from the heart into the already full aorta, and propagated as a wave through the blood column and arterial wall to the periphery. If the walls of the system were absolutely rigid, since liquids are incompressible, an impact delivered at one end would cause a pressure change to be transmitted almost instantaneously. In the case of elastic tubing, such as composes the vascular system, the pressure change is accompanied by an expansion of the tube's wall. From the equation of Bramwell and Hill ($V_p = K\sqrt{\Delta pV/\Delta V}$ in which V_p is pulse wave velocity and V is vessel volume) it is obvious that the velocity with which a pressure wave is transmitted peripherally, is largely determined by the elasticity of the vessel wall.

Because of their accessibility, pressure pulse wave velocities are generally measured in the brachial, radial or femoral arteries, although many measurements exist for the aorta. The usual order of time of arrival of the pressure pulse is brachial, femoral, radial. The velocity of the pulse wave can be determined by noting the difference in the time of arrival of the naturally occurring pulse wave at a near and at a far point of the vascular system. This can be done roughly by means of a pair of tambours overlying points on the two arteries and which are connected to writing levers or recorders. A more accurate way

is to record directly the arterial pressures at the two points from indwelling needles connected to pressure manometers, or to record the transit time of a mechanically induced external impact wave. The time difference divided into the distance traveled between two points gives the velocity of propagation of the wave. Thus,

Distance in millimeters

Time in seconds

= velocity in millimeters per second

The rate of propagation of the pulse wave peripherally depends on the degree of vessel distention by internal pressure, and on its distensibility characteristics. Thus, the level of blood pressure, the basic structure of the vessel wall and its alteration by function or disease are the important determinants of pulse wave velocity. The normal velocity in the aorta approximates 3 to 4 meters per second, in the arteries of the limbs, it is 7 to 14 meters per second, the velocity of the pulse in the femoral artery being somewhat greater than in the brachial artery. In hypertension resulting from muscular exercise, the walls of the vessels are more strongly stretched and the pulse wave is transmitted at a higher speed. Vasodilation or low pressure from many causes reduces the velocity of the pulse wave. Figure 22.3 shows this strong relation between the pulse wave velocity and ambient intraarterial pressure in the brachio radial artery segment of normal individuals (Pressures below diastolic were obtained by temporary digital occlusion of the axillary or subclavian artery). This fact must be taken into account in the comparison of velocities at different ages and in different disease states. In addition, since the rate of transmission alters with the state of elasticity of the vessel wall the velocity is increased with old age or when the elasticity is increased by disease, such as arteriosclerosis. In the brachial artery, speeds have been recorded of 5 meters per second at age of 5 years, 6 meters per second at middle age, and 8.6 meters per second at age of 84 years.

In the aorta (and arterial tree), the acceleration of the blood occurs almost simultaneously with the rise of the pressure pulse. This is to be expected since the latter causes the former. However, whereas the pressure wave travels in terms of meters per second, the movement of the red cells or plasma is much slower, at 10 to 20 cm per second. Thus, although the pressure wave may reach the vessels of the foot in 0.2 second

it requires several heart beats for the blood entering the ascending aorta to reach the foot vessels. This is because the speed of the blood depends upon such factors as the blood pressure gradient, cross sectional area of the vessel and viscosity, while the velocity of the pulse wave is determined almost entirely by the elasticity of the wall of the vessel.

B Characteristics and transformation of the pressure pulse Pressure curves simultaneously recorded from the aortic arch and a peripheral artery of the dog are shown in figure 22.4. It is obvious that the pressure pulse patterns are quite different. The aortic pressure rises quite abruptly and after an anacrotic shoulder (abrupt change in gradient) rises still further to a systolic rounded peak. The pressure then drops slowly during the last half of systole until closure of the aortic valves which is occasioned by a sharp incisura. During diastole, the pressure is first sustained and then drops smoothly. The extra arterial forces which affect the aortic pulse pattern are by impact from the contracting atrium and the bulging of the aortic valves during the isometric contraction period. These waves appear on the aortic pulse preceding the main wave and are noticeable in the immediate aortic branches but not beyond. A series of internal free vibrations are added at the incisura and at

FIG 22.3 Curve showing the relation between arterial blood pressure (abscissa) and pulse wave velocity (ordinate). (From Landowne J Appl Physiol 1953 12 93)

FIG. 224 Arterial pressure pulses recorded from the central aorta, *C*, and the femoral artery, *F*, in the anesthetized dog. Curve *F - C* beneath pulse tracings obtained by eorodirectographic subtraction of the aortic pulse from the femoral pulse. This represents the reflected or standing wave in the distal portion of the arterial tree. Time 0 1 second. Ordinate pressures in millimeters of mercury (after Alexander R. S. *Am J Physiol*, 1949, 158, 287).

the first steep rise during ejection as the pressure pulse reaches the main aortic branches. In the simultaneously recorded peripheral pulse, the onset of the pressure rise is delayed and rises a little more slowly but to a very peaked, earlier, and larger maximum, being about 30 mm Hg higher than that in the aorta. The drop of pressure in the latter half of systole and in early diastole is much quicker. The dicrotic notch and its after wave are quite large. The remainder of the diastolic curve is uneventful. Thus, in the peripheral vessel the net effect is to augment the peak amplitude of the pulse wave, obscure the incisura, and to depress the remainder of the pulse curve. Pressure curves recorded from arteries intermediately situated such as the renal, mesenteric, and carotid, show a lesser augmentation of the peak systolic pressure and a smaller dicrotic wave, pulses recorded from more peripheral arteries such as the dorsalis pedis, show an exaggeration of these phenomena. The effects of the extra arterial forces are gradually damped

in the extensions of the aorta and are lost in the radial artery.

The pressure pulse just described at the root of the aorta is basically triangular. This original pattern is largely retained as the pressure wave is transmitted down the aorta and into some of its immediate branches. The temporal distortions of the pressure pulses in their transit from the central to the peripheral arteries are effected mainly as the result of damping from friction of the blood with the vessel wall, hysteresis of the vessel wall, differences in the distensibility of the vessels, and summation of reflected pressure waves. The viscosity of the blood in the smaller arteries acts to smooth out the abruptness of pressure changes, in arteries such as the femoral, there is a possibility of considerable lag in the response of its wall to internal pressure such as occurs in isolated vessel strips, and the greater distensibility of these arteries, taken *in toto*, gives the system a low natural frequency (3 to 5 cycles per second), which tends to smooth out or make less angular the basic central pressure pattern, slow down the rate of pressure elevation, and lessen the pressure peak obtained.

In addition to damping, the other major factor controlling the peripheral pattern is wave summation. The pressure wave leaving the aortic arch rebounds from areas of increasing resistance in the peripheral arteries and arterioles, and travels retrogradely along the arterial tree. These centrally reflected pressure waves can be obliterated by damping or may summate with or be subtracted from the peripherally directed pressure wave, depending upon the phasic relationships. They do not, in general, materially alter the central aortic pattern. The magnitude and pattern of such a reflected wave can be roughly ascertained by subtraction of the peripheral pulse pattern from the central aortic pattern (see fig. 224). This reveals that the waves occur in both systole and diastole. The points of change in resistance and pressure reflection have not been firmly established, but best opinion favors a locus in the abdominal aorta, just below the diaphragm, and a point in the femoral system. Reflected components from these areas can be either negative or positive.

C Determinants of aortic pulse pressure pattern
The aorta and its larger branches can be regarded as a large elastically distensible compression chamber with cardiac ejection entering at one end and drainage occurring at the other end. The chamber possesses varying degrees of distensibility, conforming to those existing in various

portions of the aorta and its branches. The generated pulse pressure is caused by an imbalance between the ventricular outflow entering the aorta, and the peripheral run-off leaving the aorta with each systole. The systolic portion largely expresses input into the aorta, the diastolic portion expresses decompression of the aorta or peripheral run-off, since, at this time, it is disconnected functionally from the ventricle. Four factors are of major importance in determining the pressure and increments of pressure from moment to moment: the elasticity or distensibility of the vessel walls, the volume of contained blood, the volume increment from cardiac ejection, and the decrement in volume caused by peripheral drainage. These relations are expressed by the equation

$$E = \frac{\Delta P}{\Delta V} V$$

in which E = volume-elasticity coefficient, p = change in pressure, v = change in volume, and V = capacity of aorta in diastole. If the aorta and arteries constituted a simple elastic chamber, the pressure-volume relations (P/V) should be predictable from the preceding, and if P is known, V should become available. It would be helpful if such a relation could be used to indicate what is happening to the blood and whether the effect is centrally or peripherally induced. However, difficulties in such an approach are: (1) there is no way to quantitate V , (2) the pressure-volume relation of any part of the aorta is linear over only a limited pressure range, (3) distensibility

is different in various regions of the arterial tree, and (4) changes have been revealed in the distensibility characteristics of the aorta by reflex stimulation and adrenalin injection.

D. Usefulness of aortic or central artery pulse patterns. Despite the difficulties in elucidating the pressure-volume relations in the aorta, pressure pulses from the large arteries, depicting fairly well the pattern of the central aortic pulse pressure, have been found useful in predicting hemodynamic changes. Such interpretation and extrapolation is based on experiments in dogs in which changes in peripheral resistance and cardiac activity have been deliberately induced and their effects on the pressure pulses separately determined. Figure 22.5 shows the human subclavian pulse obtained indirectly. The duration of systole and diastole can be determined. In the presence of a high peripheral resistance and in a normal vessel, the pulse shows a much steeper rise throughout systole. In the presence of a low aortic resistance but with good vascular volume, the curve has an initial early spike followed by a lower systolic tip, a rapid decline and a greatly reduced slope during diastole. When the stroke volume is low, as in hemorrhage, the systolic part is small, smooth and rounded, and diastole is almost flat. Decreased distensibility of the aorta is revealed by a rapid, sustained and large elevation of the pulse, a high incisura and a gradual decline during diastole. Distinctive pulse patterns caused by lesions of the aortic valves are also shown. These are considered in detail in chapter 28. Attempts to use central arterial pressure

FIG. 22.5. Illustration of changes in contour and amplitude of subclavian and radial pulses under various cardiovascular conditions. Discussion in text. Note changes in transmission rates (Wiggers, *Circulatory dynamics*, Grune and Stratton Inc., New York, 1952).

pulses to estimate stroke volume have been numerous but none have been successful (see ch 23)

Arterial Blood Flow

With contraction of the human ventricle, a stroke volume or systolic discharge of 60 to 70 cc is ejected into the distensible aorta within less than 0.25 seconds. Of this, at least 45 cc is pushed into the aorta within the first 0.1 second. Space for this volume in the aortic arch is made by distending it and by removing some of its blood. The resulting pressure change travels as a wave throughout the length of the aorta and its branches to the capillaries (and sometimes through them), and expands the entire arterial tree radially and longitudinally. This enlargement results in a forward movement of blood from aortic valves to capillaries before the end of ventricular systole. As yet, too few studies of phasic flow have been made to justify a statement pertaining to the factors which determine the major characteristics of the flow patterns in the aorta. It is, however, worthwhile describing and considering them briefly.

PHASIC AORTIC FLOW Aortic flow pulses have been measured in dogs and, also, incidentally in a number of human subjects at the time of surgical exposure of the aorta. The former will be considered since it has been possible to record simultaneously both pressure and flow pulses, and, at times, to record at least two flow pulses at different aortic levels. The phasic flows were recorded with an electromagnetic flow meter or sonar meter. Examples are shown in figure 22.6. The phasic flow in the ascending aorta is roughly triangular in shape (22.6A). Acceleration reaches a peak ejection rate early in systole following which there is a rapid deceleration ending in a momentary, small, high frequency backflow at the time of closure of the aortic valves. The flow curve is flat with almost zero velocity during most of diastole. The considerable modifying effect of the aorta upon the left ventricular ejection pulse is seen in figure 22.6B, taken near the terminus of the aorta. The flow pulse is now a series of smooth, highly damped oscillations of a frequency of 3 to 4 cycles per second which continue to extinction, but which are renewed with each heart beat. There is quite a large backflow in very early diastole. Flow pulses in the isthmal area of the aorta (proximal portion of descending aorta) are intermediate in pattern between the central and abdominal patterns. In figure 22.6C are the calculated blood velocity curve and the aortic differential pressure curve, the latter taken by a

double lumen catheter with pressure pick up holes 6 cm apart. This shows the positive and negative acceleration waves which act on the aortic blood column to produce the flow pulsations. The effects of inertia are seen throughout the cardiac cycle. The beginning upstrokes of both pressure and flow curves coincide quite well, but when the first positive wave of the ΔP reaches its peak, flow acceleration is maximal, and when ΔP is maximally negative, flow deceleration is maximal. This represents about a 90° phase lag.

PHASIC FLOW IN PERIPHERAL ARTERIES Flow patterns and simultaneous intraarterial pressure curves characteristic of several peripheral arteries are illustrated in figure 22.7. There are certain distinguishing characteristics. A flow pattern is made up of waves whose directional changes have a qualitative correspondence with gradient changes in the simultaneously recorded intravascular pressure pulse and which may be characteristically distinctive for that artery and vascular bed. Since the flow velocity varies with the differential pressure existing at the site of the flow meter, similarity in contour of the flow and applied pressure pulse is one criterion for the comparison of flow curves from different arteries. Certain patterns, especially those of the superior mesenteric and renal arteries, have a well rounded and sustained systolic portion in relative conformity to that of the pressure pulse. Those of the hepatic and common carotid arteries are less well rounded, those of the brachial and femoral arteries have a sharp systolic peak. The flow pulse pressure is generally small in the renal and axillary patterns, and somewhat larger in the superior mesenteric and hepatic, while the femoral may be quite large. Backflow components are consistently found in the femoral and axillary patterns and, on occasion, in the common carotid, while the renal, hepatic and superior mesenteric flow curves exhibit only forward flow. However, the main feature which permits a separation of the flow curves is the variable relation of the early diastolic to presystolic flow rates. Comparison of this relation with similar early diastolic and presystolic points on the corresponding pressure curve, shows that the superior mesenteric, renal, hepatic, common carotid, and femoral patterns have, on this basis, a progressively graded dissimilarity to their respective pressure curves.

While a method of analysis and interpretation is not yet available by means of which the probable determinants of, and interrelated influences upon phasic flow can be quantitatively evaluated, a partial attempt has been made in at least one

FIG 22.6.1 Tracings from bottom to top flow in the ascending aorta, pressure in the aorta, (from Wetterer, Minnesota, Med 1954 37, 79) B Tracing from top to bottom, pressure in aortic arch, flow in terminal aorta, (from Spencer, Circulation Res 1958 6, 492) C Simultaneous recording of (1) aortic axial pressure drop between two points 6 cm apart, at level of subclavian artery, (2) computed blood velocity at this level, and (3) aortic blood pressure at subclavian artery junction (from Fry, Circulation Res 1957 5, 75)

artery. The approach is too technical to be considered here and the interested reader is referred to the paper of Shipley et al.

ARTERY TO VEIN PRESSURE AND FLOW Pressure gradients across the very small vessels of the periphery have been difficult to establish in reasonably normal, biological situations. Possibly the closest approach to this is based upon the experimental approach of Haddy, in which arterial and venous pressure are measured in the quite small vessels (0.2 mm diameter) of the dog forepaw, while constant blood flow is maintained by a pump (fig. 22.8). It can be seen that with the environmental temperature at 20° C, the pressure drop from small artery to small vein approximates 40 mm Hg and, from small vein to large vein, 6 mm Hg (fig. 22.9). Upon exposure to 0° C, the increase in pressure gradient is almost entirely through the small vessels with little gradient change between the small and large veins. Since the blood flow was maintained constant the increase in pressure gradient represents directly active vasomotor resistance changes. Unfortunately, at present it is not possible by this technique to differentiate between changes in resistance of the arterioles and venules. Expansion, however, of this type of investigation would be most fruitful.

Venous Pressure

The functional importance of the venous blood pressure has long interested physiologists and clinicians. The superficial veins, which can be observed and whose pressure values and pulse pressure contours can be easily measured, have been considered to serve as reliable indicators of the functional status of the less accessible and deeper lying portions of the systemic venous system.

THE VENOUS PRESSURE PULSE The venous pressure pulse is best determined with the subject in the recumbent position. Venous pressure is measured directly with an indwelling needle or catheter or indirectly (without pressure values) by applying a cup over a vein external to the chest, such as the jugular, and connected to a manometer or a microphone receiver. The venous pulse waves are usually timed against an electrocardiogram, arteriogram or phonocardiogram (see ch. 20). Two distinct types of pulsations, respiratory and cardiac, are seen in the peripheral and central veins. With inspiration, blood is aspirated into the chest and the external veins tend to collapse while internal veins expand, with

Fig. 22.9 Effect of temperature changes upon vascular pressures in the foreleg of the dog, flow rate being maintained constant (from Haddy, *Circulation Res.* 1957, 5: 59).

expiration, venous inflow is impeded and the external veins become distended while the chest veins tend to become smaller. These changes make up the respiratory venous pulse. The cardiac venous pressure pulse represents a retrograde reflection of a somewhat distorted version of the right atrial pulse pattern (see ch. 20). These *c-v* waves are clearly seen in the record obtained from a peripheral vein in figure 22.10.

Valuable information concerning the events of the cardiac cycle both from the experimental and clinical point of view, can be obtained by a study of the jugular pulse records. The length of the P-R interval can be roughly estimated by noting the time interval between the jugular and c waves. It is not difficult to decide whether the

FIG 22 10 The jugular venous pulse pattern (JVP) of a normal subject. An electrocardiogram (ECG) and carotid pulse tracing were simultaneously recorded. The presystolic "a" wave is caused by atrial contraction. The "c" peak is secondary to closure of the tricuspid valve although it may also represent transmission of the arterial pulse to the vein. The descending limb of the pulse tracing after the "c" wave is secondary to emptying of the vein into the right atrium. The negative "x" wave occurs during lowering of the atrioventricular septum and tricuspid valve during ventricular systole. Then the pressure rises as the right atrium fills to form the "v" waves. The second negative depression, the "y" wave represents the fall in jugular venous pressure as the tricuspid valve opens and the right atrium empties. (From Wood, P., *Diseases of the heart and circulation*, J. B. Lippincott Company, Philadelphia, 1956.)

a c interval is normal (around 0.16 second), or obviously prolonged (0.24 second or more). The orderly sequence of a, c, v, waves indicates a normal sequence of atrial and ventricular beats. With partial or complete heart block, the number of a waves is greater than the number of c v complexes. With atrial fibrillation, the a waves are absent. Premature ventricular beats of atrial origin are preceded by an a wave, those arising in the ventricle are not. A giant a wave can arise from tricuspid stenosis, severe pulmonary hypertension, pulmonary stenosis, tricuspid atresia,

nodal rhythm and partial heart block. The powerful right atrial contraction causing the giant a wave is due to the increased resistance to right ventricular filling. In tricuspid insufficiency, giant ventricular systolic (v) waves are seen. The systolic wave rises rapidly to a summit upon which vibrations of the murmur are superimposed.

NORMAL VENOUS BLOOD PRESSURE AND ITS VARIATIONS. Using the techniques previously described, mean blood pressure in the large, superficial veins of unanesthetized man at rest and in the supine position, is found to be a function of distance from the right atrium. The average value decreases from 13.8 mm Hg (188 mm H₂O) in the dorsal venous arch of the foot to about 5.2 mm Hg (70 mm H₂O) in the jugular vein. The pressure change from the surface veins to the central veins and along the central veins has been precisely determined. Great care must be taken in measuring the peripheral venous pressure since, under some conditions in the supine position, the peripheral veins may become partially collapsed and, as a result, the peripheral venous pressure becomes independent of right atrial pressure. It is generally advisable to make the measurement with the arm well below heart level to prevent this venous collapse. With this precaution, the average pressure of 7.1 mm Hg (97 mm H₂O) in the antecubital vein drops to about 4.6 mm Hg (63 mm H₂O) in the vena cava opposite the right atrium (fig. 22 11). Thus, the overall venous pressure gradient approximates 9.2 mm Hg (125 mm H₂O) with a pressure difference of only a few mm H₂O occurring between the upper thoracic veins and the right atrium. Although venous pressure measurements in the same subject are quite constant, considerable variation (up to 100 mm H₂O) may occur in the venous pressure from the same area in different persons.

Peripheral and central venous pressures are

FIG 22 11 Comparison of central venous pressure (CVP) and the peripheral venous pressure (PVP). After release of occluding cuffs at the thighs, the pressures return to control levels without a change in the pressure gradient. (From Gauer, O. H. and Sinker, H. O., *Circulation Res.*, 1956, 4, 75.)

altered in the same direction under many circumstances. They do not appear to be related to age, sex or hypertension, but they are decreased in severe hemorrhage and surgical shock. They are increased by positive pressure breathing, the Valsalva maneuver, tilting, the excitement stage of anesthesia, the apneic phase of asthmatic attacks and in Cheynes-Stokes breathing. The main pathological condition in which central and peripheral venous pressures are elevated, sometimes as high as 22 mm Hg (300 mm H₂O) in the antecubital vein, is congestive heart failure.

DETERMINANTS OF VENOUS PRESSURE The interplay of factors which determine systemic venous pressure and venous flow can be briefly stated. The veins are placed between the capillaries or the A-V anastomoses, and the right heart. The blood enters the venules with an appreciable pressure residuum (*vis a tergo*) from the arterial side, after it has passed through the capillaries. This pressure is met by the resistance to flow from the veins themselves and from the heart itself (the *vis a fronte*). The venous pressure is affected by internal factors which control the relation between the contained venous volume and the state of distensibility of its vessel walls. Finally, there are various external or extramural factors (*vis a latere*) such as the actions of respiration, muscle and gravity, which together represent the pressure effect of the surrounding tissues. Because their interplay is so complex, and flow methodology is generally so inadequate for normal situations, it is difficult to estimate their relative effect on venous pressure and flow. However, before considering the details of operation of these determinants, it must be emphasized that they act to insure that the pressure in the veins can never be less than the right atrial pressure, and whenever right atrial pressure increases, the peripheral venous pressure increases. This excess of pressure (10 to 12 mm Hg or 125 mm H₂O) in the various veins, over that in the right atrium, is an expression of the pressure gradient ($P_1 - P_2$ in Poiseuille's formula). This, together with a reasonable venous cross section, causes blood to flow from vein to atrium.

A. The contraction of the left ventricle (the "vis a tergo") The energy of the ventricular contraction (the "*vis a tergo*") is expended in driving blood through the arterioles and onward through the capillaries and veins to the right atrium. By the time the blood reaches the venules the remaining pressure may approximate 7 to 8 mm Hg. When it reaches the right atrium, the energy has been almost entirely dissipated in overcoming

the frictional resistance offered by the vascular channels, at this point, the pressure may be less than 1 mm Hg.

B. Quantity of blood flowing through the arterioles in relation to capacity of the veins Although the details are largely unknown, generally speaking, the more blood which is received from the arterial side, the greater will be the venous pressure. That is, with dilated arterioles, the difference between the arterial pressure on the one hand and venous pressure on the other, tends to be reduced, with constricted vessels the pressure difference will be increased. Rough estimates based on the volume-elasticity of the various compartments of the vascular system indicate that if a liter of blood is transfused into the circulation of man at rest, only 10 to 20 cc would be found in the arterial tree and about 980 cc in the extra arterial system (systemic venous and pulmonary circuits) and that the pressure elevation in the whole system would be only 4 or 5 mm Hg. In bleeding and transfusion experiments in man the circulation behaves like an elastic container (ch 15), with pooling of blood in the extremities by occlusive cuffs, the central venous pressure falls without any apparent sign of counter venomotor control. This emphasizes the view that normal stresses to which the circulation is exposed, if they are not too abrupt or excessive, lead to only passive change in the resistance vessels and systemic venous system, and do not cause relaxation or strong contraction of the peripheral capacitance vessels.

This relationship, however, does not always hold because the veins are capable of adjusting their capacity to the quantity of blood received from the arterial system by reflex vasomotor activity. The smaller vessels may expand to accommodate the extra blood so that little change in venous pressure results, or they may reduce their capacities and maintain pressure in spite of a reduced volume of received blood.

The participation of venomotor tone in the control of the venous pressure and venous blood flow can be shown in animal experiments in which oxygen want, high CO₂, stimulation of the carotid sinus and excessive hemorrhage are effective in reducing the size of the capacitance vessels, but proper interpretation is difficult because of the often, unphysiological strength of the stimulus. In man, using strong stimuli such as the Valsalva maneuver, asphyxia, high G, or large blood losses, the veins constrict in what may be called an emergency reaction. In the

latter case, the central venous pressure may be normal or even increased

It is significant that the central and peripheral venous pressures do not necessarily shift in the same direction. The pressure gradient from very small veins (0.5 mm diameter or less) to large central veins, is not necessarily constant and can be markedly affected by various states. With cold, hyperventilation and moderate exercise, only the peripheral venous pressure may rise significantly. This often independent action of local venous pressure and central venous pressure indicates that reflex venomotor activity of the capacitance vessels in normal persons is highly selective and regional in operation and that local small vein or venule pressure is not necessarily an index of happenings in the central venous system. Hence, the state of distensibility of the arterioles, venules and small veins, and large central veins, are not necessarily related, and net effects are unpredictable.

C The action of the right side of the heart upon the blood flow in the veins. Obviously, if the blood is not passed on again by the right heart as quickly as it is carried to it by the great veins, the venous pressure will rise. That is, there will be a tendency for the blood to be "dammed back." When the heart is beating vigorously and output and inflow are balanced, no rise in venous pressure occurs. In health the force of the ven-

tricular contraction is nicely adjusted to the quantity of blood which pours into the atrium from the veins, and no accumulation occurs. If, however, the heart fails, the venous pressure rises and back pressure effects ensue.

There now appears to be good experimental proof that the activity of the right ventricle itself actually increases greatly vena caval flow into the right atrium. This is illustrated in the vena caval flow curves of figure 22-12, in which it can be seen that there is a larger forward flow of blood during right ventricular systole than during diastole. Thus, venous inflow into the right atrium is large in the presence of closed tricuspid valves. The responsible force is believed to be right ventricular contraction itself. During such contraction, the descent of the atrioventricular junction enlarges the great venous reservoir which comprises the atria and venae cavae. Obviously, this could be a very useful mechanism for maintaining venous return during tachycardia. In slow hearts, most of atrial inflow occurs during the long ventricular diastole, but during a rapid heart rate the proportion of atrial inflow due to active systolic "injection" of blood from the veins into the right atrium, is greatly increased.

The influence of cardiac action upon the movement of blood in veins and atria does not necessarily imply that the ventricles exert an aspirat-

FIG. 22-12. Simultaneous recording in open chest dog of aortic pressure, superior vena cava pressure, and pulmonary artery pressure and superior vena cava flow with bristle flowmeter. Note acceleration of venous return during systolic ejection. (From Brecher, Venous Return, p. 111, Grune & Stratton, Inc., New York, 1956.)

ing action during diastole. This problem has been debated many years and is considered in chapter 20 in some detail. In general it can be said that under strictly controlled experimental conditions, there is some positive evidence for this. However, one must remember that there is no good quantitation of this and it would take place only in very early diastolic relaxation, which is a very short time period.

Sometimes when vigorous respiratory efforts are made, slight fluctuations of the venous pressure can be detected in the peripheral veins of the human subject. These variations rarely amount to more than 10 mm. of H_2O but may be considerably higher than this when dyspnea resulting from obstruction to the free entrance and egress of air from the lungs exists. Owing to the inertia of the blood column the aspirating effect is less evident the nearer to the periphery at which the pressure measurements are made.

The respiratory effects upon venous pressure and also presumably upon venous flow, can also be exaggerated in normal subjects by the following procedures. If a forced expiration is made with the glottis closed (Valsalva's experiment)

the negative intrathoracic pressure can be abolished and a positive pressure of several millimeters of mercury substituted. The veins of the neck, face and limbs become distended with blood as a result of the impediment to the flow into the right auricle. The peripheral venous pressure under these circumstances may rise to 400 mm. H_2O or more. In the converse experiment of Mueller in which a forced inspiration is made with the glottis closed the powerful suction effect may cause a fall of 50 mm. H_2O or so in the venous pressure of a peripheral vein. The increase in negative intrathoracic pressure may be seen by means of the X-ray to exert an effect upon the ventricle which during diastole becomes somewhat enlarged beyond its usual size.

D External forces Natural and artificial respiration have a very large effect on central venous pressure and flow. Direct measurements of flow with the bristle flow meter in the closed chest dog have shown flow to increase in both the superior and inferior vena cava during inspiration and in turn this effect is transmitted to the outlying veins (fig. 22-13). The interplay of mechanisms is as follows: the blood in the great

Fig. 22-13 Effect of spontaneous respiration on venous return and cardiac output (closed chest). Tracings from top to bottom: time and base line; aortic pressure in millimeters of mercury; pulmonary artery; superior vena caval and intrathoracic pressure in millimeters of water; pulmonary arterial and superior vena caval flows in cubic centimeters per minute; A beginning of inspiration; S acceleration of superior vena caval flow during ventricular systole; D acceleration of superior vena caval during ventricular diastole; Stroke volume (in cubic centimeters) under pulmonary arterial flow curve; Flow (in cubic centimeters) through superior vena cava during each cardiac cycle at bottom of record; Electrical frequency response of both flowmeters reduced from 400 to 40 cycles per second; Superior vena caval pressure curve damped. (Brecher, G. A. Venous Return, Grune & Stratton, Inc., New York, 1956.)

veins at their entrance into the atrium has a small, but definite pressure of about 5 mm H₂O transmitted from the arterial side. That is to say, if the thorax were opened so as to abolish the subatmospheric pressure within it, and a manometer placed in the inferior vena cava, a positive pressure of this magnitude would be registered. During inspiration the pressure within the thorax is about -6 mm Hg (81 mm H₂O) below that of the atmosphere. During expiration it amounts to -2.5 mm Hg (34 mm H₂O). Their algebraic sum during inspiration (-6 mm Hg - 0.5 mm Hg) and during expiration (-2.5 mm Hg + 0.5 mm Hg), represents the transmural pressure expanding the intrathoracic structures and causing blood to enter the thorax. This especially expands the thin-walled intrathoracic veins. A similar effect but of less degree is exerted upon the walls of the atria. The diameters of the thick-walled ventricles, however, and the comparatively

rigid coats of the larger arteries remain practically uninfluenced by the "negative pressure" during ordinary breathing. During expiration the intravenous pressure within the abdomen exceeds the intraabdominal pressure by only about 1 mm Hg. However, descent of the diaphragm during the inspiratory phase compresses the abdominal contents and since the outlying veins have valves, blood is forced into the thorax. The recent extensive use of artificial respiration in surgical and medical situations has focused attention on the effects of such procedures on the circulation. In the closed-chest dog, intermittent, positive atmospheric pressure artificial respiration (expiration occurring passively against atmospheric pressure) reduces significantly venous return to the right heart over that occurring with natural respiration. Intermittent positive negative pressure respiration (use of mild suction during expiration) augments vena caval flow over that occurring during positive atmospheric pressure respiration. The use of positive negative pressure respiration with particular attention to the negative pressure phase might be beneficial to patients in poor circulatory condition because it could be made to facilitate their venous return. In the presence of an open chest the net caval flow increase of positive negative pressure respiration as compared to positive atmospheric pressure respiration is negligible. The untoward effects of artificial respiration arise because of the positive pressure applied during artificial inspiration the intra pleural pressure instead of decreasing actually increases, and may even become positive. This decreases vena caval flow secondary to an induced increase in pulmonary vascular resistance and, in part, to the mechanical compression or "tamponade" of the heart and lungs caused by the expanding lungs. The mechanical aspects of respiration, however, are apparently not essential to maintenance of venous return or cardiac output, for in the presence of apneic oxygenation in dogs (a condition of induced ventilatory arrest with the trachea connected to a reservoir of oxygen), life continues and the cardiac output may even increase.

E Posture and exercise The venous pressure varies, of course, as a result of the gravity effect, i.e., with the position of the vein in relation to the right atrium, at which level, venous pressure is assumed to approximate zero (fig. 22-14). If man assumes the upright position and is motionless and relaxed, the measured pressure in an

HYDROSTATIC PRESSURE EFFECTS IN ERECT HUMAN

FIG. 22-14 In erect position arterial and venous pressures are both increased by about 85 mm Hg at the ankle. With the arm elevated over the head the arterial pressure at the wrist is about 40 mm Hg and the effective venous pressure is zero down to a level just above the heart. (From Rushmer, *Cardiac Diagnosis*, W. B. Saunders Company Philadelphia 1955.)

ankle vein approximates 85 to 90 mm Hg. This is slightly more than the hydrostatic pressure from the vein to the heart level. This means that there is a continuous column of blood from the right atrium to the ankle. Similarly, the arterial blood pressure measured at the ankle will be increased over that at the heart level by an amount equal to the hydrostatic level. Thus, the arterial and venous pressures at the ankle are increased by the same amount, and the pressure difference between vein and artery is the same at ankle and heart level. This means that a favorable pressure gradient exists for venous flow. Below heart level, the veins increase in fullness and the venous pressure gradient responsible for venous return from periphery to the heart is the measured venous pressure minus the hydrostatic column. This is a small gradient but, since the veins are distended, resistance is quite low. In the upright position, veins from the upper part of the body empty towards the heart. These upper veins partially collapse and their intra-vascular pressure may approximate zero. Above heart level, the pressure gradient along the venous channels is the height of the hydrostatic column above heart level. This gradient is large but since the veins are partially collapsed, resistance is high.

There is, however, a special feature of the venous system which distinguishes it from the arterial system. This is the tendency of the veins to collapse. In the low pressure system, even in the recumbent position, the veins are not usually round but may be *partially or fully, and intermittently collapsed*. For surface veins, collapse arises from increase in atmospheric pressure, in the deeper veins, it is caused by the surrounding tissue pressure acting on the venous walls. This occurs during normal respiration in the neck veins and in the inferior vena cava below the diaphragm where this process is aided by the increased intra-abdominal pressure. With deep and prolonged inspiration, these veins may completely collapse. Such a collapse tendency may be greatly augmented by an increased gravitational stress. In the upright position, the pressure in the neck veins falls to 0 mm Hg, and the atmospheric pressure on the outside of the neck causes these veins to collapse all the way up to the skull. This causes the pressure in these veins to remain at zero along their course. It is this tendency for collapse that causes resistance in the large veins for when distended, resistance is minimal. However, not all veins are collapsible, especially the venous sinuses in the skull, verte-

bral column, bones, liver and spleen, which are held open by firm walled surrounding tissues. For example, the veins in the skull are in a non-collapsible chamber, and in the standing position a negative venous pressure of about 10 mm Hg exists in the sagittal sinus because of the hydrostatic pressure difference between the top and base of the skull.

It is obvious from the preceding that the pressure gradient between two points in the venous system may give no information as to volume flow between the points, because of this tendency of the extrathoracic veins to collapse. Partial collapse can reduce blood flow despite an increase in pressure gradient along the vessel. Volume flow through partially collapsed veins is represented by a modification of Poiseuille's law to a tube with an elliptical cross section. With venous pressure constant, volume flow in a partially collapsed vein is estimated to be about 25 per cent of that through the same vein when round.

Although a change in position does not alter the relative pressure gradients on the arterial and venous sides still a normal return of venous blood is not necessarily insured. This would be the situation only if all the vasculature were made up of semi-rigid tubes and in which flow would depend only on the difference of artery and venous pressure at the level of the heart. This, however, is not true in a distensible system such as the veins. Owing to its much greater filling capacity, the volume on the venous side is greatly increased by this shift from horizontal to the erect position. In man, the decreased venous return under such conditions if of short duration because of a number of compensatory vasomotor mechanisms which operate very quickly. However, even with these compensations, the venous return is somewhat less than in the supine man. It is difficult to decide how effective are the active venomotor mechanisms in returning blood to the heart as man assumes the upright position. Direct information on venomotor control of the intestinal vessels, mostly in operated animals, indicates that they are capable of widespread constriction, but again, these situations can hardly be regarded as normal. In tilting the human subject into an upright posture, the blood pressure at the carotid sinus decreases mildly and the heart becomes smaller (fig. 22-15). About 400 cc of blood leaves the thoracic compartment to accumulate mainly in the veins of the extremities (determined by leg plethysmography). The pressure in them increases and the filling pressure of the heart drops. Cardiac output drops mildly, stroke volume de-

FIG 22.15 Effect on various cardiovascular parameters in man of changing from supine to the upright position

creases considerably, the heart rate rises. There is also a decrease in blood flow through skin, skeletal muscle, liver and kidney. These changes are at least partially explainable on a mechanical basis, i.e., tipping into the erect posture might be regarded as a functional hemorrhage into the lower portions of the body. Since the pressure in a superficial arm vein maintained at heart level rises considerably (about 10 mm Hg), possible widespread peripheral venous constriction has taken place to shift blood centrally to make more blood available to the heart for maintaining cardiac output, although its effect is not enough to maintain central venous pressure. That this limitation of peripheral blood flow is a reflex phenomenon has been shown by its absence in a sympathectomized extremity. The fact that application of a G suit before or after the subject has assumed the upright position, either prevents these changes, or re-establishes the original state of the circulation, mitigates against the role of the arterial baro receptors and favors the stimulation of low pressure receptors. While their precise stimulus and accurate location are not known, they presumably belong to the many receptors demonstrated anatomically in the thoracic vascular bed.

Since man spends most of his life in the erect position, there is no doubt regarding the practical effectiveness of these compensatory mechanisms. It is especially evident when one compares their behavior with that in persons with naturally occurring, or drug induced, hypotension, who lose very large quantities of blood into their extremities and lose consciousness upon standing up. Despite this, venomotor compensation is still far from perfect in normal persons since an excess of, at least, 400 cc of blood still remains in their extremities.

The circulation of animals such as the domestic rabbit, eel and snake, which have not acquired a compensatory mechanism, are placed at great disadvantage when the vertical position is assumed. The eel and snake can be killed by immobilization in the vertical head up position. They literally bleed to death into their veins. Thus, in the human subject if, upon assuming the erect posture after a protracted confinement to bed, the muscles of the abdomen and limbs are weak and the tone of the nervous mechanism governing the peripheral vessels lowered, the hydrostatic effect is overcome with difficulty. The blood subsides into the capacious abdominal veins and capillaries and the right heart is no longer adequately supplied with blood. The arterial pressure falls and the cerebral blood flow becomes inadequate. The subject turns pale, sweats freely and feels giddy or perhaps nauseated, and in a complete faint loses consciousness (syncope). In this situation, and in various circulatory disorders, baths can obviously have a beneficial effect on venous return. Body immersion up to the heart level increases the pressure exerted on the body and reduces pooling in the abdomen and dependent parts. In man increased gravitational stress in the head foot direction (positive acceleration) leads to practically no venous return to the right heart. The increased hydrostatic pressure distends the veins so much that they contain almost all the blood volume, and active vasomotor influences are not sufficient to combat this very high hydrostatic pressure. Again this can be effectively combated by wearing an inflated pressure suit to compress the extrathoracic parts of the body and to force blood to flow centrally.

In exercise, a much greater volume of blood enters the central veins from the arterial side. The various mechanical assists already mentioned, that increase the venous pressure gradient and venous blood flow toward the heart and decrease the venous reservoir, now operate even

more effectively. In addition, the act of muscle shortening propels blood toward the heart. In animal experiments in which skeletal muscle is perfused with blood under a constant pressure, the arterial inflow decreases and venous outflow increases during muscle shortening, upon relaxation, the arterial inflow increases and the venous outflow decreases, the net result is to augment flow. The pressure within the active muscles surrounding the veins is thus a potent factor in regulating venous pressure and flow. Intra muscle pressure rises from a resting level of 2 to 5 cm H₂O to as high as 50 cm H₂O during exercise. The venous pressure in the ankle veins which in the standing position approximate 80 to 90 mm Hg, is now greatly reduced. By rhythmical action of the muscle, the venous valves are activated and the blood column broken up, and venous pressure at the ankle may decrease to as low as 30 mm Hg (40 cm H₂O). Although helpful the presence of venous valves is not essential for this beneficial action of active muscle on venous return. Extravascular vessel compression will promote flow equally in both directions only if flow resistance is equal in both directions. Without the presence of valves, the resistance in the vessels on the capillary side of the venous system is lower than is the veins on the right cardiac side. Hence, rhythmical vein compression *per se* will drive blood toward the heart, and this has been shown experimentally to occur. It can also be observed clinically that in advanced age and under pathological conditions with incompetent or no venous valves, muscle movements improve venous return. Information on active changes in venomotor action in man is limited and is essentially contained in the observations that there is a drastic reduction in splanchnic blood volume with exercise and the pressure in the superficial veins (within a nonexercising area) increases by 10 to 13 mm Hg over that in a standing position only.

Regulation of Pulmonary Pressure and Flow

Uniquely interposed between the right and left heart and entirely enclosed within the negative pressure confines of the thorax, the pulmonary circulation exhibits certain peculiarities uncommon to the other organ perfused systems. For instance, (1) it is the only circuit in the body to receive the total cardiac output, (2) it operates at a perfusion pressure $\frac{1}{4}$ to $\frac{1}{3}$ that of the systemic circuit, (3) its mean transit time is equal to the systemic, albeit across a much reduced linear distance, reflecting the enormous surface

area of the pulmonary capillary bed, (4) it is predominantly controlled by the beat to beat pressure differential between the pulmonary artery (right ventricle) and the left atrium upon which phasic, intrathoracic respiratory variations are superimposed, and (5) it is the only arterial circuit which carries desaturated hemoglobin and which, by virtue of the alveolar capillary pressure difference, the desaturated hemoglobin and the huge surface area participates in large instantaneous gas exchanges.

PULMONARY RESISTANCE To determine the mechanisms controlling pulmonary flow it is necessary to know the resistance to flow. Classically, this should be simply the ratio of the difference of pressure across any portion of a vascular bed to the blood flow that develops. It is a convenient factor by which the pressure drop can be multiplied to give the flow. Such resistance gives information regarding the two factors upon which it depends, the viscosity and geometry of the vascular bed. Since, however, the relation of pressure and flow is not a straight line and when plotted does not pass through the origin, the mechanisms involved are not determinable from a single point relationship. To make the results interpretable, a vascular bed must be perfused in the control state and in the presence of a variable at the same pressure while flow is measured, or at the same flow while pressure is measured. In no other way can it be even roughly determined that a calculated change in resistance (Pressure/Flow) reflects vasomotor activity produced by the stimulus, or reflects only the passive change in resistance caused by alteration in left atrial pressure or in pulmonary flow. There is also an additional difficulty in measuring changing resistance in the pulmonary circulation, for here the relationship between pressure and flow is quantitatively quite different from that in the systemic circulation. The difference is that with the same volume perfusing both circuits, the pressure drop from the pulmonary artery to the left atrium is only about one fifth that from the aorta to the right atrium. This is illustrated in figure 22-16 where the differential pressure between the pulmonary artery and the pulmonary veins is only about 15 to 20 mm Hg. With present pressure methodology, figures of this magnitude can only be roughly determined. This means that while the systemic resistance at the arterioles is high and made up of relatively thick muscle cuffs the resistance at the outlet of the small pulmonary artery branches has quite thin muscular coats with relatively large luminae. The tone of the

terminal pulmonary vessels is thereby relatively low so that a rise in pulmonary venous pressure is readily transmitted to the arterial side, or so that a rise in blood volume injected into the arterial side will increase greatly the volume in the lungs. As a result of the high degree of distensibility of the pulmonary vascular bed, secondary to the opening up of fresh capillaries or further opening of those being used, the blood contained within the lungs shows wide variations under different conditions and on a passive basis.

PRESSURE PULSE IN THE PULMONARY CIRCUIT
Pressures in the pulmonary circuit are determined by means of intracardiac catheterization or by indwelling tubes already described. Pulmonary circuit pressures are much lower than those in the systemic arterial circuit. For the curves of figure 22 16, angiotomy cannulas were placed in the central pulmonary artery and pulmonary veins. Phasic pressure from the two vessels and also their differential pressure were recorded some days postoperatively in the unanesthetized dog. The results showed that the pulmonary artery pressure is 40/10 mm Hg and the pulmonary vein pressure is 2 to 12 mm Hg. The pattern of the pulmonary arterial pressure is distinctive showing a marked incisura low on the anacrotic limb. In late diastole, the pressure descent almost ceases and becomes horizontal. The pulse contours of the peripheral and central portions of the pulmonary artery display differences somewhat like those of the systemic circuit. The pulse wave velocity in the pulmonary artery under essentially normal conditions is about 4 meters per second or about the same as in the aorta at normal intra aortic pressure. This suggests that the aorta may be even more distensible than the pulmonary artery, since the

pulse velocity is inversely related to distensibility. The contour of the pulmonary vein pressure curve clearly shows a, c, and v waves, and closely resembles pressure pulses taken from the left atrium.

PHASIC BLOOD FLOW IN THE PULMONARY CIRCUIT
Figure 22 13 demonstrates that the flow through the main pulmonary artery is almost entirely during systole, the diastolic flow being flat and close to zero. This strongly suggests that there is little or no diastolic run-off of blood into the pulmonary capillaries. By the ingenious method of DuBois and associates, measurements of cyclic change in flow through the pulmonary capillaries has revealed that this is quite pulsatile with a very high peak flow during systole. By the end of diastole, pressures in the vascular bed are equilibrated and capillary flow practically ceases (figure 22 17). Flow curves in the pulmonary veins are not available.

THE EFFECTS OF THE RESPIRATION UPON THE PULMONARY AND SYSTEMIC BLOOD PRESSURES AND FLOWS
The effects of natural respiration on the hemodynamics of the pulmonary circulation are illustrated in figure 22 13. The pulmonary arterial pressure falls during inspiration and rises during expiration. One should expect that, as a result of the increased flow of blood into the right ventricle during inspiration (see superior caval flow) and the greater systolic discharge, both the pulmonary pressure and pulmonary flow would rise during this phase of respiration. However, only the pulmonary flow rises. Because of the traction exerted upon the circumference of the pulmonary vessels by the surrounding lung tissue, their capacity is increased. This more than compensates for the lack of change in the pressure gradient and for the greater amount of blood entering the pulmonary circuit during the inspiratory phase. During expiration these effects are reversed. The right systolic discharge is less but the capacity of the vascular bed of the lungs is at the same time reduced, an upward swing in pulmonary arterial pressure occurs. With maximal expansion of the lungs, or during a forced expiration with the glottis closed (Valsalva's experiment), the vessels are strongly compressed by the surrounding lung tissue, and the pulmonary arterial pressure rises sharply.

The increased capacity of the pulmonary vessels during inspiration reduces, momentarily, the flow of blood into the left atrium, the consequent reduction in the systolic discharge of the left ventricle causes a fall in aortic pressure (figure

FIG 22 16 Record from the unanesthetized dog showing the pressure pulse contours in the pulmonary artery, upper curve, pulmonary vein lower, and the differential pressure between the two, middle curve. Pulmonary artery pressure 28/10 mm Hg, mean pulmonary vein pressure 10 mm Hg, differential pressure 5 to 10 mm Hg. (From Hamilton *Am J Physiol* 1939, 123, 130)

Fig 22 17 Simultaneous pulmonary capillary blood flow curves at rest and during exercise (DuBois J Clin Invest, 1957 36, 1566)

22 13) After a few beats of the right ventricle, the greater capacity of the pulmonary vessels again becomes filled and the flow of blood into the left chambers of the heart increases, the aortic pressure rises. The succeeding expiration, by reducing the capacity of the pulmonary vessels drives blood to the left side and further increases the discharge into the aorta. The systemic pressure, in consequence, continues its rise until near the end of the expiratory phase. The large undulations which appear in the blood pressure tracings of animals are due to these effects. If the respiratory movements and the systemic blood pressure are recorded simultaneously, it is found that the blood pressure commences to fall at the commencement of inspiration and reaches its lowest point in the latter half of this phase, the blood pressure tracing then commences to rise and reaches its maximum toward the latter part of expiration. In this situation, it is presumed that the decrease and increase in peripheral resistance are on a passive basis but this has not been proved.

EFFECTS OF EXERCISE ON THE PULMONARY CIRCULATION The general form of the curve relating pulmonary artery pressure and pulmonary blood flow in man and the intact dog at rest and exercise is shown in figure 22 18. The curve indicates that pulmonary artery pressure is main-

Fig 22 18 The relationship of pressure to flow in the systemic circulation and pulmonary circulation in normal and abnormal states. Note the difference in response of the two circulations to exercise.

tained below the upper limit of normal until the flow exceeds at least three times the base level whereupon it increases progressively. This absence of pressure rise with increased flow implies

an expansion of the vascular bed from opening of new channels, widening of those already perfused, or a combination of both. Thus, the resistance decreases. It is believed (without proof) that this is on the basis of passive distension of the lungs, especially since the same relation holds when attempts are made to denervate the heart, when isolated lung lobes are perfused, or when variations in the quantity of blood in the lungs is induced by different procedures.

As pointed out earlier, to understand what is happening hemodynamically in the pulmonary circulation, it is more important here than in any other vascular bed to know both the pulmonary artery pressure and pulmonary vein (or left atrial pressure). This is because the pressure gradient is only a few millimeters of mercury, and a 5 mm Hg change in the pulmonary venous pressure could be transmitted back as a 5 mm Hg rise on the pulmonary artery side without any active change in peripheral resistance in the lung vessels. So, unless it is known what is happening in the pulmonary veins, one is at a loss to ascribe the cause of a change in pulmonary artery pressure. Keeping this in mind, little or no evidence exists in the dog that various procedures that actively affect peripheral resistance in the systemic circuit have any effect in the pulmonary bed. For example, epinephrine injection in small or large doses into the pulmonary artery, has no effect on the pulmonary circulation in its first circuit. After it has entered the systemic circuit and increased pulse pressure and cardiac output, then the pulmonary vein pressure may increase 50 to 60 mm Hg but so does the pulmonary artery pressure by a like amount, so the pressure difference is not changed. Acetylcholine, aminophylline, histamine and stellate ganglion stimulation are also without effect on the differential pressure. Hence, the passive bag theory of pulmonary function has arisen.

EVIDENCE FOR AND AGAINST VASOMOTOR CONTROL OF THE PULMONARY CIRCULATION The pressure in the pulmonary artery may increase as the result of back pressure from the left heart, an increase in pulmonary blood flow and vasoconstriction in the pulmonary vascular bed. Also, pressure changes follow alteration of intrathoracic pressure.

The pulmonary vasculature could respond to active vasoconstriction and contribute to an increase of pulmonary artery pressure. The small pulmonary vessels possess muscular coats and are equipped with dual nerve supply—sympathetic and parasympathetic, stimulation of the barore-

ceptors gives increased pulmonary flow and decreased pulmonary arterial pressure, casts of the two sides of a lung are markedly different if one side is perfused with noradrenaline up to the time of plastic injection (the latter showing marked constriction in the vessels of less than 25 microns (μ) in diameter). However, since there is little doubt that wide variations in vascular resistance can normally occur in a purely passive way, and since it is impossible to establish accurately the pressure gradient when it is so very low, demonstration of an active part played by smooth muscle under normal conditions, in the walls of the small vessels, is difficult.

In the presence of left heart failure resulting from mitral stenosis, the pulmonary capillary pressure rises, distends the capillary bed and leads to pulmonary edema. It has been postulated that as soon as the edema occurs from high back pressure, a reflex occurs giving rise to local arterial constriction and accounts, in part, for the pulmonary artery pressure elevation, at times even to 100 mm Hg, and the minimization of the pulmonary edema. Presumably, however, the mechanism for increased pulmonary resistance is not an adaptive reflex but a life saving effect of pathological changes in the small pulmonary vessels.

In normal subjects, anoxia, induced by breathing 12 per cent oxygen in nitrogen, considerably increases pulmonary arterial pressure, mildly increases cardiac output, and is without effect on left atrial pressure or central blood volume. This suggests that the vasoconstriction induced is on an active basis. Although generalized, such vasoconstriction of the pulmonary bed would seem to serve no useful purpose, local hypoxia, however, could be helpful in regulating the distribution of blood by causing vasoconstriction which, in turn, diverts blood from the affected region to vessels in better aerated parts of the lung. In experiments in man and animals in which one lung was respired with an hypoxic mixture, the lung probably developed vasoconstriction, since the arterial saturation returned to normal. This would be the case if the vessels in the hypoxic lung constricted and forced the blood normally flowing through them into well-oxygenated channels. Final proof, however, that hypoxia induces active vasoconstriction in man is contained in the experiments in which acetylcholine (a drug with strong vasodilating effects on the systemic circulation) was infused into the right atrium but in such quantities that no systemic effects were produced. In the presence of hypoxia in

duced by breathing a low oxygen mixture, in fusion of acetylcholine decreased the elevated pulmonary arterial pressure but did not change the left atrial pressure, cardiac output, systemic blood pressure, or heart rate. This seems to indicate that an active vasoconstriction caused by hypoxia is relieved by the drug. This view is further substantiated by the observation that in emphysematous patients who represent a chronic and more limited form of hypoxia with some degree of arterial unsaturation, acetylcholine in fusion lowers still further the arterial oxygen saturation. The site and mechanism of action are unknown but they could be many—a local reflex from alveoli or pulmonary veins, chemoreceptor stimulation of the sinus or aortic body, direct local action on pulmonary bed, and shift of systemic blood into the pulmonary circuit, etc. Presumably, the action is not related to sympathetic nervous control since the vasoconstrictor effect of hypoxia can be observed in man with a total sympathectomy.

In summary, then, experimental evidence demonstrates that human pulmonary vessels can constrict and dilate, but these functions have been shown only under extreme conditions. Hence, the role played by active vasomotion in controlling the pulmonary circulation is not known, and since the present methods available for such study have serious limitations, this problem will be difficult to solve.

THE OUTPUT OF THE HEART AND THE REGULATION OF ITS ACTION

Nervous Control of the Heart

THE HEART RATE

In general, the rate of the heart bears an inverse relationship to the size of the animal, and a direct relationship to the metabolic rate. The heart rate in the canary, for example, is in the neighborhood of 1000 beats per minute, whereas that of the elephant is about 25. The average rate in adult man is around 70 per minute, but there is a rather wide variation between individuals, a rate considerably below or above this average being not uncommon. Muscular training tends to reduce the cardiac rate, athletes not infrequently having a pulse rate between 50 and 60. On the other hand, a rate between 80 and 90 is sometimes seen in other healthy persons. The rate diminishes progressively from birth, when it is around 130 per minute, to adolescence, but increases slightly again in old age. Among physiological conditions which temporarily increase the heart rate are *muscular exercise, emotional excitement and high environmental temperature*. It also increases somewhat during *digestion*. The rate is lowered during *sleep* (55 to 60). Among pathological conditions which cause an increase in cardiac rate are *hemorrhage, surgical shock, hyperthyroidism, fever* (an increase of 10 beats per 1° F. rise in temperature) and certain *cardiac arrhythmias*, e.g., paroxysmal tachycardia, atrial fibrillation, etc.

Tachycardia and *bradycardia* are general terms used to denote, respectively, any considerable increase in heart rate above, or reduction below the normal average.

Ordinarily the heart rate is not under voluntary control. However, several instances have been reported of individuals possessing the power of voluntarily accelerating the heart rate. In one such case the effect was brought about apparently through the discharge of impulses along accelerator nerves since other sympathetic manifestations, e.g., vasoconstriction, glycosuria and dil-

ation of the pupils accompanied the increased pulse rate.

The heart, as we know, beats rhythmically after its complete separation from the central nervous system, but in the intact animal this automatic action is under the continuous influence of nervous impulses. The nervous mechanism comprises groups of nerve cells in the medulla—the *cardiac centers*, various *afferent pathways* along which impulses are conveyed to these centers from numerous regions of the body, and the *vagus* and *accelerator* or *augmentor* nerves which transmit impulses from the centers to the heart.

THE VAGUS NERVES

The vagus nerves are cardioinhibitory. This action was discovered by the Wehr brothers in 1845. They convey fibers, belonging to the parasympathetic division of the involuntary nervous system, from a center in the medulla (*cardioinhibitor center*) to the special tissues of the heart. The medullary center was located by Miller and Bowman in the dorsal nucleus of the vagus situated in the floor of the 4th ventricle. Weak electrical stimulation of this area produced slowing of the beat, and stronger currents complete arrest of the heart. The cardiac fibers of the vagus separate from the trunk of the nerve in the neck between the origins of its superior and inferior laryngeal branches. Intermingling with fibers of the accelerator nerves they enter into the formation of the deep and superficial cardiac plexuses whence they are continued to the atrial muscle. Here they make connection with ganglion cells. Postganglionic fibers pass to the specialized tissue of the sino atrial and atrioventricular (A-V) nodes where they are prolonged between the muscle fibers. They form a rich plexus and are seen to end as ring shaped or club shaped structures ("boutons") upon the fibers of the specialized tissue. Many postganglionic fibers do not enter the nodal tissues but terminate in the atrial myocardium proper. Those which enter the atrioven-

tricular node do not extend beyond the upper part of the bundle. None has been found to terminate in the ventricular myocardium (Nonidez), or in the lower part of the specialized conducting system.

THE ACCELERATOR OR AUGMENTOR NERVES

The accelerator fibers were described by Von Bezold in 1863. They belong to the thoracolumbar division of the involuntary nervous system and arise from cells situated in the lateral horns of the upper thoracic segments of the spinal cord. These cells constitute a spinal cardio accelerator center. The preganglionic fibers enter the gangliated cord of the sympathetic to connect with cells in the inferior, middle and superior cervical ganglia. In many animals and also often in the human subject the inferior cervical and the first thoracic ganglia are fused into an irregularly shaped structure called the *stellate ganglion* from which accelerator fibers pass directly to the heart. The heart also receives accelerator fibers directly from the sympathetic chain as far down as the 4th or 5th thoracic ganglion. In order, therefore, to remove all accelerator influence from the heart it is necessary, as shown by Cannon, Lewis and Britton, and by others in man, to interrupt these connections as well as to remove the stellate ganglia. The axons of the cells of the cervical ganglia (postganglionic fibers) form the inferior, middle and superior cardiac nerves (fig. 23.1). These fibers, especially those

forming the nerves of the right side, terminate in the sino-atrial node. Those of the left side are distributed mainly to the A-V node and bundle. According to Nonidez, the sympathetic efferent fibers which reach the heart are contained mainly in the middle cardiac nerve. The superior cardiac nerve is distributed to the large arteries at the base of the heart while the inferior cardiac nerve is mainly afferent. The spinal accelerator center is subordinate to higher centers. The precise locations of the latter are not known but the experiments of Beattie, Brown and Long indicate the presence of a center in the posterior hypothalamic region and Green and Hoff observed changes in heart rate in blood pressure and in limb and kidney volumes upon stimulating the cerebral cortex (motor and premotor areas) in cats and monkeys. A medullary center also probably exists.

TONIC ACTION OF NERVE

The separate effects of stimulation of the vagal and sympathetic fibers to the heart on the heart rate, conduction, distensibility and contractility of the heart have been considered in chapter 14. But their normal tone, reflex activation and control and their interplay or balance remain to be considered.

A. The tone of the vagus. During the normal life of the animal the vagus nerves exert a continuous restraint upon the action of the heart. In other words the vagus or rather the cardio-inhibitory center possesses tone impulses passing from it in a continuous stream to the heart. This effect, which may be compared to the action of a dragging brake, can be readily demonstrated in animals by cutting or freezing the nerves. The heart's action then immediately becomes greatly accelerated. The increase in rate following the removal of the vagal influence also occurs though the stellate ganglia have been previously excised, the result therefore cannot be due to an increased action of the accelerator nerves. The tonic action of the vagus nerves may be annulled by means of atropine, $\frac{1}{2}$ to $\frac{1}{4}$ grain being required in man to completely abolish their effects, the heart rate then increasing to 150 or 180 per minute. The difference between this rate and the normal resting rate of 70 per minute, therefore, represents the vagal effect which is being constantly exerted under ordinary circumstances. Various conditions, physiological and pathological alter the tone of the vagus center. The tone is naturally higher in some species, e.g., the dog, which is

FIG. 23.1 Diagram of the cardiac nerves. Broken lines = preganglionic sympathetic fibers.

capable of feats of endurance, than in others, e.g., the domestic rabbit. It also shows individual variations in man, athletes usually showing a higher tone than those who lead sedentary lives.

Vagal tone is apparently reflex in nature and dependent upon afferent impulses flowing to the vagus center especially along the sinus and aortic nerves. Section of these nerves causes an increase in heart rate and little further acceleration occurs as a rule when the vagi themselves are subsequently severed.

B Accelerator tone The accelerators also exert a tonic action. This has been demonstrated by excision of the stellate ganglia when the heart rate is reduced. Gasser and Meek, for example, found that when the ganglia were removed but the vagi left intact, an immediate and marked fall in rate (about 40 per cent) occurred, further slowing occurred later which was attributed to a rise in vagal tone. Slowing of the rate is produced, however, by excision of the ganglia, even though vagotomy has been performed previously, this fact of course precludes the possibility of the immediate reduction in rate following excision of the stellate ganglia being due to increased vagal tone. Chapman and associates observed slowing of the heart in man after bilateral excision of the sympathetic ganglia from the 2nd to the 5th thoracic ganglia inclusive. In some instances a reduced cardiac response to exercise was observed after this operation.

Bronk and his associates have demonstrated the existence of accelerator tone in the cat by recording the action potentials from nerves leaving the stellate ganglion. A fairly continuous discharge of impulses at a rate of from 5 to 20 per second was observed. Stimulation of the central end of an afferent nerve (e.g., sinus or aortic nerve) caused a discharge of impulses in the efferent fibers of the same frequency as those in the afferent impulses.

CARDIAC REFLEXES

Under ordinary conditions, the activities of the cardio-inhibitory and cardio-accelerator centers which result in the continuous discharge of impulses along the corresponding cardiac nerves are in turn dependent to a very large extent, if not entirely, upon the reception of impulses by afferent paths. In other words, the maintenance of the tone of the centers, and so of the normal resting rate of the heart, and the alterations in rate which occur under various physiological conditions are in large measure either reflex in nature or due to impulses received from cerebral

centers. The impulses which stream into the nervous centers arise in all parts of the body, the heart itself included. By these influences the tone of either center may be exalted or depressed, and corresponding changes produced in the cardiac rate. If the cardiac vagus on one side be cut and its central portion (i.e., the end leading to the brain) stimulated, a reflex through the cardio-inhibitory center and the opposite vagus occurs which alters the cardiac rate. The nature of the change in rate—whether acceleration or inhibition—will result from stimulation of the central end of the vagus or of most other afferent nerves cannot always be foretold. Reflex slowing of the pulse can usually be demonstrated in the human subject by pressure upon the eyeball at the outer canthus (oculo-cardiac reflex), or by the stimulation of nasal branches of the 5th nerve. Stimulation of afferent fibers in the respiratory passages as by the inhalation of irritating vapors, e.g., anesthetics, is particularly likely to cause reflex inhibition of the heart. Extrasystoles and bradycardia have been demonstrated electrocardiographically in man during abdominal operations, the irregularities being the consequence apparently, of visceral stimulation. Excitation of the central end of various peripheral nerves, e.g., the sciatic, causes reflex changes in the pulse rate. In these last instances acceleration is more readily obtained than inhibition. The irradiation of impulses on to the cardiac centers from the cerebral centers, e.g., from the motor area at the commencement of muscular exercise or from regions concerned with emotional manifestations, are held responsible for the changes in pulse rate which occurs under these conditions.

The pulse rate is generally inversely related to the arterial blood pressure, a rise or fall in pressure causing respectively a decrease or increase in heart rate. These adjustments are believed to be subserved by (1) a reflex whose afferent limb is constituted of afferent vagal fibers (aortic nerve) ending in the aortic arch and heart (2) a reflex in which the sinus nerve forms the afferent limb. These mechanisms have been considered in chapter 21. Presumably, such changes in heart rate are brought about not simply by an increase or a decrease in tone of one or the other cardiac centers, but by reciprocal variations in the tone of both. For example, the slowing of the heart which results from a rise in arterial pressure is much less pronounced if impulses from the cardio-inhibitory center have been prevented from reaching the heart by section of the vagi. After removal of the stellate ganglia, on the other hand,

the cardiac response to a rise in blood pressure is reduced to a less extent. Obviously, the mechanisms concerned are not too well understood since a fall in blood pressure causes an increase in the rate of the heart even after it has been completely denervated.

Cardiac Output and Cardiac Work

The most important external manifestation of the heart is its output of blood and the work it performs. These measurements are obtained by the Fick procedure, by the dilution principle and in some instances, by the foreign gas methods (ch 18).

DEFINITIONS AND GENERAL CONSIDERATIONS

The output of the heart per beat is spoken of as the *systolic discharge* or the *stroke volume*, and the output per minute as the *minute volume*. The value of the latter is simply the product of the stroke volume and the pulse rate (pulse rate times stroke volume = minute volume), the minute volume divided by the pulse rate, therefore, gives the stroke volume. The quantity of blood ejected by each beat of the left ventricle in the average healthy man during rest is from 70 to 80 cc. An equal quantity is, of course, discharged at the same time by the right ventricle, making a total for the whole heart of from 140 to 160 cc. The contents of the left ventricle are ejected against a much higher mean arterial pressure than the contents of the right, the mean pressure in the pulmonary artery being about $\frac{1}{3}$ of that in the aorta. The minute volume is expressed in terms of one ventricle. The output of one ventricle obviously represents the quantity of blood flowing through the lungs or through the systemic vessels during the same period. An adult of sedentary occupation pumps at least 5500 liters of blood through his body daily—from left to right ventricle through the systemic vessels, and from right to left through the lungs.

The heart cavities are not believed to completely empty themselves during the resting state, but contain around 100 cc of residual blood at the end of systole. Each ventricle has a normal capacity of approximately 200 cc.

The portion of the energy output of the left ventricle that appears as useful work can be roughly calculated from the product of mean aortic blood pressure and cardiac output. The work done by the right ventricle can be similarly calculated except that the mean pressure is that

in the pulmonary artery. The end diastolic pressure in the left or right ventricle should be subtracted from the measured aortic pressure or pulmonary arterial pressure since the end diastolic ventricular pressure does not have its origin from ventricular systole. Preferably the transmural pressure should be subtracted but this is difficult to obtain in man. Ordinarily the end diastolic pressure is small approximating up to 5 mm Hg in the right ventricle and up to 10 mm Hg in the left ventricle. However under some conditions of heavy ventricular loading such as an A-V fistula, or congestive heart failure the value may reach 30 to 40 mm Hg and hence the correction is important. The simpler calculation also assumes that the velocity factor is but a very small part of the external work of the heart. Normally, this is of the order of 1 to 2 per cent. When cardiac output is quite large in the presence of a decreased systemic pressure or especially if aortic or pulmonary stenosis occurs the kinetic factor can be up to 50 per cent of the cardiac work. For a somewhat precise evaluation of the work done by either ventricle the following formula may be used:

$$W = QR + \frac{wV^2}{2g}$$

in which W is work in gram meters, Q is cardiac output in cc per beat, R is mean aortic blood pressure in mm Hg, w is mass of blood ejected in grams and g is 9.8. The mean velocity (V) during systolic ejection in centimeters per second at the root of the aorta or pulmonary artery is equal to stroke volume (cross sectional area in square centimeters at the aortic or pulmonary root times the duration of ejection). The aortic or pulmonary diameter is obtained from cadavers. The kinetic factor is assumed to be the same for both ventricles since the cross-sectional areas of aorta and pulmonary artery are about the same.

To better compare cardiac output and cardiac work in different individuals, the values are generally expressed in terms of surface area and are spoken of as flow or work indices. Thus the cardiac index (CI), stroke volume index (SVI), cardiac work index (CWI), and stroke work index (SWI) are obtained by dividing the cardiac output, stroke volume, cardiac work, and stroke work by the surface area of the body. An average surface area is 1.7 square meters. Normal values for the right and left heart obtained in man during catheterization studies are in Table 23.1.

THE OUTPUT OF THE HEALTHY HEART NORMAL STANDARDS. PHYSIOLOGICAL VARIATIONS. The minute output of the heart under basal conditions for the average size male adult is about 5.5 liters, and the CI is 3.2 liters. The CI is slightly lower for the female and considerably higher for children. Cardiac output can be quite variable in the same person from day to day unless extreme precautions are used to maintain the resting state.

A. Conditions in which cardiac output is not changed. The cardiac output is apparently the same when a person is asleep as when he is awake and in the horizontal position. It is unaffected by menstruation and by moderate variations in the external temperature although it may be increased up to 30 per cent at environmental temperatures above 30°C, or by low temperatures that are associated with shivering. The native indigenous to high altitude undergoes considerable acclimatization by changes in his cardiovascular and respiratory systems so that at altitudes of, at least, 15,000 feet, the cardiac output is normal as are his heart rate and systemic blood pressure and systemic A-VO₂.

¹ Body recumbent, at rest and at 20°C for 15 to 20 minutes and 12 hours after food and drink.

However, the slightest exertion will increase his cardiac output which will be considerably higher in the sitting rather than in the reclining position, whereas in persons indigenous to sea level, such change in posture at sea level may decrease cardiac output.

B. Conditions in which cardiac output decreases. *Normal.* The cardiac output is decreased about 30 per cent in changing from the recumbent to the upright posture.

Pathological states. Atrial fibrillation and a very rapid heart rate may reduce cardiac output up to 50 per cent. In complete heart block and with an efficient myocardium, the output may be approximately normal, but when this exists in the presence of coronary sclerosis, myocardial degeneration, or after open heart surgery (cutting of the A-V bundle), the output may be greatly reduced. In other subjects, although the output at rest is normal, the inability of the heart to accelerate properly prevents an adequate output during muscular exertion. In congestive heart failure, cardiac output very often is reduced, and the increase in cardiac output which normally follows muscular effort does not occur or is slight. This type of failure is to some extent compensated for by a greater increase in the

systemic $A\text{VO}_2$ difference than occurs in healthy persons doing a similar amount of external work

C Conditions which increase cardiac output Cardiac output may be increased 50 to 100 per cent by anxiety and excitement and, at least, 30 per cent by eating (during first 3 hours). Anxiety, apprehension, and excitement may increase cardiac output greatly, presumably through the release and action of catecholamines. Pregnancy (in the later months) and low oxygen or high CO_2 in the inspired air are conditions which increase cardiac output up to 100 per cent. Presumably, the elevation is again related to the high level of circulating catecholamines which stimulate the myocardium. If prolonged or too severe, the output declines due to the injurious effect upon the heart muscle. In maximum exercise the cardiac output may be increased ninefold.

D Effects of drugs upon the cardiac output *Adrenaline* and *histamine* increase the oxygen consumption and the cardiac output, the effect upon the minute volume is, however, proportionately greater than that upon the oxygen consumption. *Acetylcholine*, whose effects in general are very evanescent, causes a slight increase in the minute volume. A decided rise in the cardiac output is produced by *nitrites* which, like *acetylcholine*, cause arteriolar dilation. The increase in the cardiac output caused by nitrites is probably a compensatory effect of the lower peripheral resistance, whereby the blood pressure is maintained near the normal level. *Digitals* produces no immediate effect upon the minute volume in normal persons. In subjects with congestive heart failure and atrial fibrillation the output is as a rule, though not invariably, increased as the cardiac condition improves. *Strophanthin* acts similarly to digitals. *Atropine* which increases the heart rate to 150 or 180 beats per minute does not increase as a rule the cardiac output. *Alcohol* in moderate dosage (35 cc) causes no more than a slight rise in the cardiac output.

REGULATION OF CARDIAC OUTPUT AND CARDIAC WORK DURING EXERCISE AND EXCITEMENT

Reliable determinations of cardiac output and cardiac work during exercise and excitement are not too numerous. For mild to moderate exercise, measurements are generally made by the Fick procedure with the subject in the supine position and with indwelling cardiac catheters while he pushes bicycle pedals with his feet operating against a mechanical frictional resistance. For heavy as well as light external work, cardiac

output is determined with the dilution technique while the subject runs on a treadmill. In strenuous exercise, the cardiac output may reach 35 to 45 liters per minute (table 23.1) or increase 7 to 9 times, while the body oxygen usage may increase 10 to 12 times.

Exercise and excitement make up the most important and continuous stress impacts of every day life. With present knowledge, it is impossible to portray sequentially the responses of the heart and circulation to these stimuli. A description of present information is, however, possible and some of it will stand a reasonable degree of integration. Many parameters of importance have been reassured.

A Heart rate At the transition from rest to work, the pulse frequency rises very rapidly with heavy exercise, reaching levels of 160 to 180 per minute. During short exhaustive work, heart rates as high as 240 to 270 have been recorded in normal young people. This increase in heart rate is attributed to some form of autonomic control but the mechanisms have not been established. The suspect Bainbridge reflex probably does not apply since this requires for its operation cardiac distension from increased venous return. As we shall see later, the heart is more apt to decrease in size. The tachycardia during exercise is attributed to a reflex through the carotid sinus and aortic baroreceptors resulting from a reduced arterial pressure as the result of vasodilation in the active muscle. However, the systemic blood pressure rises, not falls, during exercise. Finally, tachycardia is explained as related to direct regulation from the higher centers.

B Ventricular pressure volume relations It has long been believed that the output of the heart is governed by its venous blood supply and that the increase in minute output during muscular work requires a regulating mechanism by which venous return is augmented. To effect this, the venous blood supply and pressure in the central veins must increase to such a height that the increased venous flow and ventricular filling pressure will dilate the heart and increase the length of its fibers during each diastole and by this stretch cause a greater ventricular response in the following systole.

A very large amount of experimental work has stressed this viewpoint. Howell and Donaldson (1884) first showed the intrinsic adaptation of the heart of the dog to an artificially increased venous return. Frank in 1895, in the frog heart, came to the conclusion that the magnitude of ventricular contraction is determined by the intra-cavity

FIG. 23.2 Performance characteristics of the heart. A Relation of O_2 usage to cardiac work and diastolic volume, i.e., the energy output of the heart, utilizing the "heart/lung preparation" (Starling and Visscher, *J. Physiol.*, 1926, 62, 243) B Pressure volume function curves of the left ventricle in the open chest dog C Effect of sympathetic and parasympathetic cardiac nerve stimulation on the relation between mean left atrial pressure and left ventricular stroke work. Note lack of depressant effect of vagal stimulation upon end diastolic pressure stroke work relations (Sarnoff, *Am J Cardiol* 1960, 5, 579) D. Response of right ventricular stroke work to mean right atrial pressure and to ventricular end diastolic pressure, and the effects of autonomic stimulation. The parasympathetic response is presented only for direction and does not indicate magnitude (Sarnoff, *Am J Cardiol* 1960, 5, 579) E Change in effective end diastolic pressure (EDP) versus stroke work in the normal dog before and within 1 minute after exercise (From Gregg, *et al Physiol Rev*, 1955, 35, 130)

volume at the end of systole. In 1914, Patterson, Piper and Starling measured the pressure and volume of both ventricles with a cardiometer in a heart lung preparation of the dog while the venous return was passively and progressively increased by elevating a blood infusion reservoir connected to the right atrium. As the atrial pressure or ventricular filling pressure rose, the heart dilated and with each systole ejected a greater stroke volume at a greater ventricular pressure. This relationship called "Starling's Law of the Heart" indicated in a more formalized way that "the energy of contraction, however measured, is a function of the length of the muscle fibers," before contraction (fig 23 2 1). As these investigators indicated, this relationship is little more than the application to cardiac muscle of what was already known about skeletal muscle by Blv

in 1895 and Flick in 1882. This relationship of ventricular pressure and volume has been confirmed for the whole heart in the open chest dog and for the left ventricle in the open and closed chest dog (fig 23 2B).

Because of the difficulty of estimating volume of a single ventricle and the relative ease of pressure measurement, attempts have been made to correlate mean atrial pressure or end diastolic pressure of the associated ventricle with the stroke volume or stroke work. An elegant experimental preparation for this type of study by Sarnoff is in figure 23 3. At the outset it might be expected on mechanical and other grounds that neither mean atrial pressure nor end diastolic pressure would be a reliable substitute for the ventricular volume as a guide to the response of the ventricle. First of all, the two pressures do not

Fig 23 3 Modern version by Sarnoff of isolated heart or heart lung preparation. The coronary venous return is passed through a donor dog to maintain the blood at a normal biochemical environment before it is infused into the coronary system of the isolated heart. In older versions of the Starling isolated heart or heart lung preparation in which the coronary venous blood circulating through the myocardial wall was simply reoxygenated and returned to the coronary system, progressive deterioration in performance characteristics developed within 60 to 90 minutes. *SD*, support dog; *SOL*, support dog reservoir; *SOL*, solenoid valve electrically operated by microswitch at top of reservoir float; *SR*, air filled Starling resistance; *PET*, Potter electro-turbine; *DA*, arterial densitometer; *RES*, reservoir; *IR*, water filled inflow Starling resistance; *DV*, venous densitometer; *ROT*, rotameter (Sarnoff, *et al* Am J Physiol, 1958, 192, 141).

always follow each other. They represent only an approximation to one of the variables that determine the end diastolic volume of a ventricle. The end diastolic volume is determined not only by the filling pressure but by its duration, the resistance of the ventricle to filling (its tone), and by the systolic volume of blood remaining in the heart after systole has ended (its systolic residue). Both the latter are independent of these pressures. Finally, the relationship between these pressures and the end diastolic volume is almost flat in the physiological range, i.e., it takes large changes in diastolic volume to induce almost no change in atrial or ventricular end diastolic pressure. Despite this, most experimenters found that under ordinary circumstances, mean atrial pressure or ventricular end diastolic pressure and the succeeding ventricular response of pressure, stroke volume or stroke work were usually altered together. Sarnoff, in particular, has greatly expanded this approach and has found that the curves expressing the relation of mean atrial pressure and stroke work are shifted in one direction by conditions improving myocardial performance (stimulation of cardiac fibers from the stellate ganglia, reflex stimulation of the myocardium by a decrease in carotid sinus perfusion pressure, injection of epinephrine), while unfavorable conditions such as vagal stimulation, increase in carotid sinus perfusion pressure and coronary insufficiency shift the curves in the opposite direction. These ventricular function curves provide important objective evidence that ventricular control can involve changes in myocardial contractility, a concept now widely accepted (fig. 23 2C and D).

As one approaches the normal state, however, the evidence is equivocal for this relationship. The peripheral venous pressure in man during heavy work (28 liters oxygen per minute) can increase up to 7 mm Hg. Variations of filling pressure, however, cannot be deduced from peripheral venous pressure because of the unknown pressure gradient from the periphery to central veins. In the dog exercising on the treadmill, in the human following injection of a small amount of epinephrine or exercising mildly while lying down, there may be no direct correlation between the increased cardiac output or cardiac work and the atrial or ventricular end diastolic pressure. On the other hand, in subjects with an artificial pneumothorax, a linear relation was found between effective or transmural atrial pressure and stroke volume with an increase of 2 mm Hg providing an increase in stroke volume of 40 per

cent. This relationship also apparently holds in patients with high output failure and very large ventricular volumes.

C Ventricular volume and stroke volume. As already indicated, comparisons of direct measurements of ventricular volume with pressure or with stroke volume or stroke work have not been made in the normal state in which the aggregate complications of venous resistance, intrathoracic pressure, vascular volume, changing heart rate, neurogenic factors, and humoral influences exist. However, highly suggestive evidence has been obtained by estimating the ventricular volume in systole and diastole. In dogs, this has been done by measuring the cyclic changes in an external ventricular dimension (using the mercury filled tube of Whitnev or the sonar technique), or by measuring a changing internal ventricular dimension by an induction gauge. A limited amount of work is available in which stroke volume has been simultaneously determined by the sonar or electromagnetic flow meter technique applied to the aorta. In humans, the diastolic volume has been estimated from the X-ray silhouette while the stroke volume has been directly determined using the Fick or dye dilution principle. The essential findings follow.

In man and the dog, the left ventricular diastolic volume and stroke volume increase in the recumbent position as compared to the more or less upright position. Concurrently the central blood pool or thoracic blood volume increases by about 400 cc. The cardiac output and heart rate change in opposite directions on alteration of position, i.e., in the supine position the cardiac output increases and the heart rate decreases. Correspondingly, assuming the upright position is accompanied by a reduction in heart size and stroke volume.

In the resting dog, an increase in venous return induced by a rapid infusion of blood or by displacing blood from the splanchnic area into the thorax by abdominal compression increases the left ventricular dimension without significantly altering stroke volume or stroke work. Excitement or startle or the anticipation of exercise just before treadmill activity can lead to a transitory increase in stroke volume with enlargement of the left ventricle.

Nonexhaustive exercise by healthy dogs and normal untrained human subjects may be accompanied by increased cardiac output, primarily resulting from tachycardia with little or no progressive increase in stroke volume as the level of exertion increases. Stroke volume during such

exertion may only occasionally exceed the resting recumbent values in healthy dogs or untrained human subjects. Concurrently, the left ventricular dimension of the dog's heart remains the same or becomes smaller. However, trained athletes and patients with chronic volume loads such as in valvular insufficiency may increase cardiac output with a significant augmentation of stroke volume and a lesser degree of tachycardia. The relatively small hearts of untrained persons may show a tendency to reduce their diastolic size during exercise but the end diastolic size of the large hearts of athletes gets much smaller.

Evidence for increased contractility of the myocardium during exercise is in the increasing rate of tension development, rate of blood ejection and rate of relaxation as seen in the ventricular pressure curves and the aortic flow curves.

The preceding evidence suggests but does not offer quite certain proof, that the fundamental property of cardiac muscle of a relation between end ventricular diastolic size and energy release is not dominant but rather that in the normal dog and man an increase in cardiac output during exercise is achieved mainly by an increase in heart rate with a constant or slightly increased stroke volume. A little reflection will indicate, however, that this is a self-regulating mechanism and cannot alone explain the observed changes in cardiac output. When the heart accelerates the output per beat can be kept constant only if the venous inflow is adequate only under such circumstances can the minute volume be increased. If, for example, the beat of the heart has occurred at the end of a period of rapid filling, i.e. before or at the moment that the heart chambers are filled, simply increasing the heart rate will cause the beat to fall earlier in the period of rapid filling. Reduction in the stroke volume in proportion to the increase in rate must result and no increase in the minute volume can therefore, occur. At very rapid heart rates, as in paroxysmal tachycardia, a point is reached at which the heart does not relax sufficiently between beats to take on an adequate load of blood, and the minute volume is actually reduced.

The contribution which cardiac acceleration can make toward the minute volume is therefore strictly limited for rates from 180 to 200 are about the maximums to which the healthy heart can be speeded up. This is only about $2\frac{1}{2}$ to 3 times the normal rate. With a constant stroke volume, therefore cardiac acceleration could not increase the minute volume more than about 3 times. Yet reliable data have shown that the

cardiac output of untrained man doing strenuous exercise may increase ninefold (from 5 to 6 liters per min. at rest to 35 to 45 liters) and the oxygen consumption 12 times (from 250 cc oxygen at rest to 3000 cc). In this circumstance, it must be concluded that the stroke volume increases 2 to 3 times (even at a maximum pulse rate) to account for up to 50 per cent of the cardiac output increase.

This is borne out by some of the data in table 23.1. The left ventricular response to treadmill exercise of natives of the Morococha, Peru region (elevation 14,900 ft.), and of natives of the Lama, Peru region (elevation 500 ft.), was studied at the elevation where they had always lived. It can be seen that at sea level, on the average about half the increase in cardiac output comes from an increase in stroke volume from 41 to 75 cc. In one group at Morococha exercising at a somewhat lower level of treadmill activity (490 to 580 kg. m. per min. per m²) the cardiac output and cardiac work were almost entirely explainable by the increase in heart rate and systemic blood pressure. The data in the second group at Morococha obtained at a higher level of treadmill activity (650 to 749 kg. m. per min. per m²) represents an attempt to stress the left ventricle to maximum external effort. Each of the five persons in this group stated at the end of the exercise that he was "completely exhausted." Two of them attained a cardiac output approximating 35 liters per min. and a stroke volume of about 200 cc. On an average, the stroke volume increased from 53 to 88 cc., and accounted for about 66 per cent of the increase in cardiac output.

The preceding also indicates that the cardiac size decreases in exercise. If the ventricle does become smaller during diastole and systole then the heart must possess an adequate residual volume to effect an increased stroke volume or a constant stroke volume. Presumably, as already pointed out, the human heart at the end of systole contains about 400 cc. blood divided equally among the four cavities. This will give each ventricle a residual volume of 100 cc. in the recumbent position and about 45 cc. in the upright position and which is used as the ventricle becomes smaller with exertion. This diminishes the volume reserve of the ventricles in severe exercise. Presumably, it is replenished during each diastole from the blood volume in the thoracic pool. The mechanisms for this are not understood but it can be demonstrated that the stroke volume is directly, and the heart rate in

directly, related to the volume of blood in this central compartment

In summary, it can be stated that both changes in stroke volume and heart rate contribute significantly to regulation of cardiac output in man, but no firm conclusion can be drawn as to the relative role that stroke volume, heart rate and diastolic and systolic volumes play under various conditions of stress. Proper understanding will follow the development of adequate methodology for determining cyclic changes in ventricular volume and stroke volume in animals and especially in man.

D Body $A V O_2$ difference Since the body oxygen usage can increase 12 times in exercise it is important to know the mechanisms by which this amount of oxygen is supplied to the tissues. Continuous measurements of $A V O_2$ difference from the onset of exercise have not yet been made and so it is not known how early these changes occur. The $A V O_2$ difference is generally calculated from the body oxygen usage divided by the cardiac output, the former being determined by collection and oxygen analysis of the expired air and the cardiac output by the dilution technique, which does not require cardiac catheterization. The oxygen extraction rises but considerably more slowly than does the cardiac output, reaching in very heavy exercise a calculated maximum of 13 to 16 cc per 100 cc of blood. Since most of the increase in blood flow is presumably through the exercising muscle, this means that the oxygen extraction at times must be very nearly complete in the latter, a situation similar to that which has been observed in the heart muscle with maximal activity. In well trained subjects, it appears that the rise in $A V O_2$ difference, as well as heart rate, are somewhat smaller, while the stroke volume is larger.

E Other hemodynamic variables in exercise In addition to the heart rate and stroke volume alterations occurring in exercise, many other changes are involved which may be mild or almost insignificant in light exercise, or which may be massive in strenuous activity (table 23 I). In the presence of heavy exercise and a very large increase in cardiac output, the CWT of the left ventricle may increase 4 times, the systemic blood pressure may increase considerably, the arterial pressure pulse may increase from 50 to 100 mm Hg, the total peripheral resistance may decrease greatly. Presumably, the latter results mainly from vasodilation in the metabolically active beds for, since splanchnic blood flow in man is decreased in the presence of an elevated systemic

blood pressure resistance in the splanchnic bed must be increased. In the pulmonary circulation, the arterial pressure rises moderately, while the resistance undergoes very little change. Finally, as pointed out earlier, the central venous, atrial, and ventricular end diastolic pressure do not necessarily increase. The alterations in many hemodynamic parameters during exercise is indicated in figure 23 4.

The cause, sequence and relative importance of these and other factors in the control of cardiac output during excitement and muscular exercise is still an enigma. Following the discovery of the baroreceptors it was quite natural that they be invoked as the major mechanism controlling cardiac output during exercise. This was especially felt to be so since as already mentioned, it has been established experimentally in the dog that if the blood pressure in the carotid sinus is lowered, there results reflexly an increased heart rate, decreased systemic peripheral resistance, increased peripheral venomotor tone, increased cardiac contractility (presumably via catecholamine release in the heart) and increased cardiac output. This presupposes a fall in arterial blood pressure caused by the vasodilation in the working muscles as the factor which initiates the hemodynamic changes resulting in an augmented cardiac output. However, intra-arterial blood pressure in man and dog at the transition from rest to work has been shown not to fall and of course later in the working period it increases. Another important experiment has indicated that the output of the heart in exercise is not related to the extent of vasodilation for, if pneumatic cuffs are placed on the exercising extremities of man so that about 50 per cent of the working musculature is cut off, the oxygen usage may be halved, but the cardiac output and heart rate are not decreased.

F Simulated exercise Finally, attempts have been made to simulate in the normal animal the cardiovascular events which are known to occur in exercise with the hope that one might serve as the proper experimental substitute for exercise. These include increased venous return (already considered), decreased peripheral resistance through injection of isoproterenol, injection of autonomic hormones, electrically induced tachycardia at rates existing in exercise, chronic stimulation of the sympathetic nerves to the heart and chronic stimulation of the central nervous system. Left ventricular performance during exercise could be fairly accurately reproduced by iso-

FIG 23.4 *Left side*, hemodynamic responses in exercising man and *right side*, hemodynamic responses in the unanesthetized dog to exercise to stimulation of the cardiac sympathetic fibers and of the hypothalamic area. Dotted lines represent the less usual responses.

proterenol infusion and stimulation of the hypothalamic region in the unanesthetized dog.

REGIONAL DISTRIBUTION OF O_2 CONSUMPTION AND BLOOD FLOW. The preceding discussion indicates that despite much study of long familiar functions, their operation in the adjustments of oxygen and cardiac output to exercise is poorly understood. The response of oxygen usage and blood flow, of course, represents the average requirements of organs and regions of the body. At present, adequate knowledge is not available of the allocation of cardiac output in the resting or exercising animal, let alone man. Simultaneous measurements of flow through major regions or organs such as the heart, kidney, brain, liver, intestines, cannot be made in the same person at

the same time. Even in the experimental animal, the only method available (based on the dilution principle) involves anesthesia and/or excitement so as to vitiate the interpretation of the findings. Despite this, table 23.2 is presented showing data on distribution of flow and oxygen consumption in resting and exercising man, obtained by different types of measurement by different observers on different subjects. (In some instances, values are extrapolated from animals.) The values are certainly not absolute but the general pattern of distribution may be right. The kidney blood flow of 400 cc per 100 grams of tissue is about 6 times greater than that of any other organ (nearest is the heart with a flow of 70 cc). The heart per unit of tissue, on the other hand, uses consider-

TABLE 23 2
Distribution of cardiac output and oxygen usage

Region	Weight		Blood Flow			Oxygen Usage			O ₂ Extraction	
	Kg	% Total	L./min	% Total	cc /100 gm /min	cc/min	% Total	cc /100 gm /min	Venous O ₂ cc./100 cc. blood	A VO ₂
Total	70	100	5.4	100		250	100		14.5	4.5
Brain	1.54	2.2	0.83	15	54	63	23	3.7	12.5	6.5
Convulsion			1.15	20	75					
Heart	0.33	0.5	0.22	4	70	23	9	7.0	7	12
Liver, Intestines	2.86	4.0	1.54	29	54	55	20	1.95	15	4.0
Kidney	0.33	0.5	1.43	27	430	20	7	6.0	17	2.0
Skeletal muscle	34.0	50.0	0.92	17	2.7	55	20	0.16	12.5	6.5
Exercise			35.0	80	100	2700	90	7.9	3	16.0

ably more oxygen than any other organ. Four organs—brain, heart, liver and intestine, and kidney, make up about 7 per cent of body weight but receive 65 to 70 per cent of the output of the heart and account for 60 per cent of the total oxygen used at rest. The skeletal muscles representing 50 per cent of body weight receive only 20 per cent of cardiac output at rest and account for only 15 per cent of body oxygen usage, but during exercise they may account for 80 to 90 per cent of the oxygen consumption and cardiac output. The brain which is only 2 per cent of body weight requires more than 20 per cent of the total oxygen used by the body and during convulsions (observed in monkeys) this fraction may increase to 40 per cent and the brain fraction of cardiac output from 14 to 20 per cent. Thus, the cardiovascular response is not limited to an adjustment of the cardiac pump, complicated as this may be. Certainly, real changes occur in the distribution of the output of the pump. There is, however, no integrated picture of the circulatory responses that occur and the underlying involvement of the central nervous system and peripheral mechanisms in the allocation of oxygen and cardiac output is unknown.

Cardiac Reserve

HEART RATE, VENTRICULAR VOLUME, BLOOD FLOW, CORONARY VENOUS O₂, VENTRICULAR EFFICIENCY

Present knowledge of the reserves available to the heart to cope with various stress impacts

permits little more than their enumeration. The potential reserves are its heart rate, its systolic and diastolic volume, its blood flow, the oxygen content of the body mixed venous blood, the cardiac work, the changing efficiency of the heart, and possibly the stores of catecholamines.

The reserve in heart rate is about 130 to 140 beats per min., resulting in a maximum heart rate of 210. The reserve in stroke volume is 80 to 100 cc. since each ventricle normally contains about 150 to 170 cc., of which 60 to 70 cc. is ejected during systole. This figure is somewhat lower than the measured figure of 190 cc. for maximum stroke volume in Peruvian natives in the mountains, exercising to exhaustion on a treadmill. Attainment of such an increased stroke volume indicates an increased contractility of the myocardium. The reserve in blood flow approximates 30 liters per min., since maximum cardiac output is about 35 liters per min. in man working to exhaustion, and the resting cardiac output is about 5 liters. The potential reserve of oxygen within the body is about 900 cc. This is based upon the fact the body mixed venous blood contains 15 to 16 cc. oxygen per 100 cc. blood, and the blood volume is 5500 cc. However, neither normal persons nor persons with heart disease utilize this oxygen to the full. With maximum exertion, the oxygen extraction approximates 14 to 16 volumes per cent. This is supplemented by the ability of the human body to take up a maximum of 3000 cc. oxygen per min., or an excess of about 2700 cc. over that in the basal state. The reserve work of the heart is at about 75 kg. per

min, since the maximum left ventricle work recorded is about 80 kg per min, and the resting left ventricle work approximates 5 to 6 kg per min.

In the whole body, the efficiency value for performing external work is fairly easily obtained by measuring the external work performed by the subject and dividing this by the energy equivalent of the difference between total body oxygen consumption and the oxygen usage of the body during rest. For the beating left ventricle, the efficiency is calculated in a similar way by dividing the external work of the ventricle by the difference between the energy equivalent of its oxygen usage while beating and while at rest. The external work of the ventricle is determined by the method already indicated, the oxygen usage of the left ventricle is determined from the product of coronary blood flow through the left myocardium and the coronary A-V oxygen difference. This is converted to kilogram meters of work per minute by multiplying by 2.057 which is the energy equivalent of 1 cc oxygen in kg·m.

Accurate determination of ventricular efficiency in man is not possible since left ventricular weight cannot be determined and, hence, total left ventricular flow is not available. In the unanesthetized dog, efficiencies of 31 per cent are reported. In the anesthetized dog with good cardiac output and systemic blood pressure, efficiencies have been found to vary from 7 to 54 per cent.

By definition, mechanical efficiency is work done per unit of energy output. The work of the heart is performed during the first part of the period of systole, but as in skeletal muscle, energy is released by the heart (oxygen used) when it is doing no work. Oxygen is used before, during, and after ventricular systole. A certain amount of oxygen can be used during the early part of systole from the onset of the elevation of intraventricular pressure to the time of opening of the pulmonary and aortic valves (isometric contraction period) during which time no blood is moved and no external mechanical work is done. Also, during diastole, oxygen can be used but the muscle fibers are relaxed and not shortening. The cardiac efficiency will, therefore, vary in part with the extent of contribution of the oxygen consumption during the resting and isometric contraction periods to the total oxygen usage. In general, the former will tend to lower the calculated efficiency at low levels of work and to increase efficiency as the work is increased.

Published data on myocardial efficiency are of

particular interest because they do not include oxygen values for the resting ventricle or ventricle doing no external work. The myocardium takes up considerable oxygen in diastole as well as systole. With our present poor methodology, separation can only be made by measuring oxygen uptake, first in the beating heart during repetitive systoles and diastoles, and then in the relaxed heart or during prolonged diastole, and finally, obtaining the oxygen usage during systole by difference. To do this, the coronary arteries are perfused with blood under constant pressure while coronary A-V oxygen difference and left coronary inflow are measured continuously, first in the beating heart and then in the heart stopped by vagal stimulation or removal of an arterial pacemaker, until a new equilibrium had been established, usually within 20 to 25 seconds. The resting metabolism (absence of heart rate, blood pressure and cardiac output) during cardiac arrest approximates 2.5 ml oxygen per 100 grams left ventricle per min, or about 25 to 30 per cent of the value at the prior working level. This value during diastole averages about one third that during systole for the same time period. These values in the vagal stopped heart have some interesting characteristics. Oxygen uptake is unaffected by ventricular diastolic size. They are not fixed but vary greatly with the control metabolic level in the beating heart before it is stopped. Under some circumstances, the oxygen usage in the resting heart may equal 50 per cent of that in the beating heart. In addition, in the nonworking but beating heart which has been emptied by hemorrhage and suction, the metabolism of 3.4 ml per 100 grams of left ventricle per min, is considerably greater than that with vagal asystole. Adjustments of the mechanical efficiency taking into account the usual oxygen usage in the vagal arrested heart and in the beating empty heart, are in table 23.3. The apparent efficiency is increased thereby from an assumed efficiency of 15 per cent to 26 per cent. While it cannot be stated that alteration of the mechanical efficiency by these amounts is correct, the data do emphasize that until the oxygen usage of the myocardium doing no external work is known under various physiological conditions, calculation of or reference to figures for cardiac efficiency is premature.

THE ROLE OF CATECHOLAMINES The findings that the heart contains significant stores of noradrenaline, and that stimulation of the cardiac sympathetic fibers (isolated from the stellate ganglia) may increase stroke volume and stroke

TABLE 23 3

Effect of oxygen usage in the nonworking left ventricle on the calculated left ventricular efficiency

Efficiency =	$\frac{1.2 (100)}{8.1}$	= 15%
Efficiency =	$\frac{1.2 (100)}{8.1 - 2.3}$	= 22%
Efficiency =	$\frac{1.2 (100)}{8.1 - 3.4}$	= 26%

work without change in heart rate has stimulated interest in the catecholamines as a possible powerful reserve mechanism. The role played by local stores of catechol hormones in circulatory regulation at various points of the cardiovascular system is now the subject of much current investigation.

The presence of catecholamines has been demonstrated in the mammalian heart (von Euler 1946) and in the walls of blood vessels (Schmitter 1948). Noradrenaline forms over 90 per cent of the total tissue catecholamines, adrenaline less than 10 per cent.

The noradrenaline content of these organs is closely related to the number of adrenergic fibers supplying them and it disappears almost completely following postganglionic sympathetic denervation (Goodall 1951). Similarly administration of reserpine to the experimental animal results in practically complete disappearance of noradrenaline from the heart (Bertler and associates 1956) and the walls of arteries (Burn and Rand 1958a).

It was shown that isolated atria of animals previously treated with reserpine exhibit a slower rate and lesser amplitude of contractions than control animals (Burn and Rand 1958b). Based on this observation it is suggested that the stores of catecholamines normally present in the heart contribute to the regulation of cardiac activity by accelerating the spontaneous rate. As of now, however, there is no direct evidence confirming this view.

Isolated aortic strips of animals previously treated with reserpine were shown to be more sensitive to adrenaline and noradrenaline than strips taken from aortae of control animals (Burn and Rand 1958a). The lesser sensitivity of normal (as compared to reserpine treated) vessels is tentatively interpreted as indicating that the catecholamine stores contained in them are functional and contribute to the maintenance

of normal vascular tone. Again more direct evidence is needed before any firm conclusions may be drawn regarding the physiological significance of these stores.

In the adrenal medulla catecholamines are secreted by chromaffin cells. Cells containing chromaffin granules exist also outside the adrenals in various tissues. They were recently discovered in the skin (Adams Ray and Nordenstam 1956). It is suggested that they produce catecholamines which play a role in the local control of the peripheral circulation. The administration of reserpine results in a decrease of the noradrenaline content of the skin accompanied by the disappearance of chromaffin granules (Burn and Rand 1958a). The chromaffin reaction however is not specific for catecholamines and their presence will have to be confirmed by other means.

The above investigations point out the various possible roles that local stores of catechol hormones may play in the regulation of the circulatory system. At the present time all of these mechanisms must be regarded as hypothetical awaiting further experimental confirmation.

THE CORONARY CIRCULATION

General Consideration

Beginning with Harvey in the seventeenth century, the anatomical and dynamic details of this system have been gradually elucidated.

ANATOMICAL. Two coronary arteries, the right and left, carry blood to the myocardium. About 2 mm. from its ostium, the left coronary artery divides into the left circumflex and the anterior descending branch. The former runs in the atrioventricular (A V) groove to the left, ending in a posterior descending branch. The anterior descending branch runs downward in the interventricular groove toward the apex. Near its origin, septal branches are given off. The right coronary descends in the right (A V) sulcus and ends posteriorly as several descending branches on the right and left ventricles. The subdivisions of the main coronary ramus descend superficially in the general direction of the apex and give off myocardial branches which course directly into the ventricular muscle. At or near the apex, where the superficial muscles form a spiral and penetrate to form the innermost (subendocardial) layer of muscle, the terminal coronary arteries go along with the muscle to supply the inner layer of both ventricles and the papillary muscles. Anatomical studies in both the dog and human heart indicate that vessel branching within the myocardium is related to muscle bundles, but numerous communications exist between the different muscle layers.

As in any other vascular system, each of the two coronary arteries connects with its capillary bed, its superficial myocardial venous bed, and eventually with the right atrium (fig. 24.1). The epicardial branches of the coronary arteries and coronary veins also anastomose with each other and with extracardiac arteries and veins. There are numerous arteriovenous shunts. In addition to these pathways, the arterioles as well as the capillaries and superficial veins connect directly with both ventricular cavities by discrete, deep drainage channels, the arterioluminal, the arteriosinusoidal and the Thebesian vessels which

together comprise the deep coronary drainage circuit.

In man, approximately 50 per cent of hearts have the right coronary artery predominant, 30 per cent have a balanced coronary circulation and 20 per cent have the left coronary artery predominant. The arterial pattern of the dog heart compares with the situation in man in which the left coronary artery is predominant. In the latter, the left coronary artery nourishes about 85 per cent of the heart muscle, supplying the whole of the left heart as well as portions of the right ventricle.

PREPARATION AND METHODOLOGY

The objective of studies of the coronary circulation is knowledge of the determinants of coronary flow, of the oxygen uptake (coronary flow times the coronary arteriovenous oxygen difference) by the myocardium, and of their relation to the work of the heart in states of normalcy, of increased or decreased stress, and of disease in man. This objective is far from being realized.

The Pitot tube, orifice meter, rotameter, bubble flowmeter, and thermostromular are used to measure coronary flow by insertion between the cut ends of a coronary vessel. The thermostromular also measures flow in the intact coronary artery. The electromagnetic flow meter has also been used successfully to quantitate coronary flow in the anesthetized and unanesthetized exercising dog. In addition, the nitrous oxide method can be used in the normal dog and human being, and if used with care, reasonably accurate values for human beings can be obtained. All except the bubble flowmeter and nitrous oxide methods permit continuous recording of flow. All measures mean flow, the orifice meter, Pitot tube, and electromagnetic flow meter can be used for recording phasic flow. The oxygen saturation of coronary arterial and venous blood is obtained by continuous withdrawal of aliquots of the respective bloods through indwelling tubes and their analyses by the Van Slyke, Beckman, or by

FIG. 241 Schematic representation of the coronary circulation. The areas enclosed within the circles depict the capillary beds, collateral communications and A-V shunts (Gregg and Sahistion, *Circulation* 1956 13: 916).

oximeter techniques. The first two methods give average oxygen values over a period of time; the last permits continuous recording of the arterio-venous oxygen difference.

UTILIZATION OF THE SUPERFICIAL VERSUS THE DEEP DRAINAGE CIRCUITS IN THE NORMAL HEART. As determined by clamping of the coronary arteries, all blood in the superficial veins of the heart arises in the two coronary arteries and none comes from the deep-lying connections within the cardiac cavities. Despite the presence of these deep channels and the existence of a favorable pressure gradient during diastole for flow through them into the ventricular cavities, they are not used. Balance studies of coronary inflow and outflow have shown that most of the blood entering the left coronary artery drains into the coronary sinus. The remainder of left coronary inflow is recovered in the superficial (anterior cardiac) veins of the right myocardium that drain into the right atrium. Most of the right coronary artery inflow appears in these anterior cardiac veins and the remainder (10 to 20 per cent) drains into the coronary sinus. Thus, essentially all coronary inflow can be collected in the superficial veins of the heart, leaving little or no blood to drain by the deep channels into the heart cavities. Presumably a similar utilization of anatomical path-

ways exists in man. However, in man it is reported that 16 per cent of left coronary flow enters the left ventricular cavity by the deep drainage channels. This has not yet been confirmed.

The deep drainage channels could have an important functional role if they served as arterial channels from the left ventricle to the myocardium during coronary artery constriction or occlusion, or as venous channels for the whole myocardium in the presence of extensive superficial vein constriction or occlusion. Regarding the first situation, although essentially complete occlusion of the coronary arteries in human beings has been found at autopsy, the presence or extent of development of extracardiac arterial collaterals is not known. In addition, with functional separation of one or both coronary arteries from the aorta, no blood flow from the ventricles into the superficial coronary venous system can be demonstrated, and the hearts do not survive. Regarding the second situation, with acute closure of all visible superficial coronary veins, although such hearts may survive, large intra- and extracardiac superficial venous channels quickly appear. Hence, known observations are conflicting, and any conclusion regarding the utilization of deep coronary venous drainage channels in diseased hearts is difficult.

USE OF LEFT CORONARY ARTERY FLOW TOGETHER WITH THE CHEMICAL COMPOSITION OF CORONARY SINUS BLOOD AS AN INDEX OF LEFT VENTRICULAR METABOLISM. It is not possible to quantitate accurately the metabolism of the right ventricle in the dog because its superficial anterior cardiac veins have many exits into the right atrium and their contained blood is grossly contaminated by blood from the left coronary artery. However, drainage of the left myocardium is accessible. In most instances quantitative changes in the metabolism of the left ventricle can be obtained from measurement of the chemical composition of the coronary sinus blood together with the left coronary inflow. This is because (1) coronary sinus blood is almost entirely from the left coronary artery, (2) by means of a special cannula which permits collection of all blood draining into the coronary sinus, the percentage of left coronary artery inflow recovered in the coronary sinus is quite high (80 to 90 per cent) and reasonably constant during the induction of a variety of physiological variables and drug injections, (3) the O_2 content of the venous blood from the left coronary artery not draining into the coronary sinus is generally only slightly less than that in the coronary sinus. This is a very important and practical consideration because of the widespread use of these measurements in man and dog for just this purpose.

BASAL DATA. In the resting state, the coronary data for dog and man agree. With the left ventricular cardiac work index approximately 3.5 to 4.6 Kg M left coronary flow approximates 72 to 85 ml per 100 grams of left ventricle per minute. Correct values for left coronary flow during natural maximal stress such as exercise, are not yet available but in the anesthetized open chest dog values as high as 600 ml per 100 grams of left ventricle per minute have been recorded. Although the heart can remove essentially all oxygen from the coronary blood in its passage through the myocardium normally about two thirds is extracted with an arteriovenous difference of 12 to 14 ml and a coronary sinus value of 4 to 5 ml. This extraction changes little with increased stress, signifying that the oxygen supply is well balanced with metabolic demands.

Oxygen uptake per 100 grams of left ventricle is 8 to 10 ml per minute. Oxygen consumption during systole averages about 3 times that in diastole for the same time period.

MYOCARDIAL RESPONSE TO ANOXIA. The coronary vascular bed is very reactive to the stimulus

of anoxia, occlusion of a coronary artery for as short a time as 5 seconds results in a temporary increase in blood flow. Reactive hyperemia is considered to be the excess blood flow (over the control flow that normally would have occurred) following release of an arterial occlusion (fig. 24-2). The reactive hyperemic blood flow and its duration increase with lengthening periods of left circumflex artery occlusion up to 120 sec, peak flows also increase but in smaller amounts. The theoretical blood flow "debt" (control blood flow multiplied by the duration of occlusion) is usually greatly overpaid. Reactive hyperemia in skeletal muscle vascular beds shows these same characteristics except the blood flow "debt" is variably under or overpaid (ch. 25). Coronary vasodilator agents do not consistently affect myocardial reactive hyperemia while Pitressin usually decreases the response.

The oxygen consumption during myocardial reactive hyperemia is measured by determining the left coronary artery blood flow (rotameter) and the oxygen saturation of the coronary sinus blood (measured continuously with a densitometer). The theoretical oxygen "debt" (control oxygen consumption times duration of left coronary artery occlusion) is overpaid for 15 and 80 sec but slightly underpaid for 10 second occlusions. In contrast to skeletal muscle, where the arteriovenous oxygen ($A-V O_2$) difference decreases during reactive hyperemia, the myocardial $A-V$ oxygen difference increases during the period of increased blood flow. The rate of oxygen consumption during the increased blood flow period is greater than in the control state, showing that the myocardium has been stimulated to take up more oxygen. The basic hypothesis governing the calculation of the oxygen "debt" in these studies is erroneous for the oxygen in the blood in the coronary vascular bed during arterial occlusion, the metabolic rate during the circulatory stasis and changes in cardiac work are not considered. As further evidence that the myocardium develops an oxygen deficit, i.e., anaerobic metabolism occurs, it was found that lactic acid increases in the coronary sinus blood, often in comparison to pyruvic acid levels, following the period of anoxia.

The contracting myocardium can withstand much shorter periods of arterial occlusion and oxygen deficit than resting skeletal muscle, and repays its oxygen "debt" with an increased blood flow but a decreased $A-V$ oxygen difference.

The Determinants of Coronary Flow

Consideration of the mechanisms that control the blood supply to the myocardium involve certain difficulties not encountered in similar investigations in other organs of the body. The myocardial wall of the left ventricle not only furnishes the pressure head for driving blood into the coronary arteries but also may either offer phasic resistance to coronary flow or actually aid flow by its muscular contraction around the coronary vascular bed. Similarly, the right ventricle rapidly changes resistance to right coronary flow

at the same time that left ventricular contraction presents blood to it under a pulsatile head of pressure. However, coronary flow is related to the pressure difference (effective pressure) between the central coronary artery (identical to aortic pressure) and the right atrium divided by the sum of the viscous resistances to flow in the epicardial portion of the artery and in the peripheral coronary bed. Viscous resistance to flow (aside from change in hematocrit) is mainly governed by the mean caliber of the coronary vascular bed. Since the arterial resistance is negligible, the mean

coronary diameter and, hence, flow are controlled by the effective intravessel pressure and by two peripheral mechanisms, i.e., active changes in the state of the small mass of intravascular smooth muscle built into the coronary vessels, and the mechanical or passive effect on flow exerted during ventricular systole by the large muscle mass around the coronary vessels. The peripheral mechanisms are regarded as more important in controlling coronary flow than the central coronary or aortic pressure which does not change greatly even in exercise. It is estimated that doubling the aortic pressure might double the coronary flow, but doubling the average radius of the coronary bed might increase coronary flow about 16 times.

Insight into the complexity of the integrating action of these three flow determinants has been obtained from recording of the peripheral coronary pressure and the phasic, or moment to moment changes, in coronary inflow and outflow in the epicardial arteries and veins (fig. 24.3). At

the onset of isometric contraction of the left ventricle, there is an abrupt decrease in left coronary inflow (solid line) or even the appearance of backflow. With the rise in aortic pressure, forward flow increases initially and rapidly, only to decrease to a new intermediate level in late systole. With the onset of isometric relaxation, coronary flow increases significantly, peaking at early diastole and then declining progressively. The velocity of coronary inflow differs somewhat from the estimated intramyocardial flow (dotted line). The deficit during isometric contraction is caused by the compressing action of the myocardium on the coronary capillaries, forcing blood into the superficial vessels. Early in the period of ejection, the flow excess is caused by the uptake of blood in the superficial coronary arteries; in diastole, the excess is caused by the uptake of blood to fill the previously compressed capillaries. These demarcations of flow are much less obvious in the right coronary inflow pattern, which roughly resembles the prevailing aortic pressure

FIG. 24.3 Series of curves relating phasic variations in left and right coronary inflow and coronary sinus anterior cardiac vein outflow to aortic pressure, ventricular pressure and peripheral coronary pressure. Coronary inflow (solid lines) and anterior coronary vein flow obtained with orifice meter, coronary sinus flow with pitot tube. Broken lines, estimated intramural velocity curves (Gregg, D. E. *Coronary Circulation*. Encyclopedia of Cardiology, Vol. 1, Ch. 23, McGraw-Hill Book Co., New York, 1959).

curve. Thus, blood is flowing through the myocardium throughout the cardiac cycle, except possibly for a brief period in early systole in the left coronary artery. In the left coronary artery, the systolic rate of flow is less than that during diastole. In the right coronary artery, the systolic rate equals or exceeds the diastolic. In contrast to the left coronary inflow pattern, the flow curves in the coronary sinus and anterior cardiac veins rise and fall smoothly with most flow occurring during systole and very little during diastole.

The preceding account indicates that the coronary bed has a fluctuating resistance to coronary flow. In the left coronary artery, the peripheral coronary maximal systolic and minimal diastolic pressure values approximate 80/20 mm Hg, respectively, and inflow is cut off at these pressure levels when the left coronary artery is perfused under constant pressure. In the right coronary artery, the contour and time relations of the peripheral coronary pressure curve are similar, but the values for systole and diastole and for the cutoff of flow are considerably lower.

Elevation of right atrial pressure must increase coronary venous pressure and decrease the flow of blood in the coronary arteries provided no compensatory mechanisms set in. Such studies have not been made. However, mild elevation of the pressure in the coronary veins, draining the left coronary artery by coronary sinus constriction, may only decrease coronary flow and increase coronary arteriovenous oxygen difference. Even marked constriction of, or clamping of the coronary sinus may cause only moderate reduction in arterial pressure and left coronary flow. The smallness of the effect on coronary flow, despite elevation at times of the coronary venous pressure to near aortic systolic level, is presumably caused by the compensatory increased functioning of collateral venous communications with the anterior cardiac veins whose flow increases considerably. Similarly, right coronary inflow is not greatly reduced by clamping most of the anterior cardiac veins, presumably for the same reason.

The relation of coronary perfusion pressure to coronary flow (P/CF) is generally such that the calculated coronary resistance decreases as the coronary flow rises. This holds for almost any dynamic state of the coronary system (excised fibrillating or beating heart, heart *in situ*) and also exists in the pulmonary artery, peripheral vascular beds, and in an artificial set of rigid tubes. In the heart, it is impossible to say what

dilation from the perfusion pressure *per se*, since the oxygen consumption per minute and per heart beat is elevated without any other observable systemic dynamic change. Accordingly, if a physiological variable alters coronary pressure and flow by about the same amount and hence the ratio is unaltered, it is impossible to know whether the change in coronary flow is due to a change in effective head of pressure alone or whether the variable directly affected resistance. However, a gross change in the vasomotor state of the bed occurs when coronary flow changes considerably with a constant pressure or when flow and pressure change considerably in opposite directions.

Separation and quantitation of the determinants of coronary flow lying within the myocardial wall, i.e., the intravascular and extravascular muscle, are of extreme importance. To do this, continuous measurements are made in the open-chest dog while the left coronary artery is perfused with blood under a constant pressure. First it is done in the beating heart and then during ventricular asystole induced by vagal stimulation or by disconnecting an external pacemaker which drives the ventricles; the latter manifesting complete atrioventricular heart block which had been surgically produced earlier. By either means the mechanical effects of ventricular contraction are largely removed. Figure 24-4 illustrates that induction of ventricular asystole by vagal stimulation always increases immediately (within 1 second) left and right coronary inflow, in this instance from 56 to 78 and from 9 to 11 cc per minute respectively. Thus, ventricular contraction acts to impede coronary flow through the ventricular wall. The extent of the rise of flow is taken to represent the magnitude of the mechanical or passive factors limiting coronary flow. The magnitude of this mechanical throttling effect on coronary flow during systole normally varies from 31 to 300 per cent and averages about 50 per cent. The new flow level represents that state of coronary dilation related to the condition of the intrinsic smooth muscle of the coronary vessels at the prevailing coronary pressure. The relative contribution of extravascular and intravascular resistance to an increase of coronary flow has been tested under the different conditions of increasing heart rate, decreased arterial blood oxygen saturation, aortic constriction, transfusion and drug injections. In all instances the major portion of a flow increase is through active dilation and not through reduction in extravascular resistance. The largest re-

duction (40 per cent) in extravascular resistance came from a decrease in arterial oxygen saturation

Determinants of Normal Cardiac Metabolism

METABOLIC PATTERNS IN THE HEART The ability of the heart to do work depends basically on its biochemical activity leading to muscular contraction. Cardiac muscle has been found to have basic chemical patterns similar to those of skeletal muscle. The catabolism of fat, carbohydrate and protein produces free energy, about half of which is dissipated as heat and half is captured as phosphate bond energy, which is used for muscle cell work and for various anabolic activities such as synthesis of glycogen, lipids, proteins and enzymes. These catabolic and anabolic reactions proceed simultaneously under the influence of a complex system of enzymes, coenzymes (from the vitamin B complex), and hormones.

Coronary sinus catheterization studies in man and dog have indicated that the heart is able to choose its fuel from a variety of foodstuffs. These include mainly glucose, lactate, pyruvate, fatty acids (nonesterified) and to a lesser extent, acetate, ketone bodies and amino acids. To determine their quantitative contribution to the energy production of the heart, i.e., its oxygen consumption, measurements have been made of their cardiac extraction (coronary artery - coronary sinus difference), their total uptake (coronary flow times (coronary artery - coronary sinus difference of substance)), and the myocardial respiratory quotient (coronary sinus - arterial carbon dioxide difference) divided by (coronary artery - coronary sinus oxygen difference). Excellent correlation has been demonstrated between the myocardial respiratory quotient and the myocardial uptake of substance. The extent to which each substrate contributes to the energy requirement of the heart *in vivo* is influenced by its concentration (above threshold) in arterial blood. In addition, the state of nutrition of the organism markedly influences the kind of substrate used for energy production of the heart. Under postprandial conditions, or after glucose infusion, myocardial metabolism is mainly glucose, lactate and pyruvate, since its respiratory quotient approximates 0.9 with a high extraction of carbohydrate and a negligible uptake of amino acids. Even the substitution of 5 to 10 per cent oxygen for the normal 21 per cent in the inspired air does little to change carbohydrate uptake by

FIG. 214 Response of left and right coronary flow to vagal induced asystole. Note the prompt increase with the induction of asystole. Time lines are 1 sec apart (Sabiston and Gregg, *Circulation*, 1957, 15, 14)

the normal heart. During overnight fasting, the heart derives much of its energy from fat, as indicated by a myocardial respiratory quotient of 0.80 with a low extraction and uptake of carbohydrate. With prolonged fasting, the extraction coefficient for carbohydrate practically disappears, those for fatty acids and ketones are maximal, and the respiratory quotient is 0.70. As regards the uptake of oxygen, the coronary $A-V_{O_2}$ differences in man vary linearly with the arterial oxygen content through a range from mild anemia to marked polycythemia, so that the myocardial extraction coefficient $(A-V)/(A)$ is constant.

In addition to patterns of myocardial metabolism in the normal heart, other metabolic

changes have been reported in some pathological and diseased states. Patients with heart failure and decreased cardiac work due to valvular disease show an increased carbohydrate uptake by the heart with a normal extraction of lactate and pyruvate and increased glucose extraction. The heart in the patient with diabetes appears to derive most of its energy from fat even in mild cases with a postabsorptive respiratory quotient of about 0.7 and an increased uptake of fatty acids and a decreased carbohydrate uptake.

Thus, the heart demonstrates broad flexibility in the utilization of substrate for energy production without a change in work performance or work capacity. This makes it largely independent of fluctuations in its chemical environment. There is no evidence that substrate lack occurs in any clinical situation to the extent that it embarrasses the cardiac work capacity. Similarly the metabolic disturbances such as diabetes mellitus which alter the fuel mixture available to the heart do not also alter cardiac function. It is, however, well to defer detailed consideration of other data because an interpretation must be based on the assumption that oxidation of foodstuffs to carbon dioxide and water is the sole factor in the determination of the myocardial respiratory quotient and of the myocardial extraction and uptake of these compounds including oxygen. Without doubt, storage of and/or conversion into other compounds is occurring concurrently and these activities are especially prominent in the presence of a changing cardiac level of activity or changing levels of blood substrate.

DETERMINANTS OF O₂ USAGE OF THE MYOCARDIUM. Our knowledge is only sufficient to introduce the subject. With present poor methodology, separation can only be made by measuring oxygen uptake, first in the beating heart during repetitive systoles and diastoles, and then in the relaxed heart or during prolonged diastole and, finally, obtaining the oxygen usage during systole by difference. Estimation of the metabolism of the myocardium in the absence of a heart beat, that is during prolonged diastole has been made in the vagal arrested heart as previously described under determinants of coronary flow. The oxygen saturation of the arterial blood and coronary sinus blood is also measured continuously. This permits left coronary arteriovenous oxygen difference as well as coronary inflow to be measured continuously first in the beating heart and then in the stopped heart until a new equilibrium is established, usually within 20 to 25 seconds.

Typical results are shown in figure 24.5. As coronary inflow rises immediately with asystole from 70 to 90 cc per minute the oxygen saturation of blood in the coronary sinus also rises from a low control value of 44 per cent to a very high value of 81 per cent, thus greatly reducing the coronary arteriovenous oxygen difference. The O₂ usage at rest is 35 per cent of that in the beating heart. Calculations in many experiments show that as the result of the combination of increased coronary flow and decreased coronary arteriovenous oxygen difference, the average oxygen usage per 100 grams of left ventricle per min., decreases from the average control level of 8.1 in the beating heart to 2.3 ml in the resting heart, or to 30 per cent of the control. Individual values ranged from 1.0 to 4.0 ml. Thus oxygen consumption in diastole is about one third that in systole for an equivalent time period.

Attention is also directed to the values for oxygen usage obtained in the same type of preparation but in which the external work of the heart is reduced to zero by other means. In the potassium stopped heart, the oxygen usage of 2 cc during diastole is about the same. In the beat *à* la heart emptied by suction and hemorrhage and in the heart with induced ventricular fibrillation the oxygen usages of 3.4 and 3.8 cc are much greater. These oxygen values have some interesting characteristics. The oxygen uptake during vagal arrest or removal of the artificial pacemaker is unaffected by the ventricular diastolic size. In any one experiment, the value is not fixed but varies greatly with the control metabolic level in the beating heart. With intracoronary artery epinephrine or norepinephrine injection the values are especially high and may equal 50 per cent of those in the control state. The implications of such experiments in relation to ventricular efficiency have already been considered in chapter 14.

Patterns of Response of the Coronary Circulation

The preceding gives some idea of the fractionation of the control of coronary flow and oxygen uptake within the myocardium during a cardiac cycle. There are certain general patterns of hemodynamic responses of the heart and coronary circulation which follow primary changes in stress. The information has been obtained from both humans and animals and has been assembled from many laboratories (Table 24.1).

METABOLITES. The coronary flow is greatly increased and the coronary arteriovenous oxygen

FIG 24.5 Reproduction of tracing from original record showing changes in left coronary inflow and coronary sinus oxygen saturation during prolonged ventricular asystole (Gregg D E Verh Dtsch ges Kreislaufforschg 1955 21, 22)

difference decreased by some chemical constituents of the blood, but this response does not occur with others in both cases there is little or no change in systemic dynamics (blood pressure, cardiac work, heart rate) or myocardial oxygen consumption. The coronary response to carbon dioxide and decreased pH is minimal, intracoronary injection of intermediate metabolites will increase coronary flow and decrease oxygen extraction but it is doubtful that the normal concentration of these chemicals within the coronary vessels effectively alters flow, since it has not been possible to demonstrate in the coronary sinus blood substances having vasoactive or chronotropic action on the coronary circulation or myocardium. However, coronary flow is markedly increased coronary resistance and arteriovenous oxygen difference are decreased by mild anemia, by short periods of ischemia by

reduction of the oxygen content of the inspired air and by coronary perfusion with reduced blood but without effect on myocardial metabolism cardiac work, heart rate or systemic dynamics.

HEART RATE When the heart rate is increased considerably by electrical stimulation of the myocardium aortic blood pressure, minute cardiac output and work increase while the stroke volume and stroke work decrease. Simultaneously minute coronary flow and oxygen usage increase coronary resistance decreases oxygen extraction is unchanged but the coronary flow and oxygen consumption per beat decrease. Since acceleration of the heart means proportionally greater time per beat and per minute in systole than in diastole and since in systole coronary flow is less than in diastole it would be anticipated that increased heart rate per se should reduce coronary flow. Since it does not, it must be that increased

flow is due to arteriolar dilation from the increased metabolic activity. The same trend of flow and oxygen usage per beat and per minute also occurs at the faster heart rate when minute cardiac work is held constant or when comparisons are made at the same stroke work. This means that cardiac acceleration can augment the energy metabolism of the myocardium without manifestations of the extra energy as work.

TRANSFUSION Augmentation of ventricular load by increasing venous return and hence circulating blood volume through infusion has a clinical counterpart in the load placed upon the human heart by transfusion or by an aortocaval fistula. The increasing coronary flow is partially explainable on a mechanical basis, since the slowing of the heart should increase coronary flow per beat and per minute by increasing diastolic time in which flow is greater. However, presumably active dilation results from the increasing local chemometabolic activity associated with the increased cardiac work. The coronary flow and oxygen are used economically, for the ratio of cardiac work to oxygen consumption increases.

AORTIC COARCTATION With simulation of clinical coarctation by acute mechanical constriction of the thoracic aorta just beyond the left subclavian artery, venous return to the heart by way of the inferior vena cava is decreased, but compensatory flow through various branches of the aortic arch may increase, with a resultant maintained cardiac output and elevated left ventricular work load. With greater aortic constriction, the net cardiac output decreases, causing the cardiac work to decrease. In either case the coronary dilation and increased flow arise in large part from active changes in the bore of the coronary bed related to the metabolic demands and in part passively from the increased blood pressure and moderately decreased heart rate. The cardiac oxygen consumption is increased much more by this augmentation of pressure work than with an equal increase of volume work following transfusion. No chronic studies of aortic coarctation have been made, because, owing to development of collateral circuits, the aorta may be first partially and then completely constricted at the arch without permanent development of hypertension proximal to the occlusion. In human coarctation

not much change is reported in coronary flow and oxygen uptake, but this might be expected because systemic pressure was only mildly elevated. However, if true, the deviation might be explained by the fact that in these hearts, which are hypertrophied, there are fewer capillaries per unit of muscle to carry the oxygen and flow.

HORMONES *A Thyroid* The myocardium participates in the increase in oxygen consumption characteristic of all body tissues in thyrotoxicosis. This hypermetabolism is accompanied by an increase in coronary blood flow, a decrease in coronary vascular resistance, and an increase in oxygen consumption per minute and per beat. Since there is an increase in oxygen usage per beat, cardiac oxygen utilization is presumably related not only to the increase in heart rate but to the general hypermetabolism of the myocardium as well.

B Epinephrine The response of the systemic and coronary circulation to intracoronary artery injection of a minimal amount of epinephrine is similar to that indicated for stellate stimulation. Probably the coronary changes can be similarly explained. With doses of 0.0002 mg or less, coronary flow may increase without any change in blood pressure or heart rate and with an increased coronary arteriovenous oxygen difference. With the same or larger doses, as the systemic effects of the substance (increased aortic blood pressure, cardiac output, and changing heart rate) become evident, the coronary effects are exaggerated. In those instances in which it has been tested, norepinephrine affects the coronary circulation similarly. The circulatory responses to cigarette smoking, i.e., increased heart rate, systemic blood pressure, cardiac work, left coronary blood flow, oxygen consumption, and decreased coronary vascular resistance, parallel those with epinephrine injection and are presumably related to its release.

C Acetylcholine This hormone, intraarterially, increases coronary blood flow in the anesthetized dog. If the dose is properly chosen, this response in the beating heart occurs without a significant change in blood pressure or heart rate. The increased flow response is completely abolished after atropine. This then increases the mean bore of the coronary vessels, since the flow is elevated in the presence of a normal or lower central coronary blood pressure. Its effect on cardiac metabolism has not been determined and whether its effect is directly on the intrinsic smooth muscle of the coronary vessels or is induced through metabolic changes of the heart is unknown.

D Pitressin Of the hormones used clinically, Pitressin alone increases coronary resistance to

flow. Coronary flow decreases, the reduction occurring throughout the cardiac cycle in the presence of an increased central coronary pressure. It is believed that this drug acts by direct effect on the coronary arterioles, but the possibility of a reduced metabolic influence has not been ruled out.

NERVOUS INFLUENCES No critical evidence has been adduced that stimulation of vagal fibers to the heart causes coronary flow changes not explainable on some other basis, such as a change in heart rate. However, stimulation of the cardiac fibers from a stellate ganglion increases mean left coronary flow as the resultant of a decrease in systolic flow and a large increase in diastolic flow. Concurrently, left ventricular metabolism, cardiac output, and cardiac work increase while the systolic and diastolic size of the heart decrease. The decreased ratio of pressure to flow indicates an increased mean coronary bore. The major part of the dilation is explained by active changes in the coronary bed resulting from the release of an epinephrine-like substance which directly enhances myocardial metabolism. This process is very wasteful because the oxygen uptake is greatly increased even when cardiac work is not permitted to rise. The fact that the central coronary pressure and heart rate do not necessarily change rules them out as a necessary part of the flow-controlling mechanisms. About 30 per cent of the flow increase is due to the marked shortening of systole and lengthening of diastole. When the heart rate and blood pressure are elevated, the systemic and coronary effects are greatly accentuated.

Reports have appeared suggesting that coronary flow can be influenced reflexively and adversely by impulses arising in various body regions, especially the heart, lungs, and abdominal viscera, but the importance of these reports is doubtful because of the methodology used.

ANEMIA The coronary system participates actively in the circulatory adjustments to anemia. For hemoglobin values of 10 grams or more, the systemic circulation is essentially unaltered, and the compensation of the coronary system to the decreased oxygen carrying capacity is similar to that with hypoxia, i.e., an increased coronary flow without change in oxygen uptake. When the hemoglobin values reach 6 to 8 grams, the response of the systemic circulation is manifested by tachycardia, increased cardiac output, cardiac work, and a fall in peripheral resistance. The coronary flow may now triple, coronary venous blood may contain less than 2 volumes per cent oxygen, the coronary arteriovenous oxygen dif-

ference may be 4 ml or less, and oxygen uptake is considerably increased. The increase in coronary flow is related in part to the decreased blood viscosity and in larger part to the active dilation associated with myocardial hypoxia, which in turn arises from the low hematocrit and from the increased metabolism. Ultimately, myocardial failure will occur in severe anemia when the coronary vessels have approached maximal dilation and cannot further compensate for the decreased oxygen carrying capacity of the blood either by increased flow or by increased oxygen extraction. In the presence of coronary stenosis associated with anemia, the effect of coronary arteriolar dilation in increasing coronary flow is minimized by the high fixed resistance of the stenotic artery, and myocardial depression and failure occur at lesser degrees of anemia.

VALVULAR LESIONS. Acute elevation of right ventricular pressure by pulmonary artery constriction initially decreases right coronary flow, to be followed quickly by a maintained increase in systolic, diastolic, and mean flow in the right coronary artery and, to some extent, in the left coronary artery. Upon release, right coronary flow temporarily increases still further. During the sustained response, the systemic blood pressure can be fairly well maintained. At the same time the right ventricular work declines and its metabolism increases, the former arising from the increased pulmonary artery pressure and cardiac output, the latter from a combination of increased right coronary flow and a greater oxygen extraction from the coronary blood. The coronary response to elevation of left ventricular pressure by aortic constriction central to the coronary ostia is similar to that with pulmonary artery stenosis. In both instances, the sustained flow increase indicates a dominant influence of active coronary dilation over the increased mechanical flow inhibiting effect of increasing extravascular compression which earlier was dominant. These maintained changes in the coronary circulation could well be the early response in the human being to gradual moderate stenosis of the corresponding valves.

HEART FAILURE. The heart shares with other types of muscle the characteristic that an optimum exists beyond which further stretching reduces the force of contraction and leads to myocardial failure. In acute heart failure with progressive deterioration of the myocardium from pulmonary artery stenosis, the changes in coronary flow and oxygen usage per minute and per beat may be in the same direction as those

described for the right myocardium but of lesser magnitude. If the heart failure is severe enough, extravascular compression can become dominant over any active coronary dilation from metabolic processes, and coronary flow and oxygen usage may be normal or decrease, with the oxygen extraction at times reaching 90 per cent. The coronary circulation in the heart failing with severe aortic stenosis undergoes similar changes. When acute heart failure and chronic congestive failure simulating the human condition are induced by surgical complete heart block, changes in left coronary flow and ventricular oxygen consumption also rather closely parallel alterations in the reduced left ventricular work. In chronic left heart failure due to rheumatic, arteriosclerotic, and hypertensive heart disease, the coronary circulation apparently responds by a slight increase in oxygen usage through maintenance of the left coronary flow and an increased coronary arteriovenous oxygen difference. This corresponds with the changes indicated above for the right heart in one stage of failure. Such hearts have considerable difficulty in transforming released energy into realizable work. Studies of the coronary circulation in high-output failure from excessive transfusion or a chronic aortocaval fistula are not available.

HYPOTHERMIA. The circulatory and metabolic adjustments of the heart during hypothermia have been partially explored. The associated changes that occur which tend to reduce the coronary flow are a diminution in blood and muscle temperatures, cardiac output, heart rate, cardiac work, oxygen usage by the heart, an increased blood viscosity, and a greatly lengthened period of ventricular systole. Opposing these factors are the relaxation of the major coronary vessels, which is known to occur with hypothermia, and dilation of the coronary bed caused by the hypotension *per se*. As a resultant of these determinants, coronary flow is decreased at low temperature. However, the percentage of reduction in cardiac output is greater than in coronary flow, which results in an increase in the coronary fraction of cardiac output at temperatures of 25 to 26°C. There is little change in peripheral resistance in the coronary bed, whereas in the systemic bed an increase in peripheral resistance occurs. Myocardial function appears to be adequate. However, many hearts are apparently not too far from failure, because if total venous inflow occlusion (which decreases coronary flow close to zero) is now added to permit open cardiectomy, myocardial failure supervenes, as evidenced by

elevation in mean right atrial pressure and post mortem findings. This trend can be reversed by perfusion of the coronary system with small volumes of oxygenated blood.

SHOCK. Standardized oligemic shock in dogs is characterized during the hypotensive phase by a decrease in cardiac output, systemic blood pressure, cardiac work, stroke volume, stroke work, and by an increase in heart rate and an adequate central venous pressure. Coronary flow and coronary resistance are greatly decreased. Coronary flow is generally greater and the resistance generally less than can be accounted for by a simple decline in arterial blood pressure. At the same time, the oxygen uptake decreases, and the coronary arteriovenous oxygen difference is generally unchanged. The coronary response to sustained hypotension through spinal anesthesia or injection of procaine and Etamon is similar. With restoration to normal systemic blood pressure by reinfusion (intraarterial and intravenous routes are equally effective), coronary flow is greater and flow resistance is less than at an equivalent arterial blood pressure in the preshock state, and the augmented flow is maintained after circulatory failure subsequently intervenes.

The fact that early in the hypotensive phase ventricular end diastolic pressure does not rise indicates that the functional capacity of the heart is adequate for the work performed. However, that myocardial depression or failure is partially responsible for the hemorrhagic shock syndrome is suggested by the fact that at times after prolonged hypotension there may be evident cardiac dilation and elevated left and right atrial pressures with the heart eventually proceeding to ventricular fibrillation or standstill. Gross and microscopic evidence of myocardial injury appears in both reversible and irreversible shock. Such myocardial depression could be caused by an insufficient coronary flow during either the hypotensive or the posthemorrhagic periods. The high coronary flow during the restoration period would seem to preclude an inadequate coronary flow as an adequate explanation. During the hypotensive period, the actual coronary flow is greatly curtailed. The problem is whether the associated sizable reduction in coronary resistance is sufficient to permit enough blood to reach the myocardium to prevent it from failing. In some instances, at least, this loss of myocardial contractility is consequent upon an insufficient coronary flow, since the relation of atrial pressure to cardiac size can be reversed by increasing mildly

with a pump left coronary flow without change to either the hypotension or blood volume.

HYPERTENSIVE CARDIOVASCULAR DISEASE. An exception to the general picture of coronary compensation to increased systemic stress appears to be the response of the chronically hypertensive heart. In essential hypertension with a normal cardiac output and elevated systemic blood pressure, the coronary flow and oxygen consumption are unaltered while coronary resistance increases. This increased resistance is shared with the renal and cerebral circulations. Since these hearts are generally hypertrophied, total coronary flow and oxygen usage are increased. This deviation is explainable if it is assumed that such hearts with known coronary artery disease have an increased amount of perfused fibrotic tissue.

Correct values for left coronary flow and myocardial oxygen consumption during natural maximal stress, such as exercise, are not available because of technical difficulties of instrumentation and application. However, the data suggest that with a normal hematocrit and normal arterial oxygen content, maximal work is determined by factors within the muscle and not by limitation of coronary flow and oxygen supply.

Is there one over-all unifying mechanism controlling coronary flow? Is there a similar mechanism controlling the oxygen usage of the myocardium? The answer has been sought for many years. From the preceding discussion, it is apparent that when the primary change in stress is an increased heart rate, increased venous return (whole blood transfusion), increased cardiac work, aortic coarctation (moderate), thyrotoxicosis, cardiac action of fibers from the sympathetic nerves, intravenous injection of epinephrine or norepinephrine, severe anemia or anoxia, there is an increase in cardiac work and cardiac oxygen usage. Concurrently, coronary flow increases while coronary vascular resistance decreases. In situations of primary decrease in stress such as hemorrhagic hypotension, hypothermia, and extreme heart failure, the cardiac work and oxygen consumption decrease as does the coronary inflow. An exception to this general picture of coronary compensation to changing stress is that of complete aortic coarctation which may be characterized by a reduction in the output and work of the heart but an increased left coronary flow and oxygen usage. A second exception is that of chronic hypertension in which the cardiac work is increased, but cardiac output, oxygen usage and left coronary flow are unaltered while coronary resistance to flow increases. Thus in most

instances, coronary flow follows a primary change in cardiac stress. However, correlation of coronary flow is best with O_2 usage. This relationship is understandable since the oxygen consumption is derived from the product of the coronary flow and the coronary arteriovenous oxygen difference. Normally, most oxygen is removed from the coronary blood and the level of coronary sinus oxygen is usually fairly constant under stress, i.e., it does not change more than 10 to 15 per cent. In those instances in which the coronary arteriovenous oxygen difference increases or decreases by this amount, it does not greatly affect the relation of coronary flow to oxygen usage since the change is very small relative to the magnitude of the coronary flow change.

No final answer has been obtained as to the control of coronary flow. It has been variously related to the oxygen tension of the arterial blood, oxygen tension within the myocardium, and the action of local metabolites or vasodilating substances. Ultimately, at the cellular level, presumably, it is related to the rate of reduction of cytochrome oxidase and the needs of the hydrogen transport system.

It would be expected that the oxygen consumption during systole when ventricular muscle is shortening and developing tension, would depend in some way on the dynamic adaptation of the ventricle to its work. The presence of some such correlation was first illustrated by the experiments of Evans and Matsuoka, and of Starling and Viescher, indicating in the isolated heart a linear relation between diastolic volume and oxygen usage. More recently, it has been found that oxygen usage correlates best with the total tension developed by the left ventricle.

Most of the information thus far considered is based upon observations in the open-chest dog. It is not known to what extent it applies to normal situations since it has been obtained under conditions far removed from normal as the result of insults from anesthesia, surgery and trauma. It is true that semiquantitative values for coronary flow and oxygen usage are available in the resting human and dog. No information exists, however, in normal humans and animals as to the regulation of the coronary circulation exposed to the stresses of every day life such as exercise and excitement.

A start is being made in alleviating this situation. Successful direct measurements of coronary flow have been made in normal unanesthetized dogs by applying chronically an appropriate electromagnetic flow meter (a somewhat modified

Kolin type) directly to the circumflex branch of the left coronary artery. Although this gives correct flow values, very often it causes thrombosis within a few days because of the violent heart action. To remove the probe to a quiet area it is applied to the left internal mammary artery just above the site of its chronic anastomosis to the peripheral end of the left circumflex coronary artery (see section on coronary artery collaterals in this chapter). Illustrated in figure 24-6 are the changes in phasic and mean coronary flow in such a dog 15 months after construction of the anastomosis and 7 weeks after implantation of the electromagnetic flow meter probe. First, he stood on a treadmill then ran for 3 minutes at 12 miles per hour at a 5 per cent grade, and finally, he stood at rest. Although not measured the blood pressure and cardiac output obviously rose in this dog as they have in other dogs. A pulse pressure pattern has been sketched in for orientation purposes. The control flow is 46 cc per minute, with most of this occurring during diastole. Within 15 to 20 seconds after the onset of exercise, the changes in the coronary flow response are complete and do not change further during the 3 minute period of exercise. The changes include an increase in heart rate from 80 to 220 per minute, a reduction in duration of both systole and diastole per beat, an increase in mean flow from 46 to 111 cc per minute, as the result of a large reduction in systolic flow and an increase in diastolic flow per beat, and accentuation of back flow during systole. Calculation shows that the flow per heart beat is mildly decreased and hence, the mean flow increase is entirely on the basis of the increase in heart rate. Within 5 seconds after sudden stoppage of the treadmill the patterns and flow have started to revert toward normal, the return to normal is completed within about 7 minutes. The last record was taken so that a comparison could be made between the maximum diastolic rate of flow during exercise and that during reactive hyperemia. It was taken shortly after the 7 minute recovery period and immediately following a 5 second occlusion by a pneumatic cuff of the coronary artery in which flow was being measured. Despite the slower heart rate, maximum diastolic flow during reactive hyperemia is about the same as that during exercise. This coronary flow response to exercise shown is not that which one observes when the workload of the heart is increased by transfusion or elevation of aortic pressure by aortic constriction. It does, however, resemble a combination of the effects resulting from a mechanical increase in

FIG. 216 Response of the unanesthetized, intact dog to exercise. Curves are redrawn from the original experiment. Phasic flow curves obtained with an electromagnetic flow meter monitoring an internal mammary circumflex coronary anastomotic shunt. Upper curve, aortic pressure. Lower curve, phasic circumflex coronary flow. (Gregg, D. E. unpublished data.)

heart rate by means of an artificial pacemaker and from the augmentation of cardiac contractility resulting from stimulation of the cardiac fibers from the left stellate ganglion or following the intracoronary injection of epinephrine or levarterenol. The ultimate interpretation remains to be determined.

The Coronary Artery Collateral Circulation

The state of the human heart in the presence of naturally occurring coronary insufficiency or occlusion, or the state of the dog's heart in which coronary insufficiency has been experimentally induced, can be improved by augmentation of the coronary artery collateral circulation which naturally functions, by retrograde perfusion of the ischemic coronary bed with arterial blood, or by elevation of the ventricular fibrillation threshold, thus giving time for collaterals to develop. In addition, in man, positive and subjective benefit could arise through psychogenic effects which are not necessarily related to the heart.

Information on the coronary collateral circulation is no better than the method used to obtain it and experimental tools for study of the collateral circulation are admittedly crude. These are concerned with measurements of the effects of various prophylactic and postcoronary occlusion procedures on the electrocardiogram, mortality,

size of infarcts, exercise tolerance, and finally, on the injectable and functional collaterals in the presence of coronary occlusion or insufficiency. All are difficult to evaluate because of the considerable variability of the size of the naturally occurring collateral circulation.

The measurement which is most important, least subject to error, and which has yielded most information, is that of the collateral flow. This is determined by collecting the volume of blood that flows externally from a tube inserted into the peripheral end of an occluded coronary artery. This is done acutely in the open-chest dog before, and sometime after, a variable has been chronically induced to improve collateral flow. This is collateral flow before it passes through a capillary bed. Collateral flow can also be measured after it has passed through a capillary bed and has appeared in the coronary sinus. This can be done when extracardiac tissue with a vascular stalk has been previously placed on the heart to stimulate collateral development. The coronary sinus flow is measured before and after clamping the potential extracardiac source of collateral blood. The difference in flow represents that which has traversed the capillary bed.

NATURAL RESPONSE OF THE CORONARY COLLATERAL CIRCULATION. The natural responses of the coronary system during experimental coro-

nary artery constriction and occlusion, and which presumably are also happening in the heart of man, have been studied extensively. Within 1 minute after occlusion of a left coronary artery branch, the intracoronary pressure beyond this point drops to about $35\frac{2}{3}$ mm Hg and useful function is lost, for the muscle now lengthens during systole of the left ventricle. When, however, the peripheral end of this ligated coronary artery is permitted to bleed externally, collateral arterial blood appears immediately, averaging about 30 ml per minute for about 50 grams of potentially infarcted myocardium. Probably not more than 24 ml of this blood (containing 0.5 ml of oxygen) would perfuse the myocardial bed if the collateral flow were not permitted to bleed externally. This is because of the peripheral resistance existing beyond the point of occlusion and averaging 23 mm Hg. This level of collateral flow and oxygen content is estimated to be up to 40 per cent of that calculated as necessary to maintain indefinitely the viability of this myocardium, since the oxygen uptake of 50 grams of a heart with perfused coronary arteries at rest and doing no external work approximates 12 ml as compared to the immediately available collateral oxygen supply of 0.5 ml.

Hence, it is important to try to increase immediately this collateral flow or backflow. The level of backflow does not naturally increase and

cannot be made to increase for 8 to 10 hours by drugs or by any known physiological means such as an increased heart rate, increased flow in the other coronary arteries, induction of hypoxia or hypovolemia in the other coronary arteries. It can, however, be increased by passive elevation of arterial blood pressure (fig. 247). Why the collateral flow remains fixed, why the anastomoses function as a set of inert tubes and why they do not participate in the vasodilatory response of the normal coronary bed is not known. It contrasts with the rapid development of collaterals in other vascular beds such as the femoral and carotid arteries.

This retrograde flow can be greatly reduced by at least two conditions, namely, by excessive stretch of the myocardium and by the presence of reactive hyperemia in the other coronary arterial branches. One suspects that the reason for the decreased collateral flow in an occluded coronary artery branch while reactive hyperemia exists in the other coronaries is also the excessive stretch of the normal myocardium. Thus, the improvement that occurs in the human heart with drugs such as Neo-Synephrine in the presence of coronary insufficiency and infarction arises because of a good dynamic response in the normal but over-stretched myocardium. This would increase the collateral flow by increasing the coronary perfusion pressure and by making a smaller heart.

Most hearts with an occluded coronary artery branch die within a number of hours. Others are more fortunate; collateral wise for if they survive the first few hours then, for some completely unknown reason, within 12 hours collateral flow starts to rise, doubling within 2 days and within 3 to 4 weeks it may approximate 40 to 100 per cent of normal inflow into that coronary artery. At the same time the peripheral coronary pressure pulse beyond the point of ligation of the coronary artery branch may approximate in pattern and ordinate values the aortic pressure pattern simultaneously recorded.

These are the ordinary hearts. In other hearts, stresses, some known but mostly unknown, prophylactically enhance the potential collateral circulation without the stimulus of coronary insufficiency or occlusion (Table 242). These are exemplified in man by the increase in the incidence of the injectable collateral bed in the presence of hypertrophy, valvular disease, cor pulmonale, and anemia, and probably high altitude. This is exemplified in animals by an increase in both the injectable and functional collaterals in

FIG. 247. Relation of retrograde coronary flow to mean arterial perfusion pressure in dogs (Katus and Gregg, *Circulation Res.*, 1959, 7, 628).

TABLE 24 2

the presence of high altitude and transfused anemia. No good experimental evidence exists to indicate that physical exercise per se augments prophylactically the collateral flow as measured in a normal coronary artery immediately after its occlusion. Even with a combination of moderate coronary artery constriction and exercise, the retrograde flow does not increase.

DRUGS VERSUS CORONARY COLLATERAL FUNCTION. Since the vascular bed beyond an occluded coronary artery is presumably maximally dilated by anoxia, it is unlikely that a drug could improve a heart by immediately increasing flow to this area. Actually, the best experimental evidence offers no support for the belief that any drug penetrates the connecting collaterals or exerts any beneficial influence in the ischemic bed. It has not been possible to increase the flow of blood into this ischemic area within a short time after coronary artery occlusion or to retain myocardial shortening by the use of drugs that are known to dilate the normal coronary bed, such as papaverine, nitroglycerine, epinephrine, aminophylline, coramin, and khexin. In chronic experiments, cortisone and ACTH do not promote collateral flow or reduce the size of infarcts. The hypothesis that coronary occlusion reflexively decreases flow

in the nonoccluded coronary artery to a fatal level, it is not borne out by the experimental fact that flow in the nonoccluded coronary artery generally rises with coronary artery ligation. The alleged favorable effect on survival of prophylactic and therapeutic drugs, such as papaverine and quindine, is better explained by their known action in raising the fibrillation threshold and in reducing the excitability of the myocardium.

NATURAL RESPONSE OF THE NORMAL BUT OVERSTRESSED PORTION OF THE MYOCARDIUM. Since the collateral flow does not increase for some hours, any early natural compensation must occur, not by improvement of the circulation in the affected area, but through enhanced action of the normal myocardium which is not involved. Deletion of contracting muscle blocks following coronary artery occlusion not only reduces the total myocardial force available for raising intraventricular tension, but some of this pressure is spent in stretching the ischemic area and thus is lost for expelling blood into the aorta. The immediate consequences of this which lead to a hypodynamic ventricle are a reduction in left ventricular systolic pressure, aortic pulse pressure, systolic and diastolic pressures, duration of systole, and in stroke volume and stroke work. In this situation

left coronary inflow decreases considerably because of the mechanical reduction in size of the peripheral vascular bed. However, within a few minutes, the normal portion of the heart puts into operation compensatory mechanisms by means of which dynamic conditions are largely restored to normal, provided the normal myocardium is in a good responsive condition. Briefly, as the result of the lesser expulsion of blood with hypodynamic beats, the accumulating systolic remainder added to the oncoming blood stretches the viable muscle more and raises the ventricular end diastolic pressure or left atrial pressure. This combination of increased pressure in and increased radius of the ventricular cavity, causes the normal muscle to contract more vigorously, thereby restoring normal hemodynamics. In this situation of increased cardiac work per unit of functioning myocardium, coronary flow, arteriovenous oxygen difference, and metabolism of the left ventricle increase. The increase in oxygen uptake is equal to, and at times can be much more than that lost by the deletion of noncontractile muscle.

However, not all hearts react as well because the viable portion of the myocardium may not respond to stretch, or the same lack of response may occur later after an initial salutary response. This has been especially studied when the coronary obstruction has been induced by intra-coronary injection of microspheres. This leads to acute or progressive heart failure associated with a profound hypotension with a decreased cardiac output, and the clinical signs and symptoms of a shocklike state similar to that which occurs following the loss of blood or plasma. The clinical inference that this is due to the supervention of peripheral circulatory failure has not received heavy experimental support. On the contrary, experimental work favors the view that in this situation, circulatory failure not due to severe irregularity of the heart beat is due, successively, to defection of useful contractions in the ischemic area, a loss of contractile energy through expansion of the affected area, and failure of the still viable fractions to compensate adequately.

EFFECTS OF DRUGS AND AN EXTRACORPOREAL CIRCULATION IN THE PRESENCE OF MYOCARDIAL INFARCTION WITH SHOCK. Since protracted hypotension can, at times, lead to myocardial damage and failure, and since experimentally, the coronary collateral flow varies passively with the systemic blood pressure, attempts have been made to improve such hearts experimentally and clinically by drugs and a veno arterial perfusion.

The state of the heavily stressed normal myocardium could be improved with drugs either by increasing its oxygen supply or by using the available oxygen more economically. The major mechanism for increasing the oxygen supply is by increased coronary flow since, normally, the oxygen is largely extracted from blood passing through the myocardium. The drugs would have to promote coronary flow in the heavily loaded normal myocardium in which oxygen usage, coronary flow and coronary $A\text{VO}_2$ difference are already at a high level. Whether any drug has the desired type of dilation (active myocardial vessel relaxation, decreased extravascular compression, minimal increase in metabolism and cardiac work, minimal effect on other vascular beds), and whether it also increases ventricular efficiency, remains to be determined. In the normal dog, drugs such as papaverine, nitroglycerine, epinephrine, aminophylline, coramine, the adenosine nucleotides, and khellin augment the myocardial oxygen supply, but generally at a considerable expense to the heart, through decreased coronary sinus oxygen (with nitroglycerine coronary sinus oxygen is increased), and increased cardiac work and metabolism. In normal man, sublingual nitroglycerine leads to an increased myocardial oxygen usage (increased coronary flow and constant coronary $A\text{VO}_2$ difference), with little or no change in cardiac output and cardiac work, and with a decreased efficiency. In patients at rest with coronary artery disease, coronary flow is normal. Following nitroglycerine, coronary flow and oxygen usage are unchanged, but systemic blood pressure, cardiac work and cardiac output are reduced, hence, coronary resistance is not changed, while efficiency is decreased. It would thus seem that the dilator capacity of the coronary tree with coronary artery disease is exhausted. The mechanism whereby nitroglycerin relieves pain is not that of general coronary dilation and is unknown.

The incidence of cardiogenic shock complicating acute myocardial infarction has been reported as 12 per cent. Mortality associated with this complication may be in excess of 80 per cent. Vasopressor drugs have been widely employed in this situation. The improvement that occurs in the human heart with drugs such as neosynephrine, in the presence of coronary insufficiency and infarction, arises because of a good dynamic response in the normal but overstretched myocardium. This presumably augments the coronary collateral flow by increasing the coronary perfusion pressure and by making the heart smaller.

Although the use of vasopressor agents reduces mortality in myocardial infarction with shock, at least half fail to respond. In such patients, extracorporeal circulatory support is being tried whereby blood is pumped from a convenient vein to an artery. The major objective is to produce a sustained increase in aortic pressure and, hence, an increase in coronary, cerebral, and other important regional circulations, and yet without an increase in left ventricular work that might cause further cardiac deterioration. Conclusive evidence of the benefit of this procedure has not yet been obtained.

ATTEMPTS TO IMPROVE CORONARY COLLATERAL CIRCULATION. The state of such hearts can be improved considerably by various physiological and surgical procedures. The principles of the procedures used together with the surgical manipulations are portrayed (Table 24-3). These include section of the cardiac sympathetic nerves, induction of myocardial hypoxia by various manipulations of the coronary venous system, production of chronic epicardial granuloma by mechanical and chemical means, application of extracardiac tissue to the heart, internal mammary artery ligation, sham operations, coronary endarterectomy and coronary artery bypass.

A. Animals. Many of these procedures in the experimental animal are of positive benefit to the heart and give immediate or sustained protection against subsequent ligation of a major coronary artery ramus. This is illustrated in the data obtained in many laboratories (Table 24-4). Ligation of a major ramus of the left coronary artery causes about a 70 per cent mortality within the first 1 to 2 hours, and chronically there is considerable infarction. When partial or complete occlusion of the coronary sinus precedes coronary artery ligation, or when a portion of the coronary bed is perfused in retrograde fashion by connecting the coronary sinus to an artery, the immediate mortality is reduced considerably. With the exception of section of cardiac sympathetic fibers and internal mammary artery ligation, all other procedures listed—chronic coronary venous maneuvers, application of various chemical and mechanical irritants, separately or in combination, and application of extracardiac tissue to the heart lead to a significant reduction in mortality and infarction. There is an increase in the injectable and functional collaterals with the chronic coronary venous maneuvers and with the application of mechanical and chemical irritants to the heart. The level of collateral flow, 5 to 12 cc in

most instances, considerably exceeds the control flow of 3 cc with acute artery ligation alone, and approximates that necessary to maintain viability in the potentially infarcted area. There is as yet no evidence that the protection of the heart afforded by "arterialization" of the coronary sinus arises from passage of blood retrogradely from vein to capillary. Such a procedure reduces left coronary inflow, hence, it is more likely that the benefit arises from the increased collateral flow which is associated with the induced myocardial hypoxia. In general, the over all protection to the heart by the various procedures is probably on a collateral flow basis, but since sham operations involving manipulation of the heart also increase collateral flow, the possibility must be entertained that there may be no specific effect of some of the maneuvers, they may act by raising the ventricular fibrillation threshold, thus giving time for collaterals to develop.

In some procedures that apply extracardiac tissue to the heart, such as a pedicle skin flap, internal mammary artery ligation or its myocardial implantation, the collateral flow does not increase. These studies, however, are incomplete.

Further work should be done to determine, in addition to the usual arterial collateral flow measurements, whether blood brought in by the extracardiac tissue actually flows through the capillary bed of the myocardium in the presence of chronic as well as acute coronary occlusion. If it does, then it should be possible to demonstrate its presence in the coronary sinus flow. Preliminary experiments indicate, however, that clamping of the extracardiac source of a myocardially imbedded artery, pedicle skin flap, etc., does not usually affect coronary sinus flow.

B Man. All of the procedures listed in Table 24 3, designed to promote collateral development, including the sham operation, have been applied to the heart of man suffering from coronary artery disease. All appear to increase to some extent the work and exercise tolerance and to decrease the cardiac pain. These observations are not necessarily explained on the same basis of the improvement in the collateral circulation of the dog which follows such procedures. This is because in the dog, surgery precedes coronary artery ligation, whereas in the human, surgery follows coronary artery occlusion. Surgery in the dog is designed

to promote collaterals in the presence of a normal coronary circulation. Surgery in the human is designed to promote collateral circulation after the coronary insufficiency has been naturally established. In man, hypoxia, the greatest known vessel dilator, and a natural stimulus to collateral development, has already been working for many months. To be effective, the surgical procedure must supply a stimulus to collateral development far more potent than hypoxia. This has never been demonstrated in animals in which coronary insufficiency has previously been induced.

The explanation of the results in man are not clear. Undoubtedly, some subjects are protected and live longer because of the known experimental fact that handling the heart enhances the ventricular fibrillation threshold. Some may be improved by procedures such as de-epicardialization which could obliterate the afferent pathways for pain. However, results of the sham operation of Lillehei, Adams and of others, involving only a skin incision, strongly suggest that much of the positive benefit is on a psychogenic basis.

Coronary endarterectomy, which has been applied to man, is on a sound physiological basis, and its purpose is entirely different from the preceding. The surgeon directly re-establishes coronary flow through the original coronary artery by removing its atherosclerotic plug. It does not require collateral development and should be effective provided there exists a gross coronary insufficiency of blood beyond the obstruction, provided the vessel remains patent and thrombi do not form, and provided there are no sizeable atherosclerotic lesions beyond the region of the occluded coronary artery. Although initial operations were apparently favorable to the patients, relieving their angina, improving their electrocardiograms and work tolerance, a later report is not so sanguine. Many more operations will have to be done to establish the possible merit of this procedure in humans.

Finally, bypass of a length of an occluded coronary artery by anastomosis of its peripheral patent end to a systemic artery has not yet been attempted in man. In dogs, a nonsuture anastomosis by intima to intima contact between the left coronary artery and the left internal mammary artery has been highly successful. In almost all of the dogs, the anastomoses have been demonstrated to be patent and without myocardial infarction, as evidenced by gross observation, angiography, and measurement of coronary blood flow through the anastomosis up to the time of dog sacrifice (12 to 24 months after operation).

Since such an operation is almost always successful and without sequelae in the dog in which the anastomosed vessels are only 2 to 2.5 mm diameter, there should be no difficulty at all in the human heart in which the coronary artery branches have a much greater diameter. This procedure could, therefore, have a very practical application in the creation of a permanent new blood supply in the presence of coronary artery disease in man.

There is, however, a probable late complication to successful coronary endarterectomy or coronary bypass in man which must not be overlooked. In the presence of such a large new blood supply, the existing collateral flow might disappear. If another coronary occlusion subsequently occurs, the patient would be in difficulties because he had lost his collaterals.

Summary

From the preceding, it would appear that in the normal heart a moderate collateral circulation exists which functions immediately following a coronary artery occlusion. Different prophylactic procedures are successful experimentally in preserving life either by compensating for a deficit in the supply of collateral oxygen or by preventing ventricular fibrillation. Thus protection against occlusion of a coronary artery may be associated with a collateral development on the arterial side of the order of magnitude of that essential for viability. Human coronary surgery, which follows coronary insufficiency, has no counterpart in animal experiments and these human coronary experiments cannot as yet be interpreted on a physiological basis.

SPECIAL FEATURES OF THE CIRCULATION IN DIFFERENT REGIONS. BRAIN, SKELETAL MUSCLE, SKIN.

The Cerebral Circulation

The cerebral circulation has been investigated extensively in various experimental animals in the past. The traumatic procedures necessary for obtaining blood flow measurements, however, prohibited the study of the circulation in the human brain. This became possible only since the introduction, recently, of a method permitting indirect measurement of cerebral blood flow in unanesthetized human subjects.

The nitrous oxide method (Kety and Schmidt, 1948) is based on the Fick principle (see ch. 18). The subject breathes a gas mixture containing 15 per cent N_2O , while blood samples are obtained from a peripheral artery and from the internal jugular vein (representing mixed cerebral venous blood). Cerebral blood flow per unit weight of brain may be calculated from the arterial and venous gas concentrations and the partition coefficient for nitrous oxide between brain and blood. Results are usually expressed as milliliters of blood per 100 grams of brain per minute; in resting, normal young men the mean value is 54 ml. Assuming a weight of 1400 grams for the brain, total cerebral blood flow is about 750 ml per minute.

In experimental animals, where it is possible to check the results obtained by this method against direct cerebral blood flow measurements, there is good agreement between the two. Consideration of the cerebral circulation here will be limited to information derived from studies in man.

Cerebral blood flow is determined by two opposing sets of forces: the effective perfusion pressure and cerebral vascular resistance (see fig. 25.1). Effective perfusion pressure is the gradient between arterial blood pressure and internal jugular venous pressure; cerebral vascular resistance is defined here as the sum of all factors opposing the flow of blood through the brain, such as intracranial pressure, blood viscosity and vascular diameter.

Internal jugular venous pressure for all practical purposes is negligible as compared to arterial pressure. Even the obstruction of the vein by means of a tourniquet placed on the neck, producing pressures up to 300 mm of water, has no effect on cerebral blood flow (Moyer and associates, 1954a). Thus, arterial blood pressure is the sole important determinant of the driving force of blood flow across the brain.

The relation of arterial blood pressure to cerebral blood flow is determined by the level of the blood pressure itself. A lowering of the mean arterial pressure to a level of about 60 to 70 mm Hg by means of high spinal anesthesia, paralyzing most of the sympathetic vasoconstrictor nerves, has no effect on cerebral blood flow, which remains constant (Kleinerman and associates, 1953). This indicates a compensatory lowering of vascular resistance in the brain (see below). Similarly, an elevation of blood pressure is without effect on blood flow due to a secondary increase in resistance (Moyer and associates, 1954b). Thus autoregulation of the cerebral circulation becomes ineffective, however, when mean blood pressure falls below 60 mm Hg. In this hypotensive range, a lowering of blood pressure results in a reduction of blood flow. Initially, this is compensated for by increased oxygen extraction by the tissues, but at mean pressure levels of about 30 mm Hg, when cerebral blood flow is reduced to about 30 ml per 100 grams of tissue per minute, signs of cerebral ischemia appear (Finnerty and associates, 1954). Conversely, raising the blood pressure under these conditions increases blood flow, unlike in the normotensive range.

As seen in figure 25.1, several extravascular factors contribute to "cerebral vascular resistance." Intracranial pressure, exerted upon the freely collapsible capillaries of the brain, is a force opposing the flow of blood. Any increase in this pressure, resulting from an expansion of the contents of the rigid cranial box (such as a brain

FIG 251 Factors determining the cerebral blood flow CBF, cerebral blood flow, MABP, mean arterial blood pressure, IJP, internal jugular venous pressure, CVR, cerebral vascular resistance (From Kety S S, in *Circulation*, Proceedings of Harvey Tercentenary Congress, p 329, 1958)

tumor) elevates cerebral vascular resistance in a direct, linear manner (Kety and associates, 1948). In spite of this, cerebral blood flow does not diminish until intracranial pressure reaches very high levels (about 450 mm of water). The maintenance of normal flow is due to an increase of systemic blood pressure brought about by peripheral vasoconstriction. It has been suggested that the stimulus for the latter is ischemia of the medullary vasomotor center.

Viscosity of the blood increases resistance to flow. In polycythemia cerebral blood flow is considerably reduced, it is restored to normal levels after correcting the increased viscosity by phlebotomies (Nelson and Fazekas, 1956). In anemia, on the other hand, cerebral blood flow is increased in proportion to the decreased red cell mass, transfusion produces a return to normal flow (Robin and Gardner, 1953).

The most important component of cerebral vascular resistance is the diameter of the cerebral blood vessels. Their adjustment is responsible for the remarkable constancy of blood flow over a wide range of perfusion pressures, discussed above. The exact mechanism of vasomotor regulation in the brain is not known. Although the cerebral vessels are supplied by sympathetic fibers, there is no evidence to show that they are physiologically active in man. Bilateral blocking of the stellate ganglia fails to produce any change in cerebral vascular resistance or blood flow, contrary to what might be expected if these nerves were normally contributing to the maintenance of cerebral vascular tone.

In contrast to this is the marked sensitivity exhibited by the cerebral vasculature to changes in arterial concentration of carbon dioxide and oxygen. Carbon dioxide is the most powerful cerebral vasodilator known. Inhalation of a gas mixture containing 5 or 7 per cent CO_2 , which

raises arterial pCO_2 by 9 mm Hg, causes a 75 per cent increase in cerebral blood flow. Systemic blood pressure rises without any change in cardiac output, indicating a peripheral vasoconstrictor effect, but cerebral vascular resistance falls, showing the specific vasodilator action of carbon dioxide on the cerebral vessels (Kety and Schmidt, 1948). Hyperventilation, which lowers arterial pCO_2 , reduces cerebral blood flow.

These effects of carbon dioxide are not related to associated changes in hydrogen ion concentration. Intravenous infusion of sodium bicarbonate, which produces an increase of the total carbon dioxide content of the blood and a systemic alkalosis, has the same qualitative effect on cerebral vascular resistance as inhalation of 5 per cent CO_2 , which also raises total blood carbon dioxide but results in acidosis. Conversely, an infusion of NH_4Cl duplicates the cerebral effects of hyperventilation. Both procedures reduce the total carbon dioxide content of the blood, but the accompanying pH changes are in the opposite directions (Schieve and Wilson, 1953).

The vasodilator effect of carbon dioxide is a threshold phenomenon. No change in cerebral vascular resistance is detectable for arterial pCO_2 increases of up to 4.5 mm Hg, beyond this point there is progressive vasodilation with further arterial pCO_2 increments (Patterson and associates, 1955).

In view of the pronounced cerebral vasomotor activity of carbon dioxide on the one hand, and the absence of any demonstrable neurogenic control on the other, it is logical to postulate that cerebral blood flow is regulated, at least in part, by local carbon dioxide concentrations. It was calculated that a reduction in blood flow of about 30 per cent would be required for capillary carbon dioxide tension to reach the average vasodilator threshold level of 4.5. In all likelihood, however, a reduction of this magnitude is not necessary, since under physiological conditions any increase in carbon dioxide concentration would be accompanied by hypoxia (see below).

The cerebral vasomotor action of oxygen is qualitatively the direct opposite of that produced by carbon dioxide. Inhalation of a gas mixture containing 10 per cent oxygen, which reduces arterial oxygen content by about one third, causes a 35 per cent increase in cerebral blood flow, despite a fall in systemic blood pressure and a decreased arterial pCO_2 and pH (due to increased pulmonary ventilation) (Kety and Schmidt, 1948). The net effect of this degree of hypoxia on cerebral vascular resistance equals

that produced by the inhalation of 5 to 7 per cent CO_2 . Inhalation of high concentrations of oxygen which increase arterial pO_2 , causes a reduction of cerebral blood flow, but recently it was stated that this does not occur if care is taken to prevent concomitant hypocapnia (Turner and associates, 1957).

If as it may seem plausible, hypercapnia and hypoxia act synergistically on cerebral vascular resistance possibly in combination with other metabolic products resulting from a diminished blood supply, this could well explain the mechanism of autoregulation exhibited by the cerebral circulation. Any impairment of blood supply resulting from a drop in perfusion pressure would automatically lead to an accumulation of metabolic products which when present in sufficient concentrations, would act to restore blood flow by producing vasodilation. At the present time, however, this is still an unproved hypothesis.

Whatever is the exact mechanism of cerebral vasomotor regulation cerebral blood flow shows a remarkable constancy under a variety of physiological conditions studied so far. Mild exercise (Kleinerman and Sincetta, 1955) produces a slight increase in cerebral vascular resistance, probably due to the concomitant drop in arterial PCO_2 secondary to hyperventilation. Intellectual efforts, such as mental arithmetics, have no effect on cerebral blood flow (Sokoloff and associates, 1955). Anxiety also seems to be devoid of influences on cerebral hemodynamics (Scheinberg and Stead, 1949). Natural sleep induces cerebral vasodilation and a small increase in blood flow without changes in arterial oxygen or carbon dioxide tensions (Mangold and associates, 1955). Eating does not affect cerebral blood flow (Rowe and associates, 1959). The effects of tilting from the supine to the upright position depend on the degree of tilting. Moderate elevations (20° from horizontal) have no effect on cerebral blood flow (Shenkin and associates, 1948), but more near vertical positions which lower the mean arterial pressure at head level below 60 mm Hg cause, as it might be expected, a reduction in blood flow despite a decrease in cerebral vascular resistance (Scheinberg and Stead, 1949).

The Cutaneous Circulation

THE ANATOMY OF THE CUTANEOUS CIRCULATION AND SKIN COLOR

The architecture of the vessels of the skin has the general pattern already described on page 158. The arterioles upon approaching the bases of the

FIG. 25-2 The bed of the finger nail in a healthy subject, showing the capillary loops and the summits of the skin papillae. (After Lewis.)

papillae (i.e., the layer of the corium immediately underlying the epidermis) turn horizontally and give rise to metarterioles from which originate in turn, hairpin shaped endothelial tubes—the capillary loops. The proximal or arterial limb of the capillary loop ascends in the papilla and then turns upon itself to form the venous limb. The latter on reaching the base of the papilla joins with the venous limbs of neighboring loops to form a collecting venule. The collecting venules anastomose with one another to form a network—the subpapillary venous plexus—which runs horizontally beneath the bases of the papilla. It drains into deeper veins. The capillary loops can be seen readily in the living skin under the low power of the microscope. The vessels at the base of the human fingernail are shown diagrammatically in figure 25-2.

The color of the skin is not dependent normally upon the most superficial vessels, i.e., the capillary loops but upon the subpapillary venous plexus. The vessels of the plexus, though more deeply placed, present a greater area parallel to the skin whereas the capillary loops are disposed chiefly at right angles to the skin surface.

When the skin is unusually pale and little blood is contained in the superficial vessels (subpapillary venous plexus), the skin is more transparent and the deeper venous plexuses then contribute largely to the color of the skin, often adding a leaden tint to the pallor. When the overlying vessels are open and the skin is well supplied with blood, these deeper vessels are hidden from view.

Apart from pigmentary effects, and assuming the general arterial blood to be normal the color of the skin, i.e., the dominance of the reddish

or of the bluish hue, depends upon the extent to which the oxy hemoglobin becomes reduced during the passage of the blood through the cutaneous vessels. The degree of reduction will depend entirely, as a rule, upon the rate of blood flow. When the flow is rapid or slow the blood is, respectively, more arterial or more venous in character. The tint of the skin varies accordingly.

The depth of the skin color, i.e., the intensity of color apart from hue is dependent upon the diameters and the degree of engorgement with blood of the superficial vessels.

So, taking into account both the hue and the depth of color, an intense scarlet color of the skin indicates a normal or increased blood flow and dilated vessels, a deep blue color accompanies a slowed blood flow and dilated vessels (such as would result from obstruction to the venous trunks), or arterial desaturation (cyanosis). Pallor or a light pink color of the skin is seen when the vessels are constricted or of moderate tone, and the blood flow normal or rapid. A slowed cutaneous blood flow and constricted superficial vessels tend to produce a leaden or ashen type of cyanosis for, as mentioned above, the dark blood in the deeper venous plexuses then becomes faintly visible.

EXPERIMENTAL INVESTIGATION OF SKIN BLOOD FLOW. Blood flow in the skin serves two main functions: (1) the regulation of body temperature, and (2) nourishment of the skin. The investigation of the regulation of skin blood flow has been through the effects produced by direct or indirect warming or cooling, by pharmacological agents which act similarly to nervous system transmitters, by drugs which block the nervous supply, or by direct stimulation of nerves, baroreceptors or specific areas of the brain. Since the skin of animals (except for the paw) differs from human skin in possessing probably only vasoconstrictor fibers, data obtained from humans will be presented unless only animal studies are available. The skin of dogs and cats lacks eccrine glands, and sweating is absent (except in the paws). Techniques of blood flow measurement in human skin include plethysmography, continuous temperature recording, calorimetry, clearance rates of radioactive materials, oxygen polarography, blood oxygen saturation of cutaneous veins, pulse volume studies, and direct microscopic inspection of the vessels (ch 15). It must be emphasized that clearance rate studies do not always agree with plethysmographic measurements. The reason for this disparity is unknown although it has been suggested that the former measures only

capillary flow while the latter determines total flow (capillary and shunt flow). The limitation of human skin studies is the lack of a direct method of blood flow measurement.

THE CONTROL OF SKIN BLOOD FLOW AND THE REGULATION OF BODY TEMPERATURE. The skin blood flow in regional areas reacts and is, evidently, innervated differently. Cutaneous vessels are regulated by the sympathetic nervous system, a parasympathetic supply has not been shown in any area. Usually the sympathetic innervation is demonstrated by blocking its effects with adrenergic or ganglionic blocking agents or sympathectomy. This presumably rules out a somatic or parasympathetic nervous system control of the vasomotor reflex being studied. The type of end organ transmitter involved in the sympathetic responses is determined by the use of adrenergic or cholinergic (atropine) blocking agents. It should be pointed out that the sympathetic fibers travel with the main somatic nerves in the extremities so that both are blocked by anesthetization of the deep nerves.

A Cutaneous Blood Flow in the Hand and Foot

Only a vasoconstrictor nerve supply with adrenergic sympathetic fibers has been identified in the hand or foot to be of importance in the reflex control of body temperature. The demonstration of specific cholinesterases by histochemical methods in the digital arteriovenous anastomoses suggests they may be cholinergically controlled. Also, it has been postulated that the sympathetic nerve supply to human fingers exerts a tonic dilator influence on vessels through the release of acetylcholine. The indirect evidence for this theory includes the dilation of vessels by extracts of human digital arteries, its prevention by atropine, and the possession of a pseudo-cholinesterase activity. More recently, a substance called "bradykinin" has been suggested as an important factor causing active vasodilation in human forearm skin and, evidently, in any skin area containing eccrine sweat glands (palms and soles). During activity of the sweat glands, a proteolytic enzyme is released into the tissues where it acts on an unknown protein to produce the polypeptide, bradykinin (fig 25-3). The latter substance is a powerful vasodilator, and its concentration has been demonstrated to increase in forearm skin, reflexly vasodilated by body warming, even before sweating or a rise in skin temperature have occurred. The eccrine glands are presumably activated by a cholinergic substance via the sympathetic nervous system. This pathway is not

SCHEMATIC DIAGRAM OF BRADYKININ FORMATION IN HUMAN SKIN

FIG. 25.3 Schematic diagram of bradykinin formation in human forearm skin during body warming. Sympathetic stimulation of the sweat gland releases a proteolytic enzyme which acts on a tissue fluid protein to form a polypeptide (bradykinin). The polypeptide has a vasodilator action of the cutaneous vasculature (from Barcroft *et al.*)

believed to account for all reflex vasodilation for the vasodilation has been observed without an apparent change in sweat gland activity, and *vice versa*.

Body warming elicits a reflex vasodilation in the hand or foot which has been shown to correlate with a release of vasoconstrictor tone (a decreased number of impulses traveling over the sympathetic nerve fibers). The reflex may originate either in cutaneous receptors or by central nervous system stimulation. The vessels, themselves, are also evidently sensitive to warm temperature for the dilation following vasomotor nervous inhibition (by blocking agents) can be augmented by local heating of the hand. When the human body is cooled the toe temperature approaches environmental temperature, whereas the finger tips cool but show more fluctuation in temperature and blood flow. Similar cooling of the hands and feet occurs reflexly to cold applied to one area of the body, such as the forehead. The transmitter substance involved in the cutaneous vasoconstriction mediated by the sympathetic nervous system has been shown to be adrenergic in nature, but whether epinephrine, norepinephrine or a related amine is involved is not known.

Since vasoconstrictor tone develops earlier and is more stable and less readily reversed by body warming in the feet than in the hands, it has been suggested that the lower extremities are con-

cerned with gross adjustments while the upper extremities provide the fine regulation of body temperature.

If a finger is immersed in cold water its temperature falls rapidly to the bath temperature and blood flow slows, the vessels then fluctuate in cycles of constriction and dilation. Both the sympathetic vasoconstrictive reflex and the local direct effect of cold on the vessels are involved in the reduction of blood flow. The vasodilatory mechanism during the cyclic changes remains partially unexplained. It is probably an effective protection against cold injury. Lewis thought it was secondary to a local or axon reflex (via the dorsal root vasodilator fibers) but the absence of sensory fibers only reduces, not abolishes, the response. As mentioned before, there is evidence for an active vasodilator innervation of the arteriovenous anastomoses which may take part in this cold vasodilation.

Arteriovenous anastomoses are communications between smaller arteries and arterioles and the corresponding venous channels through which the blood may be shunted and capillary areas short circuited (figure 25.4). Included in the shunt definition of arteriovenous anastomoses should be the presence of a direct or indirect regulatory mechanism. These communications have been studied mostly in animals, especially the rabbit. In the rabbit ear, arteriovenous

FIG 254 Reversion of anastomosis and associated vessels to lowering of body temperature A^1 , artery, A^2 , arteriole, AV, arteriovenous anastomosis, C, vein. Upper figure (a), anastomosis open, lower figure (b), anastomosis closed (After Grant)

anastomoses have been shown to be very effective in controlling the body's temperature. When open, these channels would offer very low resistance vessels through which large volumes of blood could flow. It has been demonstrated by a method involving the injection of microspheres that more than one third of the total flow through the rabbit ear or dog paw may pass through such shunts. The microspheres are suitably selected in size to pass through anastomotic vessels but not capillaries. Animal arteriovenous communications are presumably supplied by constrictor sympathetic fibers and constrict or dilate to a variety of stimuli. Human digits and palms (glomus areas) and ears have large numbers of these potential shunts. The glomus areas contain muscular tufts of arteriovenous anastomoses and receive a rich nervous innervation. In man, little information, except that mentioned previously, exists regarding the control or function of the arteriovenous anastomoses. Although they have been postulated as playing a large role in the regulation of body temperature by increasing or decreasing the radiation of heat, their participation in such reflexes has not been shown in man. The high rates and wide, rapid variations in digital blood flow (1 to 150 ml per 100 ml of skin per minute) are often attributed to these channels. It is evident that

new methods of study are needed to further our knowledge of these interesting communications.

B Cutaneous Blood Flow of the Forearm

The blood flow of the forearm skin has been estimated to vary from 0 to 70.5 ml per 100 ml of skin per minute using rates determined plethysmographically before and after abolition of flow by iontophoresis of the skin. The skin of the forearm has been shown to possess both a sympathetic vasoconstrictor and vasodilator nerve supply in contrast to that of the hand and foot. It was demonstrated that the increase in forearm blood flow secondary to body heating occurred in the skin and not in the muscles by the following: (1) iontophoresis of the forearm skin with epinephrine abolishes the increased forearm flow response, (2) venous oxygen saturation from cutaneous superficial veins rises while that from muscle veins remains stable during body heating, and (3) the temperature of the skin rises with body heating but that of muscle does not. By blockage of the forearm skin nerve supply with local ring anesthesia or deep nerve blocks, the vasodilation reflex was prevented. The vasodilation could be blocked partly by atropine indicating cholinergic sympathetic fibers were involved. The experiments demonstrating the bradykinin mechanism and its activation by sympathetic sudomotor stimulation (as explained above) were performed in the forearm skin. Bradykinin vasodilation, the release of vasoconstrictor tone, and the direct effect of heat in relaxing the blood vessels may all play a part in the vasodilation which occurs in forearm skin during total body warming. A parasympathetic innervation has not been demonstrated.

The skin temperature and blood flow of the forearm decrease in response to body cooling. A longitudinal temperature gradient from the warmer trunk to the cooler hands and feet is maintained. The cooling of the forearm skin is evidently *via* sympathetic constrictor fibers as in the hands and feet.

It has also been demonstrated that subcutaneous injections of CO_2 in humans causes a vasodilation probably of the small resistance vessels. In dogs, low pH solutions intra arterially elicit a marked increase in cutaneous blood flow while alkaline solutions reduce flow.

Human skin studies utilizing the oxygen polarograph have shown that the oxygen tension increases with temperature elevations up to, but not over, about 43°C . It is postulated that heating causes an increased blood flow, dissociation

of oxygen from hemoglobin, and increased supply of oxygen and blood to the skin. At higher temperatures, the oxygen utilization would outstrip the increased supply. The role of skin metabolism in the regulation of its blood flow has received little investigation.

C Cutaneous Blood Flow to Other Skin Areas

Skin areas other than the extremities have received little study because of the lack of techniques for measuring blood flow. Most available studies have utilized the qualitative measurements of blood flow determined by the photoelectric plethysmograph or surface temperature changes. The forehead skin is believed to have a weak or absent vasoconstrictor nerve supply. During cold exposure, the surface temperatures of the head and trunk fall relatively little and high rates of blood flow continue. This has been an important finding leading to the use of head gear to prevent heat loss in cold weather. Vaso-motor reflexes to noise or distal application of cold which severely decrease hand flow, have only a slight effect on forehead blood flow. India ink injections show the vascular plexus of the forehead to be very extensive while the rapid clearance of radioactive sodium and volume pulse measurements demonstrate the blood flow to exceed that in the skin of the calf, forearm and trunk. The forehead and cheek evidently do not possess glomus so this flow is all through the capillary beds. Pharmacological agents (nicotinic acid, histamine and others) increased the skin temperature in these areas but not in the toes or fingers. Adrenergic and ganglionic blocking agents had no effect on forehead skin temperature. It has been suggested that cholinergic sympathetic fibers maintain vasomotor tone in the forehead and cheek areas but experimental evidence for this is too indirect.

D The Effect of Perfusion Pressure on Skin Blood Flow

The mechanical effects of perfusion pressure on blood flow were measured in isolated cutaneous beds of dog hind limbs. The *in situ* vascular bed was perfused via the sphenous artery from a reservoir whose height could be varied to change perfusion pressure. When the rate of flow was plotted against changes in perfusion pressure a parabolic curve (fig. 25.5) was obtained instead of a straight line. There was a progressive decrease in resistance to flow in the vessels as the perfusion pressure rose. With an increase of vasomotor tone in the vascular bed the flow for any given

FIG. 25.5 Plot of relationship between perfusion pressure and blood flow through the skin supplied by the sphenous artery in the hind limb of a dog in which vasomotor activity remained practically constant at a high level. Solid symbols represent data obtained at different times during a 7 hour interval. Yellow symbols represent the animal's mean arterial blood pressure at these times. Ordinate scale represents the perfusion pressure in mm Hg expressed as the difference in pressure between arterial and venous pressures. Abscissal scale represents the blood flow in milliliters per minute. (Slightly modified from Green, Lewis, Nickerson and Heller.)

pressure decreased. The nonlinear relation between flow and perfusion pressure may be secondary to a progressive decrease in viscosity of blood (because of a more axial flow of red cells) or to a mechanical dilation of blood vessels with the rising perfusion pressure.

E The Cutaneous Veins

In dogs and cats, it has been shown that the superficial large and small veins of the skin have a nerve supply, undergo rhythmic changes in diameter and respond to pharmacological agents. The small veins may contract separately and independently from the large veins or arterial vessels during sympathetic nerve stimulation. Since the small veins (and large veins) constrict, an increase in pressure results. Thus a reduced blood flow may occur through the vascular bed without a mechanical obstruction being present. In humans forearm cutaneous vein segments, which were isolated *in situ* by pressure have been demonstrated to constrict following a variety of normal and noxious stimuli. The venoconstriction was blocked by chemical or surgical sympathectomy or infiltration of an anesthetic solution around the vein. Venous tone decreased during the vaso-

FIG 256 Dermographism (From Adams's textbook of Pathology, after Hyde and Ormsby)

vagal syndrome and by stroking the skin over the vein. The fact that cutaneous veins constrict by cooling and are not affected by warming is evidence for the existence of only a vasoconstrictor nervous supply. The active innervation of veins is evidently very important in response of the cutaneous circulation to ordinary and abnormal stimuli, and also in determining the color of the skin.

F Vascular Responses of the Skin to Stimulation by Mechanical and Other Agencies Dorsal Root Vasodilator Fibers

1 **THE WHITE REACTION** If the surface of the skin is stroked lightly with a blunt "pointed" instrument, a line of pallor appears in 15 to 20 seconds which traces the path taken by the instrument. The line attains its maximal intensity in from $\frac{1}{2}$ to 1 minute, and then gradually fades to disappear in from 3 to 5 minutes. The white reaction proper is due to *direct stimulation of the capillary wall and has not a nervous basis*. It has been shown by Lewis to be due to the tension exerted upon the walls of the minute vessels—capillary loops collecting venules and especially of the subpapillary venous plexus—which respond to the stimulus by contraction. The sharply delineated character of the white line, and the fact that it can be obtained after the circulation through the region has been occluded by compression of the larger vessels, show that it is an active capillary response, and not the result of arteriolar constriction.

2 **THE TRIPLE RESPONSE** This comprises (a) the red reaction, (b) the flare, and (c) the wheal.

(a) *The red reaction* If the pointed instrument be drawn more firmly across the skin, especially of the forearm or back, a red instead of a white band appears after a somewhat shorter latent period (3 to 15 seconds), reaches its maximum in from $\frac{1}{2}$ to 1 minute, and then gradually fades

Like the white reaction it is strictly localized to the line of stroke, it is due to *dilation of the capillary vessels*. The red reaction can be induced in its full intensity in the skin from which the circulation has been occluded, so it is due to active dilation of the latter vessels and not merely a passive result of arteriolar dilation. *The red reaction is not dependent upon nervous mechanisms since it occurs after section and degeneration of the cutaneous nerves*.

(b) *The spreading flush or flare* If the stimulus is unusually strong, or is repeated often enough, the reddening of the skin is not confined to the line of stroke but surrounds it for a variable distance (1 to 10 cm) according to the intensity of the injury inflicted. The temperature in the suffused area is definitely raised. This flare reaction appears a few seconds (15 to 30) after the local red line, and fades sooner but remains a bright arterial color throughout. It is due to dilation of the arterioles, since it does not appear after the circulation of the part has been occluded by means of a tourniquet, also, unlike the red reaction, the flare is dependent upon local nervous mechanisms (axon reflex). It occurs after the nerves are divided but not after they have degenerated.

(c) *Local edema or wheal* When the stimulus is still more intense, the skin along the line of the injury becomes blanched and raised above the surrounding area to a height of 1 or 2 mm or even more. Such a wheal or welt is commonly produced in a normal person by the lash of a whip and other types of strong localized stimulation. In susceptible individuals, even light stimulation, such as drawing a pencil with moderate pressure over the skin of the back, will produce linear wheals surrounded by a diffuse red halo along the pencil's track. In this way letters or other designs may be embossed upon the skin (fig 256). This phenomenon is spoken of as *dermographism* or *factitious urticaria*. The wheal is preceded by and completely replaces the usual red reaction. It makes its appearance in from 1 to 3 minutes from the time of injury and is at its maximum height in 3 or 5 minutes. It is surrounded by the flare described above. The raised patch at first is clearly demarcated, but as time passes it increases in diameter and decreases in height, loses its sharpness and finally, though perhaps not for some hours, disappears. The wheal is due to the transudation of fluid from the minute vessels involved previously in the red reaction, it is, therefore, a localized edema. Increased permeability of the capillary wall is judged to be the immediate cause of the localized

edema which constitutes the wheal. Increased intracapillary pressure, distension of the capillary lumen, or reduction in pressure in extracapillary spaces have been shown by Lewis to be not responsible. That increased permeability rather than simply a rise in the filtration pressure is the dominating feature is also manifest by the high protein content of the transuded fluid. This more nearly approaches that of blood serum than the fluid of ordinary edema. Wheal production does not depend upon a nervous mechanism.

A considerable weight of indirect evidence has been presented by Lewis to support the conception that a diffusible substance is responsible for the three reactions comprising the triple response. This material, which he calls *H substance*, is thought to be liberated by the injured cells of the epidermis lying beneath the horny layer and superficial to the papillae. The possibility that more deeply lying tissues, when subjected to injury, may release the substance is not excluded, but a needle which does not penetrate beyond the epidermis elicits the typical threefold reaction. The chemical substance closely resembles *histamine* in its action. It apparently causes the red reaction and the wheal by a direct action upon the capillary wall. The flare is believed to be due to chemical stimulation of the sensory endings of the skin, thus bringing about arteriolar dilation through the mechanism of the axon reflex. Although the evidence for this theory is indirect and actual proof of the existence of such a humoral mechanism is lacking, the results of Lewis's various ingenious experiments carry conviction.

The cutaneous reactions following injuries of various sorts, e.g., burning, freezing, electrical stimulation, are believed to be produced by the same humoral mechanism. The cardinal signs of inflammation—redness, heat and to some extent the swelling and pain—can be similarly explained, namely, direct action of the dilator *H substance* upon the minute vessels, and an indirect effect through the medium of the axon reflex, upon the arterioles of the surrounding area. The ultraviolet light reaction in man is evidently secondary to a different mechanism. It has been shown that the ultraviolet light erythema is not reduced by pre-treatment with antihistamines. Also histamine introduced into areas of ultraviolet erythema produces its usual triple response. Thus, Lewis's theory of all cutaneous inflammatory processes being secondary to release of the *H substance* is not universally applicable.

The dorsal root of the spinal cord contains vasodilatory fibers supplying mostly the cutane-

ous vessels. They do not convey impulses to or from the higher central nervous system centers for control of the cutaneous circulation. No true cutaneous vasomotor reflexes are seen after sympathectomy. Experiments have shown that the dorsal root vasodilator fibers do not engage in the baro- or chemoreceptor control of vascular tone, nor in the regulation of heat loss from the skin. The transmitter substance of these fibers is unknown but they probably act in an axon reflex arrangement to affect regional blood vessels. These are probably the fibers that, upon damage to the superficial tissues, are involved in the vasodilator (flare) reaction of the triple response. Any stimulus causing damage to the skin activates these fibers such as severe cooling, heating or pain. It was mentioned previously that an axon reflex may be involved in the cyclic vasodilation occurring when a finger is placed in cold water. Severe cooling would elicit the axon reflex in these fibers from the dorsal root with a consequent vasodilation in the finger. The latter would warm the finger stopping the axon reflex discharge and then vasoconstriction would recur.

G Central Nervous System Control of Cutaneous and Muscle Blood Flow

The central nervous system regulation of blood flow is through the sympathetic fibers.

A variety of stimuli affecting peripheral receptors elicit spinal vasomotor reflexes whose efferent limbs are the cutaneous sympathetic vasoconstrictor fibers. These reflexes are usually segmentally or regionally arranged. Also in certain animal preparations the preganglionic sympathetic neurons in the lateral horns of the spinal medulla may exhibit spontaneous activity independent of afferent stimuli.

The vasomotor center located in the oblongate medulla is believed to be the primary controlling factor of cutaneous and muscle vessel vasoconstrictor tone. Experiments on dogs and cats have shown that stimulation of the midline of the oblongate medulla leads to vasodilation in both skin and muscle. This vasodilatory response is not blocked by atropine and, therefore, is secondary to a release of vasoconstrictor tone. Stimulation lateral to this vasodilator area elicits vasoconstriction in the same areas. Both these responses are absent in sympathectomized animals. The vasodilator and vasoconstrictor areas may act as an integrated unit and, evidently, are primarily involved in vascular reflexes arising from the baroreceptors in the carotid sinus and aorta. A decrease in blood pressure causes reflex

FIG 257 Schematic drawing of the oblongate medulla showing the situation of points yielding skeletal muscle vasodilation secondary to inhibition of vasoconstrictor tone (*open circles*), and points yielding sympathetic vasodilator discharges (*black dots*) (From Lindgren and Uvnäs)

vasoconstriction in the dog hindlimb via the carotid sinus baroreceptors while stimulation of the carotid sinus nerve induces vasodilation in skin and muscle

The vasomotor center possesses automaticity for a continuous discharging impulses without apparent afferent stimuli from the periphery or higher autonomic centers. The marked fluctuations from moment to moment that occur in the digital and forearm arteries and veins, and that disappear following sympathectomy, are thought to be secondary to the activity of the vasomotor center. The patterns of these continuous variations in pulse volume of the fingers, toes and ears appear to correlate with the personality types (emotional stability or lability) of the human studied.

Stimulation of a more lateral area to the vasomotor center invokes a vasodilation in skeletal muscle through the activity of the cholinergic (blocked by atropine) sympathetic fibers (fig 257). The vasodilatory area of the vasomotor center has no anatomical or apparent functional

connection with these cholinergic fibers which pass through the oblongate medulla.

The anterior hypothalamus is often referred to as the 'heat loss center' for it controls the vasoconstrictor fibers in association with the vasomotor center. Local heat applied to this area inhibits vasoconstrictor fiber discharge (vasodilation) while electrical stimulation excites the fibers (vasoconstriction). This center is thought to predominantly regulate the cutaneous vessels and, maybe, the arteriovenous anastomoses. Sympathectomy, also, abolishes these effects of the hypothalamus. Stimulation of certain areas in the hypothalamus may elicit a vasodilation in muscle via the cholinergic fibers which synapse in this area. This muscle vasodilation is often associated with a vasoconstriction of the skin.

Many areas of the cerebral cortex have been found that influence, by excitation or inhibition, vasoconstrictor fiber discharge. For example, stimulation of the motor or premotor cortical areas results in cutaneous vasoconstriction. A muscle vasodilation also occurs but is evidently secondary to a baroreceptor reflex from a rise in blood pressure. The cholinergic vasodilator fibers to skeletal muscle are also represented near the motor cortex. These fibers, which are distributed probably only to muscle synapses in the hypothalamus and mesencephalon and pass through the oblongate medulla as described above. Their function in man is not completely understood, but they appear to be involved in the control of the blood flow needs of muscle and not in the regulation of blood pressure.

Skeletal Muscle Circulation

Resting forearm skeletal muscle blood flow has been estimated to normally range from 1.8 to 9.6 ml per 100 ml of muscle per minute (compare to forearm skin flow on p 348). The blood flow in skeletal muscle is affected and controlled by a multitude of factors. Many of these regulations are poorly understood and their relative importance in the normal functioning of skeletal muscle is not known. Investigation of skeletal muscle blood flow is performed in man by similar techniques outlined under skin blood flow. The plethysmograph measures both the skin and muscle blood flow, the forearm is considered representative of muscle while the hand or foot, of skin (because of the relative amounts of each tissue in these regions). The skin is often iontophoresed with epinephrine to limit or abolish its blood flow in order to obtain forearm muscle determinations. In animals, blood flow may be

measured by more direct methods and the results of central nervous system manipulations may be studied

NERVOUS SYSTEM CONTROL OF SKELETAL MUSCLE BLOOD FLOW Vasoconstrictor fibers have been shown to supply skeletal muscle by the demonstration of an increased blood flow in human forearms following nerve blocks, and by other indirect procedures. The transmitter substance for these constrictor fibers is not known but adrenergic blocking agents remove the vasoconstrictor tone. Intra-arterial epinephrine has both a vasodilator and vasoconstrictor effect on human skeletal muscle vessels, while norepinephrine has only a vasoconstrictor action. Vaso-dilator cholinergic sympathetic fibers also supply skeletal muscle as demonstrated by a responsiveness of the bed to acetylcholine, blocking of the vasodilatory response with atropine, and the results of studies performed during vasovagal syncope. Despite a fall in blood pressure in the latter, the forearm blood flow increases (and hand flow decreases). If the patient had a sympathetomy, the forearm blood flow does not increase demonstrating that an active vasodilation via sympathetic nerve fibers had presumably occurred in the intact extremity. These vasodilator fibers appear to be activated by higher brain centers and do not participate in reflex blood pressure adjustments.

At present, the vasoconstrictor fibers are believed to be primarily concerned in postural and other homeostatic blood pressure adjustments. When the legs of a subject are raised, an increased blood flow occurs in the forearm but not the hand. This reflex has been shown to be secondary to an increased volume of blood in the thorax and an elevated central venous pressure which probably stimulates receptors in the low pressure vascular bed of the thorax. Since atropine does not abolish the forearm vasodilation, it is considered to be a result of a release of vasoconstrictor tone.

HUMORAL FACTORS IN SKELETAL MUSCLE BLOOD FLOW Recent studies in humans have shown that the increase in forearm blood flow during hyperventilation is prevented by breathing an air mixture containing 5 per cent CO_2 , occurs only in the muscles and not in the skin, and is not abolished by blocking the nerve supply to the limb. This evidence points to a humoral mechanism, involving a low CO_2 tension, which causes the increased forearm blood flow by a direct action on peripheral vessels.

An elevation or a decrease in the pH of blood perfusing a dog's hind limb elicits a vasodilation

Lactic acid increases the blood flow, but sodium lactate titrated with a buffer to a pH of 7.4 does not. There is indirect evidence that the vasodilatory effect of epinephrine may be through the action of released lactic acid.

MECHANICAL EFFECTS ON SKELETAL MUSCLE BLOOD FLOW When perfusion pressure is plotted against skeletal muscle blood flow (as determined in isolated muscle beds of the hindlimb of a dog), a parabolic shaped curve is found in the upper and lower ranges (fig. 25.8), as in the skin vascular bed. These two normal relationships of pressure to flow are joined in the intermediate range by a sigmoid curve (a large drop in perfusion pressure changes blood flow little). It was postulated that the reason for the sigmoid curve was a reactive dilation at perfusion pressures below mean normal aortic pressure to maintain blood flow to the muscular bed. The two parabolic areas on the curve would represent perfusion pressures during two states of vasomotor activity of the vessels. Because of the shape of the curve changes in vasomotor activity, secondary to a variable being tested, cannot always be predicted from the perfusion pressure and blood flow.

METABOLITES AND SKELETAL MUSCLE BLOOD FLOW, EXERCISE AND REACTIVE HYPEREMIA The skeletal muscle vascular bed is subjected to very active and widely ranging fluctuations in blood flow. The idea has often been expressed that the formation of metabolites by the muscle cells is the main factor in controlling the bed. Since direct stimulation of an animal's curarized muscle still elicits an increased blood flow, while motor nerve excitation does not, it is felt that the hyperemia of contracting muscle is secondary to a local physicochemical change. Also, humans with sympathetomized extremities can perform as well as those with an intact innervation. Local or reflex warming or cooling has little effect on the intrinsic vasomotor tone of muscles. It has been suggested that the metabolites, accumulated from muscle cell metabolism, may act directly on the smooth muscle cells of vessels or indirectly via a local nervous mechanism, such as peripheral ganglion cells or an axon reflex. The existence of ganglion cells among the muscle fibers has not been proven.

In the dog, muscular activity induces a dilation of the femoral artery which is mediated by an axon reflex (elicitable by acetylcholine). This mechanism, if it was shown to be present in the smaller arterial branches, could account for the vasodilation. In the cat limb, post exercise muscle hyperemia is blocked by substances (cocaine, botulinum toxin) which are likely to abolish such

FIG. 258 Plots of relationship between perfusion pressure and blood flow in the portion of the canine quadriceps muscle supplied by the branches of the femoral artery between the inferior epigastric and saphenous branches. Plots A and B were obtained 6 hours apart in the same animal. A' and B', dashed lines, flow during first 2 seconds of perfusion at each pressure, A and B solid lines, stabilized flows after maintenance of perfusion pressure for 10 to 20 seconds. Arrows indicate changes of flow with time at each perfusion pressure. MP, represents the level of mean arterial pressure. Ordinate scale represents the perfusion pressure in mm Hg, expressed as the difference between arterial and venous pressures, abscissal scale, blood flow in milliliters per minute (from Green, Lewis, Nickerson and Heller)

axon reflexes. The vascular reactivity is not paralyzed by these agents for the vessels continue to respond to epinephrine and acetylcholine. Since botulinum toxin specifically paralyzes cholinergic nerve endings, the fibers in the axon reflex may be cholinergic. However, a strong argument against this theory is that the vasodilation of exercise hyperemia is not blocked by atropine (although atropine has been found not to block cholinergic fibers in all areas).

The role that local metabolites play in stimulating such axon reflexes is not known. Anoxia, increased CO_2 tension, lactic acid, hydrogen ions, histamine, acetylcholine, adenosine triphosphate, adenylic acid, and potassium ions, have been suggested as the local determinant eliciting exercise vasodilation. Most of the metabolites have been studied by infusion into the muscular vascular bed or by examination of venous blood leaving the muscle following exercise hyperemia. Each has received little support as the dilator metabolite, but a combination of two or more of these factors may provide the answer.

The circulation in human skeletal muscle has been studied during sustained muscular contraction by indirect methods. It was found that below a certain critical strength of sustained contraction

of the calf muscle, blood flow was not decreased, but, above this critical point, the vessels were evidently compressed, for a hyperemia followed release of the contraction.

During rhythmic contraction of calf muscles, blood flow was increased during and immediately following exercise. It was felt that increased flow (vasodilator metabolite mediated) alternating with decreased flow (mechanical compression of vessels) paralleled the relaxation and contraction of the muscle. Mechanical obstruction, metabolite formation, and the action of muscles on the venous flow are probably all intricately involved in the muscular blood flow of exercise. It has been shown that an increase in venous pressure may alter arterial inflow to muscle. The sympathetic nervous system probably does not have a significant effect on the circulatory changes during exercise, for vasodilation is similar during and after exercise in normal and sympathectomized limbs. Also, the vascular bed of the exercising hindlimb of the dog is not responsive to sympathetic stimulation.

Following a period of complete occlusion of the arterial supply to a limb, the blood flow increases markedly and then returns to the control level. This phenomenon has been named "reactive

hyperemia." Actually, it is the blood flow in excess of that expected (the control blood flow) which is usually referred to as reactive hyperemia. The response occurs both in skin and muscle and can be decreased by cooling, epinephrine, or tobacco smoking. The reactive hyperemic blood flow and its duration correlate with the previous length of occlusion of the artery. This has been shown to be true for occlusion periods up to 10 minutes.

The blood flow and oxygen debt incurred during the period of occlusion are calculated by multiplying the control blood flow or oxygen usage before circulatory arrest by the duration of occlusion. Of course, this assumes that the blood flow and oxygen usage of the muscle would have remained at the previous control rates if the blood flow had not been occluded and that the metabolic rate of the muscle is not affected by the circulatory arrest. In the isolated, gracilis muscle of dogs and in the human forearm, the oxygen debt was approximately repaid for different periods of occlusion, while the blood flow debt repayment ranged from 50 to 200 per cent of that expected. It appears probable that the muscle blood flow is at least partially controlled by the need for oxygen.

The metabolites incriminated as the cause of exercise hyperemia have also been postulated as eliciting reactive hyperemia. Since reactive hyperemia occurs in sympathectomized and denervated limbs, nervous system control is not considered as important. The mechanical effect of the lack of pressure in the vessels during the period of occlusion has been demonstrated to play a role in the dilation. If the forearm is "packed" with venous blood before the circulatory arrest, the ensuing reactive hyperemia is decreased. However, the peak flows of the reactive hyperemias are not altered so that intravascular pressure cannot be the entire cause of the dilation. Lewis and Grant postulated that H-substance was involved in the production of reactive hyperemia, and some observers (others have not) found an increased histamine concentration in the venous blood after circulatory arrest. However, antihistamines do not decrease or abolish the reactive hyperemia response. As in exercise hyperemia, the vasodilator metabolites and effects of pH cannot be ruled out by studying only the venous blood, tissue studies would probably be more informative. Failure to discover the causative agent of vasodilation in muscular exercise and following arterial occlusion has been a major obstacle to the understanding of muscle physiol-

ogy and the diseases involving a decreased blood supply to human limbs. It seems likely that the study of aerobic and anaerobic tissue metabolism of skeletal muscle will be more profitable than blood flow studies, which evidently do not correlate with oxygen usage.

ARTERIOVENOUS ANASTOMOSES IN SKELETAL MUSCLE The question of whether arteriovenous shunts actually exist as functional units in skeletal muscle is still unsettled to most physiologists. Microscopic studies on the circulation of rat skeletal muscle revealed many communications between small arteries and veins which did not enter the muscle proper. During inactivity, most of the flow was through these anastomoses and not to the muscle fibers. When the rats were bled in small amounts, the muscular arterioles closed and flow in the capillaries ceased while it persisted in the anastomotic channels. However, that such communications actually function in man and possess a means of shunt regulation has not been demonstrated. Indirect evidence for the existence of functional anastomoses are decreased oxygen consumption and increased lactic acid production during vasodilation, such findings would occur if capillary flow was reduced.

SUMMARY

Although much investigative work has been performed, wide gaps still exist in our knowledge of the physiology of the cutaneous and muscle circulations. Most of the information concerning the control of these vascular beds has been gained from indirect and circumstantial evidence. The important limiting factor is the lack of a good technique for the direct measurement of blood flow in human skin and muscle. The indirect methods, currently in use, all have their inadequacies. Another drawback is the difficulty in distinguishing the many variables (metabolic, nervous, temperature, bradikinin, arteriovenous anastomoses) that affect the cutaneous and muscle circulation. In human experiments, skin and muscle flow cannot be satisfactorily studied individually, and the contribution of the blood flow in bone, fat and subcutaneous tissue cannot be evaluated. The central nervous system control of the peripheral circulation has been investigated in animals only, much is known about efferent fibers but little concerning afferent pathways. The study of the metabolic control of blood flow in skin has been neglected while that of muscle has not advanced far enough. In conclusion, many isolated facts are known concerning the mechanisms controlling cutaneous and muscle vascular

reactivity, but little is apparent of their integration in the homeostasis of these tissues

Peripheral Vascular Disease

RAYNAUD'S PHENOMENON AND RAYNAUD'S DISEASE

A distinction must be drawn between *Raynaud's phenomenon* and *Raynaud's disease*. *Raynaud's phenomenon* is understood to be the intermittent spasm of the small arteries of the extremities. The affected members, the fingers and less commonly the toes, become cold, numb, waxy pale (dead fingers) or cyanotic. The attacks are precipitated by exposure to cold. It is secondary to some other abnormal state, e.g., thromboangitis obliterans, arteriosclerosis, cervical rib, etc.

Raynaud's disease is the occurrence of *Raynaud's phenomenon* as a primary affection, i.e., not associated with some other arterial condition. It is a vascular spasm of the digital arterial bed and is bilaterally symmetrical. The disease, which is rare as compared with *Raynaud's phenomenon*, was first described by Raynaud in 1862. Young women are predominantly affected. The fingers, sometimes the toes, or rarely the ears and nose, are the seat of periodic attacks of vascular spasms. The attack lasts as a rule for a few minutes, but may persist for an hour or two. The color change commences in the finger tips and spreads toward the bases of the fingers. As the attack passes off the part again becomes cyanotic, then red and hot, the numbness is replaced by burning pain. The pulse at the wrist or ankle persists during the attack. Thrombosis of small arteries may lead to ulcers, sclerodactyly, rarefaction of the terminal phalanges, and other trophic changes. Gangrene sometimes results.

The disease has been generally attributed to hyperactivity of the vasomotor (vasoconstrictor) nerves. Sympathetic ganglionectomy is, therefore, frequently resorted to in an effort to abolish the attacks. Lewis has shown, however, that a typical attack may be induced in a subject upon whom this operation has been performed, by exposing the affected part to cold (as by immersing it in cold water). He concludes therefore that the fault lies not in the nervous control but in the vascular wall itself. The following observations cited by Lewis substantiate his view.

(1) If one finger of a subject of the disease be immersed in cold water, an attack confined to this finger may be induced. Such a localized result

cannot be explained upon the basis of a nervous reflex.

(2) Anesthetization of the ulnar nerve of a normal person by means of novocaine causes dilation of the vessels of the little finger (removal of vasoconstrictor tone). The vascular spasm in *Raynaud's disease* cannot be released in this way.

(3) If a subject suffering from *Raynaud's disease* affecting both hands, and upon whom a unilateral ganglionectomy had been performed, be seated in a cool room with both hands placed in cold water, the vascular spasm which results is more pronounced on the nonsympathetized side. If, however, the rest of the body is warmed while the hands are immersed in cold water, the attack is more pronounced on the sympathetized side. In the first experiment the greater degree of spasm on the nonoperated side is attributed to the added effect of a vasoconstrictor reflex. The lesser degree of spasm on the nonoperated side in the second experiment could be attributed to the inhibition of vasoconstrictor impulses. Though a nervous influence is evident in these observations the essentially local nature of the fault is also indicated.

Simpson and associates do not consider that *Raynaud's disease* is due primarily to a fault of the vascular tissue. These observers maintain that only in the advanced stages of the disease is the vascular wall itself abnormal and that in milder cases the fault is essentially vasomotor in character. They point out that Lewis' crucial experiments were performed upon severe or complicated cases of the disease.

Ganglionectomy, even though it may not remove the fundamental cause of the condition, does often exert a decidedly beneficial effect. The attacks are less frequent and intense after the operation, normal vasoconstrictor tone and as just indicated the reflex response to cold having been abolished, a more intense reaction of the arterial wall itself must occur before arrest of the circulation to the part can result. However, relapses often occur 1 to 2 years following the operation in those who were benefited.

ERYTHROMELALGIA

Erythromelalgia is a rare but interesting condition characterized by attacks of painful redness of one or both feet, or occasionally of the hands. The pain is burning in character and is induced by warming or exercising the part, or by allowing it to hang down. Rest, elevation of the part or the application of cold tends to relieve the pain. Erythromelalgia has been attributed to vasodila-

tion resulting from some abnormality of the vascular nerves Lewis finds, however, that the essential abnormality in these cases is not vasodilation, for an equivalent degree of vasodilation may occur in normal subjects in response to warmth or exercise, yet pain does not result. Erythromelalgia, or *erythralgia* as Lewis prefers to call the condition, is probably not of vasomotor origin. The abnormality in these cases is apparently a hypersensitive state of the cutaneous pain fibers to heat or tension. This "susceptible state" of the skin in erythralgia is altogether analogous to that seen in inflammation, and in that which can be induced in any normal person by certain types of cutaneous injury—exposure to ultraviolet light, repeated rubbing or stretching, burns, etc. It is well known that the pain endings of skin injured in these ways are very sensitive to warmth or to tension. Warming the part either by increasing the blood flow through its vessels, or by the application of heat causes burning pain. Pain also results when the part is dependent, the engorged vessels then causing tension upon the hypersensitive nerve endings.

Lewis suggests that in the pain associated with erythralgia and with the types of cutaneous injury just mentioned, a chemical substance liberated in the skin serves as the immediate stimulus to the nerve endings. The observation that the pain which follows repeated rubbing or stretching of the normal or of the erythralgic skin is prolonged and intensified by arresting the circulation to the part, supports this conception.

ACROCYANOSIS

In this disorder, the hands and less commonly the feet, are persistently cold, blue and sweaty. Exposure to cold intensifies the cyanotic color. In the case of the hands the cyanosis commences at about the level of the wrist and deepens as it is traced toward the fingers. There is puffiness of the fingers, but trophic disturbances are unusual. The milder forms of the disorder are closely allied, according to Lewis, to chilblains. The disorder is presumably due to increased tone of the cutaneous arterioles resulting from hypersensitivity to cold. The condition does not have a nervous basis, the fault is in the vascular wall itself, the cyanosis persisting unchanged after anesthetizing the ulnar nerve with novocaine. In acrocyanosis the cutaneous circulation is slowed as a result of arteriolar constriction, capillary dilation occurs with an increase in the quantity of blood in the skin. The slower blood flow, by allowing the hemoglobin to

give up a greater part of its oxygen store, is responsible for the blue tint of the skin.

THROMBOANGITIS OBLITERANS (BUERGER'S DISEASE)

This is an organic vascular disease involving, as a rule, the medium and small arteries (and to a less extent the veins) of the extremities. The condition in the majority of cases is confined to the lower limbs. However, coronary, cerebral, renal and other systemic arterial involvement occurs. The vessels are stiffened and hard. The adventitia is thickened, the media shows atrophy of its muscle and an increase in connective tissue, and, active proliferation of the intima occurs, several layers of cells being formed. The marked narrowing of the vascular lumen which results is followed by thrombosis. This and not the intimal proliferation itself is responsible for the final obliteration of the vessel. Organization of the thrombus, i.e., its invasion by fibroblasts and its conversion into fibrous tissue, follows. Some restoration of the circulation through the vessel may occur later as a result of the formation of new channels within the substance of the organized thrombus, but whether or not such a process of revascularization results the blood supply to the part is always greatly reduced.

Among some of the earlier manifestations of the condition are fatigue of the limbs upon exertion, intermittent claudication, hypersensitivity of the vasoconstrictor reactions of the extremities to cold resulting in attacks of pallor or cyanosis, coldness and numbness or a dull ache, superficial migratory phlebitis. A definite reduction in blood flow through the part may be demonstrated by plethysmographic or calorimetric methods. Extreme variations in the color of the limb result from altering its position in relation to the level of the heart, when the affected member is dependent, undue redness or cyanosis results, whereas when raised above heart level it becomes intensely pale and waxy in appearance.

As the pathological changes progress, the pulse disappears from the wrist or ankle, or even from the popliteal or brachial artery, ulcers and other trophic disorders appear and ultimately gangrene of the toes or fingers sets in, requiring amputation. The vascular obliteration tends, however, to creep upwards necessitating amputation at successively higher levels.

The cause of the disease is unknown, some believe it to be of infective origin. Excessive use of tobacco is strongly suspected of being a predisposing factor. Buerger and others have remarked

upon the very high incidence of the condition in Jews, of a series of 150 cases reported by Brown and Allen from the Mayo Clinic, over 50 per cent were Jews. The disease occurs almost exclusively in males, whereas Raynaud's disease with which it is likely to be confused, especially in its early stages, affects females predominantly. Another feature distinguishing it from Raynaud's disease is that in the latter, the color of the skin is affected little or not at all by elevation of the limb, and the pulse in the larger arteries does not disappear.

It is, of course, only during the earlier stages of the condition, i.e., when spasm due to increased vasoconstrictor reactivity is a contributing factor, and before organic changes have progressed to the point where they have occluded the vessels, that treatment can be expected to bring about any real benefit. When a spastic factor can be demonstrated, sympathectomy frequently results in very notable improvement. Even when the larger arterial vessels are obliterated, sympathectomy, by removing the vasoconstrictor tone of collateral vessels, may be followed by a definite improvement in the blood supply to the part. Remarkable improvement often follows the withdrawal of tobacco smoking. It has been reported that discontinuation of smoking, in thromboangiitis obliterans causes a decrease in platelet adhesiveness.

There are several methods to choose from for the detection of vascular spasm. The temperature of the part may be taken by means of a skin thermometer or a thermocouple before and after one or other of the following procedures, which, normally, causes vasodilation and raises the temperature of the part: (a) heating the entire body by a warm environment, (b) local anesthesia of sympathetic ganglia (or by the ganglionic blocking agents), (c) spinal anesthesia which temporarily paralyzes the vasoconstrictors, (d) anesthetization of a peripheral nerve, and (e) general anesthesia. A rise in temperature of the part, following one of these procedures, indicates the previous existence of a spastic element. The greater the degree of spasm the more pronounced and rapid is the temperature rise. If the occlusion is entirely organic in nature, no change in temperature results.

Instead of recording the skin temperature, the blood flow through the affected part may be estimated by the plethysmographic or calorimetric method before and after one of the procedures just enumerated.

INTERMITTENT CLAUDICATION

This is a condition (described by Charcot in 1856) in which, as a result of organic (usually atherosclerotic) narrowing of the arteries of a limb (usually the lower limb, *claudicare*, to limp) and consequent restriction of its blood supply, severe pain is experienced in the muscles during exercise. This pain occurs after the same amount of exercise on each occasion and disappears with rest. The pain has been attributed to a muscular cramp or to spasm of the vessels. Neither of these explanations can be entertained, for the muscles are flaccid during the attack. The abnormal stiffness of the arteries seems to preclude the possibility of their being narrowed appreciably by spasm and the smaller vessels are in all likelihood dilated rather than constricted during the attack.

The essential cause of intermittent claudication is a relative anoxia of the muscles—they are called upon to perform work for which the oxygen supply is inadequate. Lewis has shown that pain identical in character with that occurring in this condition can be induced by exercising any normal limb during the arrest of its circulation. When the circulation is restored, an immediate increase in the volume of the limb occurs which is taken to indicate that the vessels were dilated during the pain. In a patient suffering from the disease in one limb it was shown that the pain occurring in the limb during exercise was practically the same with regard to its time of onset, development and duration as that induced by exercising the sound limb during circulatory arrest.

The fundamental importance of anoxia in the production of the pain is also evident from the observations of Pickering and Wayne who found that exercising the muscles of an anemic subject in whom there was no evidence of arterial disease caused the characteristic pain of intermittent claudication. Kissin also showed that exercise performed by normal persons during anoxia (induced by breathing an air mixture containing a low percentage of oxygen) caused the typical cramp-like pain. The clinical experiments of Lewis indicate that the direct cause of the pain is not oxygen lack itself but the stimulation of sensory nerves by the metabolic products of muscular activity. Ordinarily these are removed by oxidation, but they accumulate when the blood supply is inadequate. He refers to the pain stimulus as "factor P". The evidence supporting this concept is as follows:

(1) The pain does not vary with the individual contractions but is a steady ache.

(2) Using a standard test (maximal grip exerted by thumb and index finger, recorded isometrically, and repeated at the rate of one per second) it was found that in normal subjects with the circulation to the arm arrested, the pain commenced in about 35 seconds after the commencement of the exercise and took another 53 seconds to reach the point where it became intolerable. The pain disappears within 3 seconds after restoring the circulation—presumably as a result of the removal of "factor P". If, on the other hand, occlusion of the vessels is maintained, the pain persists.

(3) Lewis found that the time of onset of the pain is determined by the total amount of work performed rather than by the length of the exercise period. Thus, when the circulation of a normal limb is arrested, pain ensues after the same number of contractions of equal strength whether they are repeated in rapid or in slow succession. On the other hand, if a constant rate is maintained, the pain follows sooner with strong than with weak contractions. If, however, the circulation to the part is only partially obstructed (Katz and associates) or if air containing a low percentage of oxygen is breathed (Kissin), the amount of work necessary to cause pain is lessened by increasing the rate at which the contractions are repeated—the chemical factor presumably accumulating more rapidly as a result of the shorter time intervals allowed for its removal.

(4) If, after the pain has been relieved by restoring the circulation to the part the vessels are again occluded and the limb exercised, the time of onset of the pain ensues earlier, the shorter the period during which the blood had been permitted to flow. This result suggests that products accumulated during the previous exercise period, if not given sufficient time to be removed are carried over to the second period and the concentration necessary for stimulation is reached sooner.

The nature of the chemical pain factor is unknown, Katz and associates believe it to be acid in character and nonvolatile. The ingestion of sodium bicarbonate was found to increase the amount of exercise required to cause pain.

"IMMERSION FOOT", "TRENCH FOOT"

During the Second World War this name was given to a state of the vessels and tissues of the feet brought on by severe and prolonged chilling of the feet by cold water. It was seen most frequently in persons who had been shipwrecked and immersed for hours in the sea at northern lati-

tudes. But it may also result if the feet alone are kept cold and moist, sailors working under the stress of wartime conditions in wet boots, or soldiers during duty in wet trenches (trench foot) may then suffer. In cases of immersion foot the feet during the period of exposure are swollen, numb and pulseless. Their color varies with the temperature from bright red to deep blue or waxy white, or may be mottled with areas of blue and white or blue and red. Within a few hours (2 to 48) after removal from the water the feet become hyperemic and severely painful the pain often being described as burning, scalding or stabbing in character. The swelling increases, blistering, ulceration, local wasting of muscles and, in the worst cases, gangrene result. Capillary damage permits fluid of high protein content to leak into the tissues. These effects are likely to be most severe if the temperature of the members has been quickly restored to normal. The hyperemic stage, after 6 to 10 weeks may merge into one in which the feet are pale and cold and very sensitive to exposure to cold. Damage to peripheral nerves and sympathetic fibers is a regular occurrence in severe clinical immersion foot. Anesthesia, motor weakness and muscular atrophy may last for many weeks.

The hands may be affected by cold water in the same way as the foot but much less commonly, since they are rarely exposed to conditions of such extreme severity.

While the members are actually exposed to the cold water the vessels are in strong constrictor spasm and a decreased blood flow results. A decrease in tissue oxygen tension is found most likely secondary to the lessened dissociation of oxygen from hemoglobin (the oxyhemoglobin dissociation curve is displaced to the left by cold). The metabolism of the tissues both as a result of the cold and the anoxia is greatly reduced. It is believed therefore, that a minor degree of tissue damage occurs at this time and the greater part after removal from the water, when the temperature of the parts rises. The vasoconstriction is a reflex response due to the action of cold on the general body surface, as well as to its local effect upon the vascular walls, and also probably to the absence of vasodilator metabolites. In the hyperemic stage there is maximum dilation of the vessels, the warming of the body having overcome the vascular spasm.

Since the intensity of the hyperemia and the tissue damage are enhanced by a rise in temperature every effort is made to prevent rapid warming of the affected members. Ice bags or blasts

of cold air are, therefore, applied locally to maintain the skin temperature of the feet around 21°C . It is also necessary to keep the entire body at as low a temperature as is consistent with comfort, this is achieved preferably by means of some form of cool cabinet.

Frost bite. Prolonged exposure to severe cold causes vasoconstrictor spasm, and when freezing occurs the circulation in the small vessels of the part becomes completely arrested. After the part has thawed, intense hyperemia usually follows, and most of the tissue damage is believed to be caused at this time. The increased capillary permeability secondary to the freezing together with the high capillary pressure of the hyperemic stage causes edema and swelling of the part. This of itself may cause strangulation of the circulation, but thrombosis also occurs. If the resulting ischemia is extreme, gangrene follows. Measures are directed toward the reduction of these effects by thawing the part rapidly and by the administration of an anticoagulant, e.g., dicoumarol or heparin.

SPECIAL FEATURES OF CIRCULATION IN DIFFERENT REGIONS. SPLANCHNIC CIRCULATION; RENAL CIRCULATION

The Splanchnic Circulation

The splanchnic circulation may be represented as consisting of three parts (1) the mesenteric bed, supplying the gastrointestinal tract, (2) the splenic bed, and (3) the hepatic bed

A unique feature of this circulatory system is that the combined outflow from two of the components (mesenteric and splenic) constitutes the major portion of the inflow of the third one (hepatic), through the portal vein. In its hemodynamic implications, this anatomical arrangement has been compared to the Wheatstone bridge in an electrical circuit (Bradley, 1958), because of the placement of the resistance vessels (fig. 26.1). This serves mainly to emphasize the large number of variables that influence blood pressure and flow in any one point of the system, and the potential fallacy of conclusions based upon measurements of a single variable, such as portal venous pressure.

As in other regions of the circulation, it is the measurement of blood flow that presents the greatest source of difficulties. Direct methods to this date can only be applied at the cost of considerable surgical and anesthetic trauma, and with various degrees of interference to flow (particularly venous flow) due to cannulation procedures. This latter obstacle has been eliminated by the application of noncannulating electromagnetic flow meters (Green and associates, 1959). Indirect methods, based on the Fick principle and the ability of the liver to clear certain dyes, such as bromsulphalein from the blood stream (Bradley and associates, 1945), do not have these disadvantages, but—aside from their failure to meet strictly the criteria of the Fick principle—can be used only for measurement of total splanchnic outflow (i.e., hepatic venous flow), not for that of its various components.

THE MESENTERIC CIRCULATION

Hemodynamically the intestinal circulation has both certain features in common with other vascular regions and others peculiar to itself. Perfusion studies on isolated denervated intestinal loops in the dog show that the pressure-flow relationships in the mesenteric bed are essentially similar to those in other areas such as the skin or skeletal muscle (Selkurt and associates, 1958). There exists a 'critical closure' pressure of the order of 15 mm Hg below which flow ceases, above this point progressive increments of pressure result in greater and greater increments of flow; in other words, vascular resistance decreases with increasing perfusion pressure. The reasons for this deviation from Poiseuille's law (dilatation of blood vessels with increased intraluminal pressure and the opening up of 'dormant' capillaries) have been fully discussed in chapter 25.

The hemodynamic characteristics peculiar to the mesenteric circuit derive from the location of these vessels in the walls of viscera capable of actively or passively changing their intramural tension. Isolated, perfused intestinal loops exhibit two sorts of spontaneous contractile activity: rhythmic segmental contractions, and alterations of the muscular tone. Each of these has a definite influence on blood flow within the loop (Siddly and Bean, 1958). During segmental contractions, there is an increase in venous outflow and decrease in arteriolar inflow, proportional to the strength of the contraction; reverse changes occur during relaxation. In addition to these phasic changes associated with individual contractions, there is close relationship between mean blood flow per unit time and the frequency of rhythmic segmental activity. All other things being equal, the minute volume flow increases

FIG 201 The Splanchnic Circuits. The vascular resistances in the splanchnic bed (A) are shown here in diagrammatic form (B). The resistances indicated are determinants of pressures in the portal vein and in the liver sinusoids and of flows through the portal vein and hepatic artery. R_1 , hepatic arteriolar resistance; R_2 , splanchnic (i.e., mesenteric, pancreatic, gastric and splenic) arteriolar resistance; R_3 , portal venular resistance; R_4 , postsinusoidal or hepatic venular resistance. The dotted line represents a fifth resistance lying in the direct communications between the portal vein and inferior vena cava. (From S. E. Bradley, *Circulation*, Proceedings of the Harvey Tercentenary Congress, p. 358, 1953.)

with increasing frequency of contractions. Changes in the gut's muscular tone are of longer duration and involve greater lengths of intestine than segmental contractions. An increase of tonus results in reduction of both arterial inflow and venous outflow. Following cessation of tonic contraction, blood flow temporarily increases above precontraction levels, in a manner analogous to the reactive hyperemia observed in skin, skeletal muscle and myocardium (see ch. 25). Since segmental and tonic contractions occur independently from one another and may be more or less superimposed, their effect on intestinal blood flow can be quite complex. If these processes observed in the isolated loop also operate in the intact animal or man, the musculature of the intestine may emerge as a factor in the regulation of splanchnic and systemic blood flow.

Passive changes in intramural pressure, such as those occurring in acute distension, also influence intestinal circulation (Noer and associates, 1951). It was shown in serosal vessels of rabbit's intestine, that at intraluminal pressures of 15 to

20 mm Hg, segmental contractions cease, accompanied by slowing of blood flow in the venules. With progressive rising of the pressure, circulation slows, then ceases, first on the venous, then on the arterial side. While such levels of intra-intestinal pressures are clearly outside the physiological range, these circulatory changes are the basis of the massive trapping of blood and leakage of plasma into the wall and lumen of the gut observed during acute intestinal obstructions.

In the maintenance of normal mesenteric circulation, the hemodynamic characteristics of the local vascular bed and the possible influence thereon of the intestinal smooth musculature are supplemented by a rich network of vasomotor nerves. These nerves belong to the sympathetic nervous system; their preganglionic fibers are contained in the splanchnic nerves, the postganglionic fibers form large plexuses around the abdominal aorta and accompany its branches to all the viscera. The function of vasomotor nerves has been discussed in detail in chapters 21 and 25. Electrical stimulation of the splanchnic nerves in

anesthetized dogs produces sharp decline in mesenteric artery flow, along with increasing the arterial (and portal vein) pressures, indicating that vasoconstriction has occurred. There is no evidence for the existence of vasodilator fibers in the splanchnic nerves (Deal and Green, 1956). Intra arterially injected norepinephrine reproduces the effect of splanchnic nerve stimulation (see ch 21), while section of the nerves or administration of ganglionic blocking agents increases mesenteric flow.

Vasomotor reactions in the mesenteric circuit are of considerable importance in various circulatory adjustments (see p 253). Not all vasomotor activity, however, is necessarily mediated by the nervous system. In the dog, experimental elevation of the portal venous pressure results in a reduction of mesenteric blood flow greater than the decrease in mesenteric artery portal vein pressure gradient, indicating that mesenteric vascular resistance had increased (Selkurt and Johnson, 1958). This change in resistance is shown to be independent from nervous activity and due to 'myogenic' response of the arterioles to the pressure increase transmitted through the capillaries (Johnson, 1959). It is not known what role, if any, this venous arteriolar response plays in the intact animal.

THE SPLENIC CIRCULATION

The nature of the intrasplenic circulation is a long standing, unsettled controversy. Lack of agreement is centered around the manner of connection between arterial and venous capillaries: whether their lumina are continuous with one another ('closed circulation') or is arterial blood discharged directly into the meshwork of the splenic pulp from which it seeps back into the venous capillaries ('open circulation'). The basis for suspecting a discontinuity of the circulatory bed (unparalleled elsewhere in the body) is the presence of blood cells and intra arterially injected foreign material in the splenic pulp, seen on histological examination, this is attributed to experimental artefacts by adherents of the 'closed circulation' theory. Microscopic transillumination studies in the living animal (Whipple and associates, 1954) suggest that both open and closed circulatory patterns function simultaneously ('combined circulation'), but it is debatable whether these observations on mouse spleen are applicable to the human organ in view of the demonstrated structural differences between the two (Snook, 1950).

In certain mammals (dog, cat, horse, guinea

pig) the spleen serves as a reservoir of blood. Under ordinary circumstances, blood is stored in the distensible venous sinuses, to be released into the circulation when need arises (as during exercise, anoxia, hemorrhage).

Evidence indicates that this splenic emptying mechanism is under sympathetic regulation (Green and associates, 1960). Stimulation of splenic nerve fibers in the dog results in simultaneous decrease in arterial inflow, increase in venous outflow, and decrease of splenic weight. The inflow response can be reproduced by intra arterial norepinephrine injection, while the outflow response can best be reproduced by injection of epinephrine. This suggests the existence of separate mechanisms for the control of splenic inflow and outflow: a norepinephrine mediated arteriolar inflow constriction and an epinephrine mediated emptying mechanism. This latter might be due either to venular relaxation causing passive elastic recoil of splenic tissues, or to primary contraction of splenic smooth muscle fibers.

In man, there is no evidence to indicate that splenic contractions take place under physiological circumstances, nor do injections of adrenaline raise the circulatory plasma or red cell volumes (Parsons and associates, 1948) as one would expect if the spleen served as an important blood depot.

THE HEPATIC CIRCULATION

In addition to receiving its arterial blood supply through the hepatic artery, the liver is also perfused by the mesenteric and splenic venous outflow through the portal vein. As pointed out earlier, this unique circulatory arrangement leads to considerable complexity of splanchnic hemodynamics, and information regarding the various factors determining blood flow through the liver is still fragmentary. The following may illustrate the difficulties encountered.

The hemodynamic properties of the portal venous bed of the isolated liver show a great deal of similarity to those of other vascular beds, such as the mesenteric described earlier. There is, in particular, a progressive decrease of vascular resistance with increase of perfusion pressures throughout the physiological pressure range (up to 12 to 13 cm of H₂O) (Breuer and associates, 1956). This would indicate that relatively small changes of portal pressure are associated with marked flow effects and that, consequently, portal venous pressure is an important determinant of total hepatic flow.

As may be seen from figure 261, however,

portal venous pressure is under the influence of a variety of factors. Mesenteric and splenic arteriolar tone regulate inflow, while the outflow is determined by venular tone and hepatic sinusoidal pressure. The latter, in turn, is dependent upon hepatic arteriolar tone and hepatic venous pressure (determined by inferior vena caval pressure) which regulate inflow and outflow in the sinusoids. Active contractions of the portal and hepatic veins are possible additional factors, all capable of altering portal venous pressure and thus influencing total hepatic flow.

Experimental separation of all these variables has not been possible up to now, nonetheless, certain important observations have been made.

Continuous simultaneous direct measurements of hepatic arterial and portal venous flows in anesthetized dogs show the contribution of the portal vein to total hepatic flow as being approximately 65 per cent in one study (Selkurt and Brecher, 1956), and 80 per cent in another (Green and associates, 1959). The effective portal perfusion pressures under these circumstances are 6 and 8 mm Hg, respectively. In such preparations, splanchnic nerve stimulation causes an increase in both hepatic arterial and portal venous pressures, with a concomitant reduction in the corresponding flows. The calculated increases in resistance of the portal venous and hepatic arterial beds approximately equal one another, suggesting an equal degree of splanchnic vasomotor innervation. Compared to the mesenteric bed, they are both less sensitive to vasomotor stimulation. The effects of epinephrine and nor epinephrine are similar to those of splanchnic nerve stimulation, causing, however, a less marked increase in the resistance of the portal bed. Thus, even though portal vein and hepatic artery pressures increase and hepatic arterial blood flow diminishes, portal flow does not change much and may even increase (Green and associates, 1959). In fact, the net effect of epinephrine in the resting, nonanesthetized human is an increase of total hepatic flow, as estimated by indirect Bromsulphalein retention (BSP) measurements, along with an elevation of portal venous pressure (Bradley, 1952). Norepinephrine under similar conditions causes a decrease of estimated liver flow in man (Bearn and co workers, 1951), while in normal, anesthetized dogs, it has no flow effect (Smythe and associates, 1953).

The hemodynamic properties of the hepatic vascular bed and the nervous and humoral controls exerted on it play an important part in cir-

culatory homeostasis by adjusting splanchnic blood flow in response to varying body needs. Blood flow through the splanchnic bed is sufficiently large to enable it to serve as a reservoir. The circulating splanchnic blood volume in man at rest and in the anesthetized dog, measured by isotope dilution techniques, forms approximately 20 per cent of the total blood volume (about 1000 cc in man) (Bradley and coworkers, 1953). Splanchnic blood flow (i.e., the total amount of blood perfusing the liver through the hepatic artery and portal vein), estimated by the BSP method, amounts to approximately 1,500 cc per minute in man, or about 20 per cent of the resting cardiac output.

Changes in splanchnic hemodynamics occur under various physiological and pathological conditions. In man, occupation of the erect position is associated with widespread reflex vasomotor adjustments opposing the hydrostatic forces which would lower the blood pressure in the upper half of the body (see ch 22). The splanchnic bed is an important effector end organ in these reflexes. Passive tilting of human subjects from supine to upright position causes a decrease of splanchnic blood flow without similar changes of mean blood pressure, indicating that an increase in splanchnic vascular resistance has occurred (Culbertson and associates, 1951). This channels blood to other vascular areas, notably those in the upper regions of the body. In subjects with previous splanchnicectomy, the same tilting procedure causes arterial hypotension and a proportional decrease of splanchnic blood flow without changing the vascular resistance (Wilkins and coworkers, 1951). This would indicate that the vasoconstriction is normally mediated through the splanchnic sympathetic nerves.

Vasomotor adjustments and redistribution of circulating blood are also prominent during exercise. In normal human subjects, performing light exercise in the recumbent position, circulating splanchnic blood volume and splanchnic blood flow decrease significantly (Wade and associates, 1956). As exercise is usually associated with an increase in arterial blood pressure and cardiac output (see ch 18 and 23), the reduction in splanchnic flow must be caused by increased vascular resistance. The advantages for the organism of such vascular adjustments are evident, vasoconstriction diverts blood flow to those organs that need it most (e.g., the exercising muscles). Moreover, the extra blood derived from the reduction in circulating splanchnic blood volume serves to boost

venous return, thereby contributing to the elevation of cardiac output

Finally, the splanchnic circulation plays an important role in the response of the organism to a reduction of circulating blood volume, such as occurs after hemorrhage. This response is conditioned to a great extent by the amount of blood lost, and it may vary, accordingly, from transient vasomotor changes to a state of irreversible circulatory collapse resulting in death.

It might be expected from the splanchnic responses to tilting and to exercise that blood loss would produce vasoconstriction in the splanchnic bed, in order to maintain flow in other parts of the body such as the brain and heart. This is not the case, however, as shown by animal experiments.

Acute removal of about one third of the total blood volume of the anesthetized dog results in a fall of cardiac output, mean arterial pressure, splanchnic flow (as measured by the BSP method) and splanchnic blood volume. The changes following this degree of blood loss are, in general, reversible. Splanchnic flow decreases in proportion to the fall of blood pressure, without significant change in splanchnic resistance. Thus, the splanchnic bed, unlike the vasculature of skin, skeletal muscle and kidneys, does not participate in the systemic vasoconstriction following hemorrhage. On the other hand, splanchnic blood volume diminishes to a greater extent, proportionally, than the reduction in total blood volume (Reynell and associates, 1955). Removal of larger amounts of blood, resulting in irreversible shock, produces more marked but qualitatively similar changes in hemodynamic parameters. The metabolic consequences, however, are quite different. Splanchnic oxygen consumption is not affected by the moderate blood loss, the diminished flow is compensated for by increased oxygen extraction by the tissues (Hamnick and Myers, 1955). With more massive hemorrhage, however, blood flow is so reduced that this compensation is inadequate and splanchnic oxygen consumption falls, resulting in hepatic hypoxia.

Thus, the splanchnic hemodynamic response to hemorrhage is a reduction of splanchnic blood volume rather than an increased resistance to flow. Diminishing the store of blood contained in the splanchnic bed amounts to an "auto transfusion" and tends to re-establish the circulating blood volume. On the other hand, the failure to increase local vascular resistance indicates the priority given to the maintenance of adequate splanchnic oxygenation. The latter seems to be

of great importance for the organism, as a factor in determining the outcome of hemorrhagic shock. Indeed, it was shown that oxygenation of the liver (Frank and associates, 1946), or of the intestine (Lillehei, 1956), by perfusion through the splenic vein or superior mesenteric artery, protects dogs from the otherwise fatal outcome of shock induced by massive hemorrhage. The exact mechanism whereby splanchnic hypoxia contributes to the irreversibility of shock is not known. One current hypothesis postulates the elaboration of vasotoxic substances by the hypoxic intestine, and the failure of their removal or detoxification by the hypoxic liver (Selkurt, 1959).

Renal Circulation

Renal circulation and renal function are so closely interrelated that reference to only one without consideration of the other always has to be artificial and incomplete. Also, much of our knowledge about renal blood flow stems indirectly from the behavior of some special functions of the kidney. The reader is referred to the chapter on "Urine Formation" where renal function, the anatomy and the clearance method for renal blood flow measurements are considered in detail.

METHODOLOGY OF RENAL BLOOD FLOW The renal blood flow in man is usually measured by the clearance technique. There are some restrictions necessary in connection with this method: (1) rapid changes in the renal blood flow cannot be detected since a single clearance period covers 5 to 15 minutes and gives only average values during this time, (2) determinations can be carried out only when urine is produced at the same time, since, for the calculation of renal blood flow, it is necessary to know the amount of the clearance substance (usually paraaminohippuric acid) which is excreted in the urine. For example, in shock and in certain renal diseases, when no urine is produced, renal blood flow cannot be evaluated by this method. (3) The urine formation is also stopped when the arterial blood pressure is less than 50 mm Hg, since the hydrostatic pressure in the glomerular capillaries is insufficient to produce a glomerular filtrate.

In order to get a more exact picture of the renal hemodynamics, it was necessary, therefore, to turn to animal experiments. Nearly all the direct and indirect methods for the measurement of blood flow described in chapter 18 have been applied in these animal experiments. However, these methods fail to elucidate the pattern of distribution of the intrarenal blood flow. During

the last two years, two methods have been developed to separately determine the blood flow of the renal cortex and medulla (1) Under certain circumstances the accumulation rate of a substance in a tissue can be used as a measure of the blood flow. This method has been applied to the determination of blood flow to the different renal areas. When radioactive albumin is introduced into the arterial circulation, the radioactivity builds up in the tissue. The rate of accumulation of the radioactivity is a function of the blood flow to the region. (2) The other method utilizes the transillumination of the different parts of the kidney by implanted micro light sources. The intensity of the transmitted light is measured by micro photo cells which are either inserted under the renal capsule for measurement in the cortex, or placed against the papilla for measurement in the medulla. After a single injection of dye (Evans blue) into the renal artery, dye dilution curves can be recorded in different areas (fig. 26.4), permitting calculation of the mean circulation time. (3) In addition, blood volume (V) in the different areas can be calculated in accordance with the spectral characteristic of hemoglobin. The logarithm of the ratio $(I_{0.67})/(I_{0.750})^1$ is proportional to the hemoglobin concentration in the tissue (Hb_{tissue}). Knowing the local intravascular hemoglobin concentration (Hb_{blood}), the ratio $(Hb_{tissue})/(Hb_{blood})$ therefore represents the blood volume (V) in the tissue. According to the Stewart Hamilton formula, the ratio $(V)/(t)$ represents the blood flow in different areas.

NORMAL RENAL BLOOD FLOW Under resting conditions, in the recumbent position, and with a normal mean arterial blood pressure about 100 mm Hg, about 1200 cc of blood per minute pass through both human kidneys, or about 20 per cent of the cardiac output. This is called the renal fraction of the cardiac output. Since the average weight of both kidneys is about 300 gm, normally 1 gm of kidney is perfused by 4 cc of blood per minute. However, this value is only an average for the whole kidney since there are great differences in the distribution of the blood supply within various renal areas. Blood flow values per gram of tissue have been found to be similar in dogs (4 to 5 cc per gm per minute). However, smaller animals have a greater renal perfusion rate. Values up to 10 cc per gm per minute have been obtained in rats by the PAH clearance method. For a better comparison

FIG. 26.2 Pressure gradients in the mammalian renal circulation

of values obtained from different laboratories, it has become the custom to express renal blood flow in cc per gm per minute.

In the kidney, there are two capillary beds connected in series: the glomerular capillaries and the peritubular capillaries. They are separated by the vasa efferentia, which functionally and anatomically behave like arterioles. The main resistance to flow in the kidney is divided almost equally between the vasa afferentia (preglomerular) and vasa efferentia (postglomerular), and thus the main pressure drop occurs in these segments (fig. 26.2). It has been demonstrated by micropuncture studies in the cortex of mammalian kidney, that the hydrostatic pressure in the peritubular capillaries is usually 14 to 18 mm Hg, and is about the same as the hydrostatic pressure in the proximal tubules. At the present time, there are no direct measurements of the hydrostatic pressure in mammalian glomerular capillaries. However, by indirect calculations, this pressure has been assumed to be normally in the range of 60 to 70 mm Hg.

Ever since the investigations of Wirtz and associates showed the significance of the renal medulla upon the concentrating mechanism of the kidney, and the functional difference of this area from the renal cortex, interest has grown in

¹ $I_{0.67}$ = transmitted light during 100 per cent oxygen saturation of hemoglobin. $I_{0.750}$ = transmitted light during 0 per cent oxygen saturation of hemoglobin.

FIG 263 Blood flow rates (cc per gram per minute) in different areas of the dog kidney

FIG 264 Dye dilution curves in the renal cortex and medulla of the dog after rapid injection of Evans blue into the renal artery (11 a ren). The passage of Evans blue was measured by small photocells which separately picked up reflected light from this cortex (upper curve) and transmitted light through the medulla (middle curve). The photocells were sensitive at the Evans blue absorption wave length (640 mμ). The lower curve represents systemic blood pressure (BP). (From Kramer K. and associates Pflüger's Arch ges Physiol 1960 270, 251)

the distribution of total renal blood flow to the component parts of the kidney. Up to the present all the data on the intrarenal distribution of blood flow are the results of experiments in dogs because of the operative procedures involved in obtaining these measurements. The results show that the perfusion rate in the renal cortical tissue is much greater than in the medulla (fig 263) and indicate that only 1 to 2 per cent of the total renal blood flow passes through the inner medulla. Thus low blood flow in the inner medulla is associated with a low velocity of the blood in the vasa recta of the medulla. The mean circulation time of the blood through the vasa recta is about 50 seconds, and only about 2.5 seconds through the cortical capillaries (fig 264). On the other hand the vascular volume in the cortex and in

the medulla seems to be the same in both areas, the vascular volume has been calculated to be about 20 to 22 per cent of the tissue volume. More than one factor is known to cause this low velocity of blood in the vasa recta. The resistance to flow in these vessels is very high because of the unusual length (as compared to other capillaries) of the vasa recta which may be as long as 20 mm. The composition of the blood is changed as it passes through the medulla especially when the end urine is highly concentrated. The medullary blood becomes more and more dehydrated as it reaches the tip of the papilla, by transmembrane shunting of water from the descending to the ascending limb of the vasa recta. This water shunt mechanism results in a diminution of the intravascular blood volume and in an increase of the blood viscosity. Thus the unusual length of the vasa recta, the decreasing intravascular blood volume and increasing blood viscosity all contribute to the low velocity of medullary blood flow.

INTRARENAL HEMODYNAMICS AND RENAL FUNCTION Intrarenal hemodynamics and renal function are so interrelated that change in one will always affect the other. An increase in the cortical blood flow, if correlated with elevated glomerular capillary pressure, causes an increase in the glomerular filtration rate. In these circumstances the excretion of osmotically active substances will be increased. This latter effect is partially caused by an increase in the tubular load, i.e., a greater amount of osmotically active substances offered to the tubules by the increased glomerular filtration rate. On the other hand in the presence of an increase in cortical blood flow there is a concomitant increase in the peritubular capillary

pressure which, by itself, may affect the total excretion by means of decreased proximal tubular reabsorption

Medullary blood flow seems to be important for the concentrating ability of the kidney. In the renal medulla, the osmotic pressure progressively increases from the base to the tip of the medulla and becomes a determinant in the concentration of the final urine delivered to the renal pelvis. An increase of blood flow in the medulla tends to wash out the osmotically active substances from this area, decreasing the osmotic pressure and causing a lower concentration of the final urine. In this manner, renal function is affected by primary changes in medullary blood flow and, conversely, medullary blood flow may be affected by primary changes in renal function. In water diuresis, the medullary blood flow is greater than in antidiuresis. The cortical blood flow and the glomerular filtration rate are unchanged under these circumstances.

AUTOREGULATION OF RENAL BLOOD FLOW The blood flow (F) in an organ is directly proportional to the arteriovenous pressure gradient ($P_a - v$), and inversely proportional to the resistance (R), i.e., $F = (P_a - v)/R$. In most organs, when only the arteriovenous pressure gradient increases, the blood flow increases more than the increase in pressure gradient, meaning that there has been a concomitant decrease in the resistance caused by the passive distention of the vessels with pressure. The pattern of behavior of the renal blood flow is different; it reacts in the manner just described at perfusion pressures only up to 90 mm Hg. However, when the arterial perfusion pressure rises above 90 mm Hg, the resistance increases so that the total blood flow in the kidney remains nearly constant (fig. 26 6, curve N). Above 250 mm Hg the blood flow again becomes directly dependent on the arterial pressure. This phenomenon is known as the autoregulation of renal blood flow because it is also present after cutting the renal nerves, after injecting ganglioplegic drugs, and in the isolated perfused kidney.

Simultaneous measurements of blood flow in the cortex and inner medulla of the kidney have shown that autoregulation is present solely in the cortex. Since only about 1 to 2 per cent of the total renal blood flow passes through the inner medulla,¹ a solitary increase in medullary blood flow does not actually cause a measurable increase of total renal blood flow. Therefore, in the presence of a rising arterial perfusion pressure, the total renal blood flow remains nearly constant in spite of an increasing medullary blood flow.

Hence, it is more accurate to limit discussion of autoregulation solely to the cortical blood flow.

There are at the moment, three theories which attempt to explain this special behavior of the renal blood flow.

A Myogenic theory When the arterial perfusion pressure is increased, the vessels become distended. The smooth muscles, especially in the preglomerular vessels, react to this distention by shortening, thereby constricting the vessels so that a new high resistance is established. Thus implies that the tonus of the vessels is increased by an autonomic myogenic reaction to increasing arterial perfusion pressure.² It has been demonstrated in the dog kidney that when the arterial perfusion pressure is suddenly increased the blood flow is only increased passively during the first 3 to 4 seconds. Following this, the resistance in the vascular bed increases to such an extent that the blood flow nearly ceases at about 15 seconds. After 20 to 30 seconds, the blood flow increases to the normal level of the autoregulation (fig. 26 5). This initial latency and the phasic changes of the resistance are in accord with the contracting properties of smooth muscle. The autoregulation can be abolished by drugs which paralyze the smooth muscles (potassium cyanide, papaverine, and procaine (novocaine) in high concentration). Likewise, the phasic changes of the resistance, caused by rapid pressure increases, are removed by these drugs (fig. 26 5).

There are experimental indications that the autoregulatory mechanism resides within the preglomerular vessels. The glomerular filtration rate is controlled, among other things, by the intraglomerular capillary pressure. The constancy of the glomerular filtration rate and its independence from arterial perfusion pressure changes above 90 mm Hg, constitutes indirect evidence of a constant, intraglomerular capillary pressure. Furthermore, by paralyzing the vascular smooth muscles with papaverine, the glomerular filtration rate now becomes directly proportional to the arterial perfusion pressure. Thus, there is strong evidence to support the contention that the auto-

² Contraction of the smooth muscles as the result of elevated intravascular pressure has been described for many vascular systems. In contrast to the kidney, these myogenic reactions are not powerful enough to constrict the vessel to such an extent that blood flow remains constant in spite of an elevated perfusion pressure. It is not necessarily true that the single muscle cell of the renal vessel reacts differently than in other organs. A spatial arrangement of the muscle cells, specially oriented, can increase the net effect of the single cell contraction on the diameter of the vessel.

FIG. 26.5 Pattern of flow in the renal artery of dogs following sudden increase in the arterial perfusion pressure from 0 to 150 mm. Hg before and after vascular muscle paralysis by papaverine. The phasic changes in renal blood flow in the normal kidney indicating a concomitant inverse change in resistance can be abolished by papaverine. The steady state blood flow of 4 cc per gram per minute at 150 mm. Hg in the control (autoregulated kidney) is increased under papaverine to about 9 cc per gram per minute. (See also figure 26.6 difference between curve N and curve O at 150 mm. Hg) (Modified after Thureau K and Kramer K. *Pflüger's Arch. ges. Physiol.* 1959 269, 77)

regulatory mechanism depends upon the integrity and reactivity of the preglomerular vascular muscles.

B Cell separation theory In a vascular system in which small vessels branch off from a large one, the small vessels receive cell poor plasma from the outer zone of blood in the large vessel, because the erythrocytes remain in the axial stream of the large vessel. This separation of plasma and erythrocytes at the bifurcation of vessels is called plasma skimming or cell separation. For the kidney, it is assumed that this cell separation takes place to an unusual degree at the origin of the afferent arterioles. The blood remaining in the interlobular arteries becomes more and more concentrated with erythrocytes and flows through special erythrocyte shunts directly into the veins without flowing through the peritubular capillaries, which are perfused only by cell poor plasma. The degree of the cell separation is supposed to be dependent on the arterial perfusion pressure, so that blood with a hematocrit up to about 80 per cent in the distal part of the interlobular arteries can be produced. In this range of hematocrit, the viscosity of the blood is high and varies greatly with small changes in hematocrit. This variable viscosity which is dependent on the arterial blood pressure, is believed to be the cause of the variable resistance responsible for the autoregulation. According to this theory, a cell free perfusion of the kidney should not show any

autoregulation. However, it has been demonstrated by different investigators that autoregulation does occur even when the kidney is perfused by dextran, a cell free plasma, or blood with a very low hematocrit. It would, furthermore, be expected that the oxygen saturation of the blood in the distal peritubular capillaries should be lower than that in the mixed venous blood. However, investigations have shown that the oxygen saturation in this area is not different from that in mixed venous blood. Also, the passage times of plasma and erythrocytes from the renal artery to the renal vein are the same, but, according to the cell separation theory, they should differ.

C Intrarenal pressure theory By insertion of a 24 gauge needle into the renal tissue, it was found that the intrarenal tissue pressure measured in this way increases disproportionately with increasing arterial perfusion pressure. From this data, it is calculated that the elevated tissue pressure has a clamping effect on vascular geometry and resistance to flow. This assumes that the needle pressure selectively measures only normal tissue pressure and that no vessels have been ruptured by the needle insertion. In any case, measurements of the intracapillary and intratubular pressures in the rat kidney by the micropuncture technique have shown that these pressures do not change when the arterial perfusion pressure is elevated above 90 mm. Hg.

The present great interest in the investigation of autoregulation of renal blood flow may introduce some new theories in the future. At the present time, however, the myogenic theory is the most favored.

NERVOUS CONTROL OF RENAL BLOOD FLOW The highly developed plexus renalis contains sympathetic and parasympathetic fibers. However, under normal physiological conditions, not too much is known of the significance of this rich nerve supply to the kidney. The interpretation of the results of experiments with regard to the nervous control of renal blood flow is complicated by the fact that the vascular system of the kidney has an autonomic and variable tonus which is independent of any innervation (see autoregulation of renal blood flow) and may interfere with nervous vascular reactions. For a better understanding of this vascular behavior, see figure 26.6 which shows pressure flow curves resulting either from change of nervous vascular tonus or from autonomic tonus.

Much investigation has been going on to gain information about the nervous control of the renal blood flow under resting conditions. Renal

blood flow has been measured before and after denervation of the kidney

In *unanesthetized* man and animals in recumbency, the renal blood flow of the denervated kidney does not differ from that of the innervated kidney. This implies that under resting conditions there is no sympathetic nervous influence in the renal vascular bed. Furthermore, the nonexistence of a sympathetic tone of the renal vascular bed, under resting conditions, has been confirmed by animal experiments in which depressor reflexes in the systemic circulation were produced. Stimulation of the reflexogenic areas of the carotid sinus and aortic arch causes vasodilation in the kidney only when a sympathetic tone of the renal vessel has been *previously* produced by asphyxia or by anesthesia.

In anesthetized animals it has been shown that the renal blood flow may increase after denervation but, since the sympathetic tone in the peripheral vascular bed is usually augmented during anesthesia the denervation therefore eliminates only the unphysiological sympathetic stimulation produced by the anesthesia and thereby permits return of the blood flow to normal values. Accordingly, in a dog where one kidney is denervated the renal blood flow decreases only in the innervated kidney during pentobarbital injection. The blood flow of the denervated kidney shows no change.

Neurogenic vasoconstriction of the renal vessels is produced by severe hypoxia, i.e., arterial oxygen saturation below 50 per cent. However, in the range of decreasing arterial oxygen saturation between 100 and about 50 per cent, there seems to be no change in renal blood flow, and this is true either in anesthetized dogs or in *unanesthetized* man. The vasoconstrictor effect of severe hypoxia can be eliminated in the dog by abolishing the chemoreceptors in the carotid sinus and aortic arch, indicating that the constrictor response to hypoxia is induced by stimulating the peripheral chemoreceptors.

Vasoconstriction in the dog kidney also occurs during hypercapnia while breathing a mixture of 5 to 30 per cent CO_2 in oxygen. In these experiments, the pH of the blood simultaneously decreased from 7.49 to 7.21. Since the constriction is abolished by renal denervation, hypercapnia and this degree of acidosis seem to produce only neurogenic rather than local vasoconstriction.

A decreased discharge rate of the pressoreceptors in the carotid sinus or aortic arch in dogs, caused by lowering the intrasinus or intra aortic blood pressure, or by damping the pulse pressure

FIG. 26.6 Pressure flow curves in the kidney. The thin lines through the origin of the graph represent equal resistances to flow expressed in terms of $\frac{\text{mm. Hg}}{\text{cc}}$ per gram per minute.

Curve 1: Pressure flow curve under normal conditions. The increase of resistance above 80 mm Hg is independent of extrinsic factors (see autoregulation of renal blood flow). Curves 2 to 6: Pressure flow curves with increasing vascular tone secondary to various extrinsic factors such as increase sympathetic stimulation or epinephrine. With increasing extrinsically induced vascular tone the pressure flow curves become more and more linear simultaneous to a decrease in autoregulation. Curve 0: Pressure flow curve after paralyzing the smooth muscles of the renal vessels. Note the abolition of autoregulation; also note that under normal conditions (curve 1) there is no myogenic tone in the renal vessels between 0 to 80 mm Hg.

in these areas, leads to neurogenic vasoconstriction in the kidney as well as in other organs.

In connection with the nervous control of the renal blood flow, the question also arises as to whether or not there exists a nervous control of the function of the tubular cells. After denervation of the kidney, an increase of sodium excretion is often found, suggesting a decreased absorptive capacity of the tubular cells. However, in nearly all these experiments the glomerular filtration rate simultaneously increased. It is well known that this increase of the glomerular filtration rate can cause an elevated sodium excretion without altered tubular function. Moreover, those experiments in which the excretion of electrolytes was increased *without* a corresponding increase in the glomerular filtration rate, by no means prove a primary changed tubular function after denervation. As yet, it is still unknown whether changes of the intrarenal distribution of blood flow occur after denervation since, for example, even small changes in medullary blood flow can affect the composition of the end urine.

Exercise, posture and central blood volume. Effects on renal blood flow. In the upright exercise-

ing man, renal blood flow is diminished when compared to blood flow under resting conditions while supine. If, however, exercise is performed in recumbency, the blood flow in the kidney remains nearly unaffected. Also, the dog, which usually does not change its posture during exercise, shows no change in renal blood flow when running 5.6 to 10 mph at a 15° slope on a treadmill.

These findings give rise to the supposition that the upright position *per se*, in which exercise is usually performed, leads to the decrease in renal blood flow. Indeed, it has been found that the usual response on changing from the recumbent to the standing position is a decrease in renal blood flow. Under the extreme conditions of prolonged standing, the renal blood flow may decrease by about 50 per cent of the control value. These changes are accompanied by similar reductions in glomerular filtration rate and urine output. Since the arterial blood pressure is little or unchanged, the reduction in renal blood flow is primarily caused by an elevated resistance to flow. This is only part of a generalized elevation in total peripheral resistance secondary to the upright position. This enhanced peripheral resistance is caused by an augmented neural vasoconstriction rather than by a humoral mechanism. The afferent mechanisms involved are poorly understood but it is believed that this can be effected through reduction of central blood volume. The central blood volume in the thorax can be reduced to subnormal values by means of positive pressure breathing. It has been shown, that under these circumstances the renal resistance to flow increases. Since the blood volume in the chest is also diminished in the upright position, this reduction in central blood volume, induced by changing from the recumbent to the standing position, may be one factor involved in the renal constrictor mechanism. Conversely, an increase in central blood volume above normal by blood infusion, tilting of the body to the head down position, or negative pressure breathing, should produce a neurogenic vasodilation in the kidney. But, as pointed out in the preceding section on nervous control of renal blood flow, under normal resting conditions there are no sympathetic discharges to the renal vessel, and hence a neurogenic vasodilation is nonexistent. It is not surprising, therefore, that an increase in central blood volume fails to result in a renal vasodilation. However, there is another interesting effect of an increased central blood volume upon the kidney which should be briefly mentioned here. It has been found that elevation of central blood

volume simultaneously increases the urine output. Since renal blood flow and also the glomerular filtration rate are not altered under these conditions, and, since the resultant diuresis is caused primarily by an increased free water excretion (i.e., without concomitant excretion of osmotically active substances), there is strong evidence that an increase in central blood volume inhibits antidiuretic hormone (ADH) secretion of the neurohypophysis. It is suggested that this ADH inhibition is reflexly induced by stimulation of stretch receptors located predominantly in the left atrial wall and sensitive to an increase in central blood volume. Whether this mechanism has any significance in the regulation of the total blood volume, is the subject of present investigations.

Returning to the discussion of renal blood flow during exercise in man, there is no doubt that the change to the upright position *per se* is one factor involved in the decreased renal blood flow. But reductions in renal blood flow down to 20 per cent of the control value, as measured in severe exercise in man, can hardly be explained by this orthostatic mechanism alone. It is a matter for further investigations to establish the other factors which determine the changes in renal blood flow during exercise.

The effect of some pharmacological agents upon renal circulation. Epinephrine and norepinephrine both have powerful vasoconstrictor effects upon the renal vessels. Each drug acts upon smooth muscles and its action can be abolished by adrenergic blocking agents. Single intravenous injection of 2 μ g per kg of epinephrine causes complete cessation of renal blood flow. During continuous intravenous infusion of low doses (10 to 15 μ g per minute) of epinephrine or norepinephrine in man, there occurs a 30 per cent decrease in renal flow without change in the glomerular filtration rate. The result indicates that low concentrations of the pressor agents predominantly produce efferent arteriolar constriction. Since the systemic arterial pressure is concomitantly elevated, a small rise in resistance must also occur in the afferent arterioles or, otherwise, there would occur an increase in the glomerular filtration rate. Similar results have been found in the denervated kidney in man. The effect of 2 to 10 μ g per minute of 1 norepinephrine, given intravenously, has been studied in the homo-transplanted kidney of an identical twin recipient and in the innervated kidney of the donor. In both kidneys the renal blood flow decreased 25 per cent, when given 2 μ g 1 norepinephrine, and

50 per cent, when given 10 μ g, without changes in the glomerular filtration rate, revealing the similarity in the response of the innervated and denervated kidney to 1 norepinephrine in an anesthetized man. Despite the decrease in renal blood flow following minute doses of epinephrine, there occurs a moderate swelling of the kidney. Experiments in dogs have shown a simultaneous increase in renal blood volume. It has, therefore, been concluded that an increase in resistance to flow also occurs in postcapillary segments (probably venular) which leads to an elevated intracapillary pressure and a resultant distention of the renal capillaries.

Pitressin is an extract of the posterior pituitaries of oxen and hogs with an antidiuretic vasopressor action. Infusions of 1 to 2 mV per kg per hour, with which significant antidiuretic effects can be produced, have no effect upon the renal blood flow in man. Higher, nonphysiological doses, increase the resistance to flow in the kidney by direct action on the renal vessels. Repeated injections elicit tachyphylaxis.

The injection of serotonin (5 hydroxytryptamine) into the renal artery in dogs, produces constriction of the renal vessels. This constrictor effect has been shown in innervated as well as in denervated kidney and persists after the application of sympatholytic agents. Thus, serotonin probably acts directly on the smooth muscles. However, intravenously injected serotonin may be followed by a renal vasodilation reflexly induced by the action of this drug upon depressor receptors whose afferent fibers arise within the chest and are mediated through the vagus nerve. In patients with malignant carcinoma, the urinary excretion of serotonin or its metabolic products is elevated secondary to the high circulating blood level. In these patients, the glomerular filtration rate and renal blood flow are usually diminished.

1 Hydrozinophthalazine (Apresoline) produces a vasodilation in the kidney which persists for hours following a single injection. The mechanism of the vasodilatory effect is still unknown. It seems that Apresoline has no direct paralyzing effect upon the renal vessels since injection into the renal artery produces an initial vasoconstriction, followed in several minutes by the onset of vasodilation, the latter becoming more marked during the next 30 minutes and persisting for 2 to 3 hours.

REACTIVE HYPEREMIA In both cardiac and skeletal muscles, and in some other organs, the blood flow temporarily increases over the control value after releasing an arterial clamp. This over-

shoot of blood flow, lasting from several seconds to several minutes, depends upon the duration of occlusion and may exceed the estimated blood flow debt incurred during the occlusion period. If the term reactive hyperemia is restricted to this overshoot, then by definition, the renal circulation does not show this phenomenon. After releasing an occlusion of the renal artery, there occurs a brief 3 to 5 second overshoot of blood flow (fig 26-5), which, however, is independent of the duration of occlusion and is, in no instance, greater than the estimated blood flow debt. Furthermore, after interruption of the renal blood flow for several minutes, the re-established blood flow, following the initial overshoot, usually decreases temporarily to subnormal values.

HYROTHERMIA AND RENAL BLOOD FLOW At the onset of the cooling phase, as the body attempts to maintain a normal temperature (shivering phase), the renal blood flow increases 20 to 45 per cent above the control value. This has been observed utilizing paraaminohippurate (PAH) clearances in both anesthetized and unanesthetized man and animals. This initial increase in renal blood flow can be abolished by inhibiting shivering with di-tubocurarine. As the rectal temperature falls below 32° C (90° F) the renal blood flow progressively decreases and, at 27° C (80° F) is only 50 per cent of the normal value. This decrease in blood flow is also observed in the isolated dog kidney which was perfused by cooled blood, and in which the renal blood flow was directly measured. A major part of the decreased blood flow is caused by an increased resistance related to the augmented viscosity of cooled blood but this factor alone, however, is insufficient to explain the degree of change in blood flow. It is still unknown which other nervous or humoral factors are involved.

Regional cooling such as the immersion of an extremity into ice water for some minutes, sufficient to produce a painful sensation, in man is attended by a 20 per cent decrease in renal blood flow. This is probably caused by a nervous reflex, stimulating sympathetic discharges to the renal vessels.

ARTERIOVENOUS OXYGEN DIFFERENCE AND OXYGEN UPTAKE OF THE KIDNEY The oxygen difference between arterial and venous blood in the human kidney (A-V oxygen difference) is about 1.7 cc per 100 cc of blood, which is small compared with an A-V oxygen difference of 4 to 5 cc per 100 cc of blood between arterial blood and mixed venous blood of the right heart. From the renal A-V oxygen difference and the total renal

blood flow (1,200 cc per minute) the oxygen uptake of both human kidneys is calculated to be about 21 cc per minute. In isolated dog kidney as well as in dogs' kidneys *in situ* the A-V oxygen difference has been found to be fairly constant in spite of renal blood flow changes which means that the oxygen consumption in the kidney parallels the blood flow. Up to the present little information is available concerning this phenomenon but data from recent experiments suggest that the increase of oxygen consumption accompanying elevated blood flow is caused by an increase of reabsorptive activities especially for sodium which is believed to be an active oxygen consuming mechanism. The renal oxygen uptake has often been related to 100 gm of renal tissue. Assuming a total weight of 300 gm for the two kidneys the oxygen uptake rate would be 7 cc per 100 gm per minute. However for this latter calculation of oxygen uptake the same restrictions as mentioned for the similar calculation of renal blood flow, have to be considered since the different renal areas have also different oxygen uptake rates.

In the renal cortex of anesthetized dogs the oxygen uptake has been calculated to be 8 to 9 cc per 100 gm of tissue per minute in the inner medulla only 0.3 to 0.4 cc per 100 gm of tissue per minute. Since oxygen uptake and blood flow in the medulla compared to the cortex are diminished by about the same factors the A-V oxygen difference therefore may be the same in both areas and consequently no different than the A-V oxygen difference of the kidney *in toto*.

The A-V oxygen difference in the renal medulla of anesthetized dogs has also been indirectly calculated by means of the oxygen tension of the final urine which is assumed to be in equilibrium with the medullary venous blood. Usually the oxygen tension in the urine is less than in the mixed renal venous blood and in these experiments the difference during air breathing was 20 ± 3 mm Hg. Thus by this method the A-V oxygen difference in the medulla has been calculated to be 8.5 cc per 100 cc of blood which would indeed be very high. However there are indications that oxygen pressure in the medulla may also be influenced by the counter-current exchange mechanism. In this case oxygen pressure would progressively decrease to the tip of the medulla by transmembrane shunting of oxygen from the descending to the ascending limb of the vasa recta. The low oxygen tension of the final urine would represent only the low oxygen pressure at the tip of the medulla rather than the

oxygen pressure of the medullary venous blood and therefore could not be used for calculations of the medullary A-V oxygen difference.

For the outer zone of the renal medulla there exist only determinations of oxygen uptake in excised tissue slices incubated in Warburg vessels. Under these circumstances an oxygen uptake of about 4 cc per 100 gm of tissue per minute has been found.

CONCLUSIONS

Renal hemodynamics exhibit certain peculiarities which need re-emphasis. Under basal conditions there exists no neurogenic tone in the renal vessels and the kidney is protected against elevations of arterial blood pressure by an autonomic mechanism which usually maintains the cortical blood flow, the glomerular filtration rate and the intrarenal capillary pressure at constant levels. A neurogenic vasodilation is generally nonexistent and only vasoconstriction can be produced via the nervous system. This behavior is absolutely contrary to that of the coronary circulation where the experimental physiology up to the present time has demonstrated only dilatory reflex mechanisms. Renal hemodynamics are poorly understood by solely using measurements of the total renal blood flow. The renal artery supplies blood at varying flow rates to the differently functioning areas and function and blood flow seem to be mutually interdependent; this has only been demonstrated in animals. The human kidney however still holds secret its distribution of intra renal blood flow since at the present time techniques applicable for use in humans have not been developed.

REGULATION OF THE CIRCULATION UNDER STATES OF STRESS

Dilation and Hypertrophy of the Heart

CARDIAC DILATION Dilation is an increased capacity of the cardiac chambers brought about by the elongation of the myocardial fibers. This increased capacity may result from many physiological or pathological factors. The force of ventricular contraction increases with increments in diastolic volume until overdistension occurs, and the force of contraction then decreases with a rise in diastolic pressure. An increased diastolic volume is a physiological means automatically brought into play to increase the cardiac work and to mobilize the energy reserves of the heart. The nearer the fibers approach their maximal physiological length during diastole, the greater will be the encroachment upon the heart's reserve. It has also been shown that the oxygen consumption of the heart muscle is proportional to its end diastolic volume (or its fiber length, fig 27 i). Thus, the heart which is supporting a greater load expends a greater amount of energy to attain its cardiac output.

From the above discussion, it can be seen that cardiac dilation can be a compensatory mechanism of the heart in meeting everyday stresses although other factors (humoral and neurogenic) are also important. Dilation also occurs when an increased diastolic volume is secondary to a pathological state. An increased venous return to the heart, an increased outflow resistance, a reflux into the heart chambers or intrinsic myocardial disease impairing the contractility of the muscle may induce dilation. However, the heart cannot continue to dilate indefinitely with an increase in work. A point is reached beyond which further dilation leads to a decline in work. The heart is unable to expel sufficient blood from its chambers, and the activity of the heart is no longer adequate to supply the peripheral tissues with their needs. Therefore, beyond this certain point, dilation becomes detrimental. It is claimed that the diseased heart reached this detrimental

point of dilation with less stretch of the myocardial fibers than the normal heart, but the experimental evidence for this is not adequate. Dilation can be a reversible phenomenon even when caused by pathological states. However, this is not always so, and the heart may continue to fail even when the underlying cause is removed.

CARDIAC HYPERTROPHY The average weight range of the human adult heart is approximately 250 to 350 grams. In disease, 500 grams is not an unusual weight, and hearts weighing 1,000 gms or more are seen. The increased weight of the ventricular muscle is due to an increase in length and diameter of the individual muscle fibers. Lanzbach, in 1947, found this was true of hearts hypertrophied up to 500 grams but, contrary to previous studies, reported a splitting of fibers longitudinally, and thus, an increase in the number of fibers in hearts weighing over 500 grams. With the increase in size of fibers, there is not a corresponding increase in the number of capillaries. Hypertrophy, then, differs from normal growth for, in the latter, the capillaries multiply and keep pace with the muscle as it grows, in hypertrophy the capillaries do not multiply and, per unit of muscle, actually decrease. This could become a limiting factor in the extent of development of hypertrophy especially in hearts with an already compromised blood supply.

The biochemical alterations in the myocardium in hypertrophy have received little study. The electrolyte and fluid concentrations in the intra and extracellular spaces have a normal relationship in the hypertrophied heart of rabbits following the production of aortic insufficiency. In rats exposed to reduced atmospheric pressure and increased environmental temperature to produce hypertrophy, the total protein of the heart increased by 42 per cent. An increase in the fractions containing myoglobin, contractile protein and mitochondria was found. The latter increase may indicate an expansion of the oxygen trans-

FIG. 27.1 Lower chart shows the work done plotted against the oxygen consumed. In calculating the work of the heart the velocity factor (p. 23) was neglected. Upper chart gives data from the same experiment work being plotted against the diastolic volume of the ventricles. The volumes are expressed as x plus known values. The x represents the lowest value of the volume during the experiment which is impossible to measure when a cardiometer is used to record heart volume. This cardiometer enables one to measure only an increase over this minimum value. The figure shows a direct correspondence between work done and ventricular volume. (After Starling and Vischer.)

porting and utilizing systems. The increased fractions in hypertrophy differ from those found in normal growth. This fact, plus the absence of capillary growth, indicate that hypertrophy is not caused by the same process which induces the left ventricle to become the more muscular of the two ventricles after birth.

The mechanical factors leading to hypertrophy are the same myocardial stresses mentioned for dilation, hypertension and valvular disease lead the list of actual diseases. As in dilation, the chamber undergoing the stress may be the only one involved or all chambers may become hypertrophied, including the atria.

The factors which actually induce the cardiac muscle to hypertrophy are unknown. Experi-

ments by Eyster and associates on the production of aortic insufficiency or stenosis in dogs illustrate the basis for the injury theory. These animals showed an early dilation of the heart (by roentgenograms) which disappeared within a few days and was followed by the development of hypertrophy. In dogs relieved of their aortic stenosis during the dilation phase, hypertrophy still developed. The sudden dilation of the heart was theorized to injure the myocardial fibers which led to their hypertrophy. Recently, these experiments have been criticized and repeated. An increase in the heart weight-body weight ratio was found only when the cause of the heart stress was continued and not if the stress was removed during the dilation phase. Also, the theory does not agree with clinical findings which often show dilation not followed by hypertrophy in patients. Other experiments in rats have shown that dilation of the heart caused by a reduced ambient pressure after explosive decompression was reversible and not followed by hypertrophy.

Another explanation for hypertrophy invokes the greater surface area of the muscle as supplying a greater area for nutrition which leads to fiber growth. A defective blood supply, either by a deficient coronary circulation or by an anemia, has been postulated as the cause of hypertrophy. A fourth theory would explain hypertrophy as essentially of hormonal origin in which the somatotrophic hormone of the anterior pituitary plays the leading role. Experiments on rats showed that this hormone produces an increased heart mass in the absence of an increased work load. Thyroxine was found to possess a lesser degree of this activity while cortisone inhibited the effect of the somatotrophic hormone. The work theory holds that hypertrophy is primarily due to the increased load on the heart and experiments demonstrating a hypertrophy of experimental animals' hearts under the stimulus of exercise are cited as evidence.

The above theories and our knowledge of the factors involved in the production of myocardial hypertrophy are inadequate. Animal experimentation is very difficult to evaluate since hypertrophy is usually judged on the basis of the heart weight to body weight ratio. The animals have often gained or lost weight during the experimental period. The degree of myocardial edema must also be taken into consideration as a cause of the increased bulk of the heart. Moderate hypertrophy must be present before microscopic findings are present; animal experiments usually deal with minimal hypertrophy. The most valid

method would seem to be a long term study of a very large group of control and experimental animals of the same weight and breed with a comparison of their heart weights and microscopic findings. A definition of cardiac hypertrophy must take into account the presence of muscle edema, fat, and fibrotic tissue in the muscle being weighed.

In human disease there is a marked difference in the degree of hypertrophy found in response to similar pathological stresses. Some patients with serious hypertensive disease demonstrate little or no hypertrophy at autopsy. Also, the clinical course of patients with heart disease has not been proven to vary from those with as compared to those without hypertrophy. A disease entity exists called "idiopathic" myocardial hypertrophy in which young people succumb to congestive heart failure and the only autopsy finding is myocardial hypertrophy.

Hypertrophy has been called a compensatory mechanism of the heart in response to an increased load whereby the increased mass of the heart permits it to release more energy. Several studies have shown that a hypertrophied animal heart has the ability to react to a further stress, i.e., it has a reserve. Rats who developed cardiac hypertrophy due to aortic constriction were able to raise their cardiac output more than control animals in response to overloading of their circulatory systems. From this experiment, it was concluded that a hypertrophied heart had a greater reserve power than the normal heart. However, the fact that hypertrophy is beneficial to the heart has been questioned. It has been pointed out that the ST-T changes in the electrocardiogram in hypertrophy are similar to those of coronary insufficiency, that hypertensive patients without hypertrophy fare as well as those with increased mass of heart muscle, and that hearts developing hypertrophy after acute cardiac insults do not always improve.

Hypertrophy of the heart may be preceded or accompanied by dilation of the heart. It is claimed that dilation is the immediate response of the heart to stress while hypertrophy is a more gradual developing phenomenon to chronic stress. Experimental data, with the above criticisms in mind, show hypertrophy developing as early as 2 days in rats, and in 2 to 3 weeks in dogs subjected to the stress of hypertension or valvular disease. However, the hypertrophy was based on heart weight to body weight ratios. There is no adequate explanation why some hearts show neither hypertrophy nor dilation, some only one, and some both of these phenomena under the

same pathological conditions. Both have been shown to be occasionally reversible in animals and humans when the stress is removed.

The importance of hypertrophy lies in the fact that it is the response of the heart to most forms of stress. Our limited knowledge concerning the etiology and development of hypertrophy is a major stumbling block in the understanding of the physiology of the heart. It is apparent that improved methods of investigation and measurement of myocardial hypertrophy are needed.

Arterial Hypertension

The blood pressure may be persistently above or below the normal range. These departures from the normal are termed *hypertension* and *hypotension*, respectively. It is difficult to make a sharp separation of the normal from the abnormal, but an elevation above the average normal for a particular age group may be considered to be definitely abnormal. In the adult elevations of systolic pressure above 140 mm Hg and of diastolic pressure above 90 mm Hg are usually considered hypertensive levels although such a sharp distinction is not reliable unless considered in relation to age. The clinical syndrome of hypertension appears to be a result of the elevated diastolic pressure. Usually, the systolic pressure is also raised but it need not be. Also systolic hypertension may occur without a diastolic pressure elevation. Systolic hypertension alone is not believed to be clinically important unless very high levels threaten the integrity of the blood vessels. Systolic hypertension with a decreased diastolic pressure often accompanies a variety of diseases such as hyperthyroidism, heart block with a slow rate and aortic insufficiency. A reduction of blood pressure below the normal range for the age group (systolic below 90 to 110, and diastolic below 60 in adults) is usually termed hypotension.

EXPERIMENTAL RENAL HYPERTENSION

Experimental hypertension most similar to essential (of unknown etiology) human hypertension is that following renal artery constriction. Moderate to severe chronic constriction by a special clamp of a renal artery in the dog, which causes a definite and immediate reduction in renal blood flow, is followed by a rise in systemic blood pressure. However, this hypertension usually persists for only a few weeks. (In the rabbit, rat, goat and sheep, hypertension lasting many months generally follows constriction of one renal artery.) In the dog, permanent (years) systemic hypertension follows constriction of both

FIG. 27-2 Demonstration of renin in the blood of a patient with acute glomerulonephritis and hypertension. Blood pressure curves are those of a cat under dial anesthesia. The figures above the curves indicate the rise in blood pressure in mm Hg. 2—Response to injection of unincubated control equivalent to 10 cc serum. This response, it will be observed, is about the same as that given by the saline control (1). St. A—Response to 0.75 cat unit of standard hypertensin. S—Response to 10 cc physiological saline. 1—Response to incubated sample equivalent to 5 cc serum. When calculated for renin, this is equivalent to 2.4 cat units of renin per 10 cc serum. 3—Response to sample incubated with hypertensinase. Note that this gives approximately the same rise as the saline control. St. B—Response to 1.2 cat units of standard hypertensin (after Dexter and Haynes).

renal arteries, constriction of one renal artery with subsequent removal of the other kidney, or wrapping of both kidneys in silk or cellophane. The latter is presumably the result of ischemia induced by compression of the renal parenchyma by the thick membrane of connective tissue which develops under the silk or cellophane. This type of hypertension is benign and lasts for years. Its manifestations are almost identical with those seen in the benign phase of human essential hypertension, for there is an increase in systemic blood pressure, total peripheral resistance and left ventricular hypertrophy, but a normal heart rate, cardiac output, blood volume and renal excretory function (by the usual tests which may not be sensitive enough to detect early changes). By more extensive constriction of both main renal arteries, there results hypertension, impairment of renal function, and appearance of some chemical substance in the blood which causes development of a fulminating type of hypertension, closely resembling the malignant phase of essential human hypertension, characterized by arteriolar hyaline degeneration and necrosis in all vascular beds. Even the kidney with the constricted renal artery may show severe vascular damage when the blood pressure is greatly elevated (in rats). By severely constricting one renal artery and tying off the ureter of the other kidney, these lesions develop in the arterioles of the kidney with intact renal artery and with its ureter tied off.

HUMORAL FACTORS The pathogenesis of the early phase of sustained hypertension is not clearly understood but a neural reflex from the

ischemic kidney is not the cause since renal denervation, splanchnic, and total sympathectomy fail to interfere with development of hypertension from renal artery constriction. The early phase of hypertension is caused by some humoral mechanism since release of the clamp or excision of the kidney, in an animal hypertensive because of constriction of one renal artery, restores a normal blood pressure.

The humoral pressor mechanism for the early period of hypertension is explained either by failure of the kidney to produce an essential agent in the absence of which hypertension develops, or by the release of a pressor substance from the ischemic kidney. Pressor substances may not only arise from an ischemic kidney but pressor enzymes and polypeptides may have a non-renal origin.¹ An abundance of evidence supports the view that the pressor mechanism of acute renal ischemia is mediated by the release of a humoral substance, renin. Renin is a proteolytic enzyme free from any direct pressor effect. It acts on an alpha 2 globulin substrate in plasma to produce angiotensin (angiotonin or hypertensin). The alpha 2 globulin is produced, apparently, in the liver, since it disappears from the blood after hepatectomy. Two different chemical forms of angiotensin have been obtained in purified form. The decapeptide, angiotensin I, is the initial product of the action of renin on its substrate, and lacks pressor activity. This decapeptide is transformed to the vasoconstrictor octapeptide, angiotensin II, by a chloride activated enzyme of the plasma. The octapeptide has been synthesized. Failure to consistently find renin by assay methods in humans or animals who have renal hypertension of long standing, has caused doubt that this theory explains the chronic phase of the disorder. However, Dexter and Haynes, (fig. 27-2) and Skegg and his associates have demonstrated circulating angiotensin in the peripheral blood of hypertensive patients, large amounts were found in dogs with acute renal hypertension and in patients with malignant hypertension but barely increased levels in patients with benign essential hypertension. Possibly the methods are too insensitive for accurate assay since renin and angiotensin can either not be recovered or only in small amounts from the blood of an animal that has been made acutely hypertensive due to

¹A vasoconstrictor substance (pepsitensin) closely resembling angiotensin in its effects has been obtained by the action of pepsin upon plasma globulin.

TABLE 27 1

Summary of effects of injections of renin on blood pressure and antirenin titer in 61 renal hypertensive dogs with hypertension of 4 to 36 months' duration

Each symbol represents treatment results in one renal hypertensive dog. 0, no antihypertensive effect, +, decrease in blood pressure one third toward normotension, ++, decrease in blood two thirds toward normotension, +++, decrease in blood pressure to normotension. Four different preparations of hog renins were used. Antirenin titer is expressed in antirenin units per milliliter. (From Wakerlin, G. E., *Circulation*, 1958, 17, 653.)

Maximum antirenin titer	Antihypertensive Effect of Hog Renin

renin or angiotensin infusion. However, the blood pressure of a dog hypertensive for months to years from constriction of the renal arteries can be returned to normal by repeated injections of renin resulting in the development of antirenin in the blood (table 27 1). This is convincing evidence that the humoral mechanism is still active in elevating the blood pressure. Unfortunately, this procedure is not effective in humans.

Renin is confined to the cortex of the kidney. Although previous studies supported a tubular origin of renin, recent reports demonstrated renin only in areas of the kidney which contained glomeruli and not in purely tubular areas. As postulated many years ago, by Goormastigh, the juxtaglomerular cells may be the source of renin. These cells contain granules which exhibit histochemical properties similar to those of renin. There was a good correlation between the number of these granules and the renin content of the kidney (Marshall and Wakerlin). More recent studies by the Hartrofts and by Tobian demonstrated that the granularity of the juxtaglomerular cells increased or decreased when renin would be expected to be increased or decreased, respectively, according to the animal's blood pres-

sure. Also, fluorescent antirenin antibodies have been demonstrated to attach to these granules.

The stimulus for the production or liberation of renin by the kidney is not known. It is denied by Page that ischemia of the kidney is itself responsible, for, though the immediate effect of constriction of the renal artery is a fall in pressure in the vessels of the kidney, and a reduction in blood flow, later on the renal blood flow may return to normal. Nor did anoxia of the renal tissue seem to be a necessary condition for the development of renal hypertension, because no increase over the normal was found in the arteriovenous oxygen difference of the ischemic kidney (Levy and associates). Moreover, anoxia induced by cyanide does not cause renin to appear in the circulation although a kidney so poisoned produces renin when the renal artery is clamped.

Kolff and his associates have shown that the production of a "renin" response from constriction of canine renal arteries occurs irrespective of a pulsatile or nonpulsatile (by use of a de pulsating chamber) renal blood flow. It has been postulated that the release of renin from the kidney may be secondary to changes in the transmural pressure affecting renal vascular

baroreceptors The latter theory has been elaborated with the juxtaglomerular cells as the baroreceptors, for the granularity of these cells varies with changes in perfusion pressure

Ischemia of one kidney without interference with the kidney of the opposite side is not followed by permanent hypertension, nor is the elevation of blood pressure, even while it lasts, as great if a normal kidney is present, the return of the blood pressure to normal after excision of an ischemic kidney is much less rapid if the opposite kidney is also removed. Also, in order to demonstrate the maximum effect of the pressor substance liberated by the ischemic kidney, a recipient animal must first be nephrectomized. Finally if both kidneys are removed from rats, hypertension will develop if the animals are kept alive. These facts show that the presence of a normal kidney evidently has a protective effect, and are the basis for the "renoprival" theory of hypertension. The normal kidney may produce some material which lowers the blood pressure, or it may destroy or excrete a pressor substance. Excretory removal is not likely, for the diversion of urine into the bloodstream does not result in hypertension. The fact that removal of a unilateral ischemic kidney causes the blood pressure to return to normal, and that antirenin, which lowers the blood pressure in chronic renal hypertension, has no effect when both kidneys are absent, show that renoprival and chronic renal hypertension are probably unrelated in etiology.

Braun Menendez and his associates demonstrated the presence in normal kidney tissue of an enzyme which inactivates the pressor principle (angiotensin). This enzyme, called *hypertensinase* by its discoverers, and *angiotensinase* by Page and his colleagues, is possibly responsible for the effect exerted by normal kidney tissue upon the development and severity of renal hypertension. *Hypertensinase* is also found in intestinal mucosa, pancreas, as well as in the erythrocytes, minimal amounts are present in liver and in serum. Attempts to obtain a material from extracts of normal kidney tissue which would neutralize or inactivate the pressor substance responsible for clinical hypertension have not, so far, been very successful.

Two other possible humoral pressor systems in the kidney warrant brief mention. Helmer and associates found an increased concentration of sustained pressor substance (SPS) in the renal vein blood of chronic renal hypertensive rats. The relation between SPS and renin is not clear, but it may be a precursor or derivative of renin

Shorr and his colleagues suggest that hepatorenal factors enter into the mechanism of renal hypertension. They demonstrated that constriction of the renal artery by a clamp caused the appearance in the blood of the renal vasoexcitatory material (VEM) which normally cannot be detected. A little later, the hepatic vasodepressor material (VDM) was found in low concentration in the blood, it increased progressively until in the chronic hypertensive phase, it counteracted the action of VEM. More evidence is needed before the VEM-VDM system can be assigned a pathogenetic role in renal hypertension.

In the latter stages of the benign phase of experimental hypertension although renal pressor substances may circulate in diminished but sufficient amounts to maintain elevated blood pressure, evidence suggests that other mechanisms are involved. Following injection of ganglionic blocking agents a reduction in blood pressure does not occur in early renal hypertension or during renin infusion but does develop in late renal hypertension. This fits in with the established fact that in late renal hypertension the baroreceptor mechanism is reset at the higher blood pressure level possibly due to changes in the walls of the carotid sinus from prolonged exposure to high blood pressure. The carotid aortic reflex is the principal depressor response to elevations of blood pressure. In chronic renal hypertension, it still responds to acute pressor stimuli but presumably, not to the sustained renal pressor stimulus. In addition, there now occur generalized morphological vascular changes secondary to the hypertension which may act to perpetuate the disorder.

THE ENDOCRINES IN RELATION TO EXPERIMENTAL HYPERTENSION Although the evidence points to angiotensin as acting directly upon the vessels, the possibility must be considered that it exerts its effect by stimulating a ductless gland such as the pituitary or adrenal, to secrete a vasoconstrictor substance. The endocrine glands could also cause hypertension by stimulating the kidney to produce a pressor agent.

The adrenal medulla probably does not play a role in experimental renal hypertension, for the hypertension is not prevented or modified in any way by bilateral excision of all medullary tissue. Tumors of the adrenal medulla, called pheochromocytomas, do produce a clinical syndrome in which hypertension is the outstanding feature. The elevated blood pressure is secondary to the excess production of catecholamines (which can be measured in the blood and urine).

Goldblatt has found that constriction of the renal arteries fails to cause a rise in blood pressure after bilateral removal of the adrenal cortex, even though the animal is maintained in good condition by a high salt and low potassium diet (ch 58). But if cortin is administered in the adrenal ectomized animals, renal ischemia is followed by the usual hypertensive response. The blood pressure of hypertensive rats is lowered by adrenal ectomy and is only partially restored by the administration of desoxycorticosterone. Since hypertension is not sustained, and evidently, vascular tone and responsiveness are decreased when the adrenals are absent, the adrenal cortex is said to have a "permissive" action in renal hypertension. There may also be an "additive" effect of the kidney and adrenal cortex, for the administration of desoxycorticosterone to uninephrectomized rats, or of desoxycorticosterone and renin to normal rats produces a more severe hypertension with more intense vascular damage than either procedure alone. It is of interest that renin has been found to stimulate growth of the zona glomerulosa of the adrenal cortex in rats. However, these results should not be taken to imply that the renal principle mediates its action through the adrenal cortex, for Houssay and his colleagues found that in short term experiments in which an ischemic kidney was transplanted into a nonhypertensive animal, complete adrenalectomy of the latter or ligation of the adrenal veins did not prevent the rise in blood pressure.

Desoxy corticosterone is capable itself of inducing hypertension in normal animals, provided that the diet contains adequate amounts of salt. It is ineffective upon a salt poor diet. Damage to the renal vessels (nephrosclerosis) is caused by the administration of this hormone, it also increases the retention of salt (enhanced tubular reabsorption) and an increase in the volume of the extracellular fluids. Both the renal effect and that upon water and salt metabolism are probably responsible for the hypertension caused by this cortical hormone.

In this regard, it is pertinent that Tobian has found an increased concentration of water, sodium, potassium and magnesium in the aortic tissue of renal and desoxycorticosterone hypertensive rats, renal arteries from hypertensive patients also showed an increased sodium and water content. It is postulated that the electrolyte and fluid changes may lead to edema of the vessel walls. The narrowing of the vascular bed by this process could cause an elevated blood pressure secondary to the increased peripheral resistance.

Other authors have reported a low serum magnesium and a high plasma sodium with a normal potassium in hypertensive patients. These studies have been stimulated by the recent discovery of a clinical hypertensive syndrome associated with an excess production of the adrenal cortical electrolyte hormone, aldosterone. Patients with hyperaldosteronism show an elevated serum sodium with a low potassium, one patient has been reported with a low serum magnesium level. The hypertension in this syndrome may be cured by removal of the aldosterone producing tumor hyperplasia or normal appearing adrenal cortex.

There is no evidence that the posterior lobe of the pituitary plays a role in the development of renal hypertension, but the anterior lobe appears to be implicated through its action upon the adrenal cortex. Ablation of the anterior lobe in animals with renal hypertension lowers the blood pressure, which is raised to its previous level by the administration of adrenocorticotrophin or of a crude anterior lobe extract. So far as is known neither the thyroid nor the sex glands are in any way responsible for renal hypertension.

NEUROGENIC FACTORS IN EXPERIMENTAL HYPERTENSION. Hypertension has been produced in animals by a variety of neurological manipulations. Russian researchers especially emphasize the problems of vasomotor control by the central nervous system. They postulate that a disturbance in the central nervous system is the primary factor in the pathogenesis of essential hypertension and renal involvement is only secondary. In animals they were able to produce stable hypertension by conflicting conditioned signals resulting in experimental neurosis. By indirect tests, early involvement of the central nervous system in essential and experimental hypertension was shown. This has led to the theory that, in man, excess nervous strain weakens the functional capacity of the brain cortex which is reflected in a decreased effectiveness of the cortical inhibitory centers controlling blood pressure. The nervous and emotional strain of modern civilization has frequently been suggested as an underlying factor in the development of essential hypertension, many groups have studied hypertensive patients in relation to emotional instability and strain, but conclusions cannot be drawn because of the presence of many experimental variables and the inconsistency of the results.

Denervation of the carotid sinus and aortic vasosensory areas in dogs produces chronic arterial hypertension (200 to 250 mm Hg) for

1 to 3 years, and considerable tachycardia with extreme lability of the pressure and rate. In some dogs, the blood pressure and heart rate tend to return toward normal during sleep. Hypertension caused in this way differs from essential or renal hypertension, for cardiac output and limb blood flow are elevated (since stroke volume is unchanged, the rise in output is secondary to the increased heart rate), and total peripheral resistance is relatively unchanged.

Constriction of the internal and external carotid arteries bilaterally above the carotid sinus to approximately one third normal size gives a high level of hypertension in a large percentage of dogs for at least 4 years. The pathogenesis is not known. Hypertension has also been produced in animals by subjecting them (rats) to loud noises, by stimulation of the hypothalamus or of certain areas of the cerebral cortex.

In dogs completely sympathectomized except for the renal innervation, cutting of the buffer nerves increases sympathetic vasomotor discharge to the kidney, resulting in chronic hypertension. Subsequent renal nerve section relieves the elevated blood pressure. Electrical stimulation of the renal sympathetic nerves induces hypertension as long as the stimulus is maintained (3 months). Blood pressure returns to normal levels upon cessation of stimulation.

A high blood pressure often accompanies an increased intracranial pressure in patients. The heightened blood pressure is apparently due to a generalized vasoconstriction resulting from the reduced oxygen supply to the vasomotor center. Cushing pointed out that the increased pressure within the cranial cavity caused compression of and slowing of the blood flow through the vessels supplying the medulla. In animals, sudden occlusion of the common carotids after the vertebrals and other branches of the subclavian have been ligated, causes a pronounced rise in blood pressure. Even though the carotid sinus has been excised, chronic hypertension may be produced in dogs by cerebral ischemia produced in a similar way. Permanent hypertension has been produced by the injection of an inert substance such as kaolin into the cisterna magna of rabbits (Dixon and Heller) and thus interfering with the blood supply to the medullary centers, and cerebral anemia produced by ligation of the carotids and vertebrals causes hypertension in the dog. Even some of these apparently purely neurogenic types of hypertension appear to be, in part at least, of renal origin. For example, renal

denervation corrects the hypertension caused by cisternal injection of kaolin.

PRIMARY OR ESSENTIAL HYPERTENSION (HYPERPIESIA)

The immediate cause of the raised blood pressure in this disease is also an increase in the peripheral resistance, i.e., a vasoconstriction or narrowing in some way of the peripheral vessels. As implied in the name "essential" or "primary", the etiology of this abnormality is unknown. The disease is more common in women than men, shows a familial tendency, and usually has its onset from the 3rd to the 5th decade. The systolic and diastolic pressures are elevated although the latter is the characteristic finding in diagnosis, and the former may be within normal limits.

The hemodynamic effects of hypertension primarily involve the left heart. The left ventricle must compensate for the increased load imposed by the elevated peripheral resistance which tends to limit its stroke output. A greater residual volume causes stretching of the myocardial fibers with an increased initial tension which leads to an augmented force of contraction to restore the stroke output. Humoral and neurogenic influences undoubtedly play a part in increasing the stroke volume (ch. 23). The work of the left heart increases as measured by cardiac output and mean arterial pressure in large series of catheterized patients. These calculations probably underestimate the situation for the kinetic energy of ejection becomes a large factor in the work of the left ventricle in hypertension. The work of the heart is nearly proportional to the blood pressure elevation for the cardiac output has usually been normal when measured in patients. The oxygen consumption per unit weight of left ventricle of patients with chronic hypertension is normal. Due to the hypertrophy of the left ventricle seen in most hypertensives, the total weight and therefore, the total oxygen consumption of the heart is increased. The pressures in the pulmonary circulation and right heart are normal unless failure of one of the ventricles is present. Most hypertensive patients have an increased total peripheral resistance which is probably uniformly distributed both in the splanchnic area and extremities. The distribution of cardiac output and the level of blood flow to various body regions remains essentially normal.

The pressure in the capillaries and small veins is within normal limits, and the slope of pressure through these vessels is not materially different from that in health. The fall in pressure through

FIG. 27-3 Diagrammatic representation of fall in blood pressure in vascular circuit in subjects with hypertension compared with the normal. Shaded and stippled areas represent alteration in the pressure relationships in the skin vessels after the injection of histamine. The lower boundaries of these areas represent the pressure gradient under natural conditions, the upper boundaries this gradient after the injection of histamine (after Ellis and Weiss, modified).

the arterioles is much greater than in health (fig. 27-3). Ellis and Weiss found mean pressures of 155 and 12 mm. respectively in the brachial artery and in the capillaries—a fall of over 140 mm. Of this about 125 mm. must have occurred in the arterioles. Normally the fall of pressure in the latter vessels is less than half this figure (approximately 50 or 60 mm.).

In most cases of hypertension, there is no significant change in venous pressure, circulation time, blood volume or viscosity. With strenuous exercise, patients without cardiac symptoms show a normal increase in cardiac output and oxygen consumption, but no change in pulmonary artery or wedge pressures.

In hypertensive subjects the reactivity of the peripheral vessels to nervous stress or to cold, as by the immersion of a hand in icewater, is usually greater than normal. The latter procedure—the so-called *cold pressor test*—is employed for investigating the vascular responses. In most hypertensives the reaction is excessive, a sharp and inordinate rise in diastolic pressure occurs without an increase in cardiac output or pulse rate, which is taken as indicating a hypersensitive vasoconstrictor mechanism. Hines has studied this reaction in normal as well as in hypertensive subjects over a period of years, and has classed them into three groups, *hyper reactors*, who respond to the test by a rise over 23 mm. Hg, *normoreactors*, who give a rise of between 10 and

TABLE 27 2

The reaction of the diastolic pressure to the cold pressor test, correlated with the subsequent development of hypertension (Hines)

Classification*	Cases	Hypertension 15 Years Later	
		Cases	Per centage

Normoreactors	48	8	17
Hyper reactors	57	31	54

* Blood pressure normal, less than 100 mm. Hg diastolic.

20 mm. Hg, and *hyporeactors*, with whom the rise was less than 10 mm. Hg. The subjects with normal blood pressures and who were hyper reactors, showed a definite susceptibility to the development of hypertension in later life (see table 27-2). In these, as well as in the hypertensive hyper reactors, the magnitude of the response tends to increase progressively after 40 years of age. Actually the cold pressor test elicits a complex response of reflex vasoconstriction, pain perception and possibly an adrenergic discharge. Ganglionic blocking agents abolish this abnormal reaction.

SUMMARY. Dr Goldblatt's view is that the primary cause of essential hypertension in man is intrarenal obliterative vascular disease from any cause, usually arterial and arteriolar sclerosis, or any other condition that brings about the same disturbance of intrarenal hemodynamics. Although essential human hypertension is supposedly unassociated with obvious disturbance of renal function, this does not mean there is no functional disturbance of any kind; it refers specifically to the usual tests for excretory function. One of the strongest supports for the idea that the hypertension is the result of renal vascular disease and not its cause, is the finding that evidence of severe renal arteriolar sclerosis was not found at autopsy in individuals who had had normal blood pressure, and that moderate to severe renal arterial and arteriolar sclerosis occurred in almost 100 per cent of cases in which hypertension had existed. The recently published reviews of human unilateral renal hypertension confirm that interference with the renal blood supply can cause a form of human hypertension similar to that created experimentally (25 to 50 per cent permanently cured by excision of the kidney). The recent report of the ability to arrest the

course of hypertension by transplanting a normal kidney and removing two diseased kidneys is a further verification.

The popular assumption that essential hypertension is mediated by a neurogenically maintained increase in peripheral arteriolar resistance lacks substantial experimental proof. Failure of total sympathectomy to cure essential hypertension is the strongest argument that the autonomic nervous system is not primarily involved in maintenance of increased peripheral resistance.

If Goldblatt's mechanism applies, either ischemia must be functional and inapparent at autopsy or biopsy, or the release of renal pressor enzymes in early stages is secondary to an enzymatic defect not detectable with the microscope.

The treatment of essential hypertension is predominantly medical with the use of various pharmacological agents. Surgical treatment ranging from subdiaphragmatic splanchnicectomy to 'total' (thoracolumbar and accessory ganglia) sympathectomy is usually reserved for selected patients; such surgery removes the sympathetic vasomotor tone from a large segment of the systemic vascular system resulting in a decreased peripheral resistance and an increased capacity of the vascular bed. Since sympathectomy does not offer better results than medical treatment, its popularity has declined. The ganglionic blocking agents, by reducing cholinergic transmission in the autonomic ganglia, produce a 'chemical sympathectomy' and have the most profound effects of the pharmacological agents used. The blocking agents probably reduce both arteriolar and venous tone, producing an increased systemic vascular volume and a decreased cardiac output by a combination of venous pooling and failure of reflex vasoconstriction. Because of postural hypotension and the side reactions from a concomitant parasympathetic blockade (constipation, urinary retention, mydriasis), these drugs are being used less frequently and in smaller doses in combination with less potent antihypertensive agents.

Alkaloids of the plant, *Rauwolfia serpentina* Benth. are widely used antihypertensive preparations. Their action is very complex. Besides a sedative effect, *Rauwolfia* derivatives presumably decrease sympathetic nervous tone, probably by an action directly or indirectly on the hypothalamus. Serotonin has been shown to be displaced from its binding sites in the brain which may lead to the reduction in sympathetic outflow

and relative parasympathetic overactivity. Catecholamines are also released by these drugs from hypothalamic centers and from peripheral postganglionic sympathetic nerves. The lack of sympathetic transmitter substance, leading to a decrease in vasoconstrictor activity, may be the drug's main hypotensive action.

Hydralazine, another moderate hypotensive agent, possesses many complex actions. It has been shown to inactivate pressor materials derived from renin, to inactivate some decarboxylase enzymes, and to probably stimulate monamine oxidase, the enzyme involved in inhibition or destruction of catecholamines and serotonin. The drug produces a prolonged dilation of constricted blood vessels and unlike other hypotensive agents increases renal plasma flow despite the decrease in blood pressure. Schroeder maintains that the relaxation of vasoconstriction is not due to sympatholytic activity but to a direct effect on the vascular smooth muscle cell which may be related to the drug's chelating action on trace metals.

The veratrum alkaloids are not widely used in the treatment of hypertension for the hypotensive dose approximates the emetic dose. The therapeutically used veratrum alkaloids or mixtures, produce a vasodepressor reflex by means of the baroreceptors of the carotid sinus, aortic arch and left ventricle, and not by their parasympathetic stimulatory effects. Some veratrum alkaloids do have an action directly on higher vasomotor centers.

Recently, diuretics of the benzothiadiazine family (such as chlorothiazide) have been found to have hypotensive properties. Their action has been assumed to be similar to the hypotensive effect of a low sodium diet (which is still a very useful treatment for hypertensive patients). The antihypertensive mechanism of these diuretics is believed to be a result of a decreased plasma volume with loss of sodium, chloride and water from the body and a subsequent decreased cardiac output and blood pressure. Restoration of the blood volume with dextran, early in treatment, restores the blood pressure towards normal levels. However, the blood pressure reduction has been shown to be maintained even when the plasma volume, exchangeable sodium and cardiac output return to normal levels with more prolonged treatment. Therefore, other mechanisms may be operative in the antihypertensive action of these drugs besides a purely diuretic effect.

A large number of new agents are being tested in the treatment of hypertension, most of which

are either serotonin, monoamine oxidase or catecholamine inhibitors. One of the latter drugs, guanethidine, had been found to inhibit the peripheral release of catecholamines from postganglionic sympathetic nerve fibers. A predominantly postural hypotension is produced, as with ganglionic blocking agents, but without the parasympathetic side effects. The role of serotonin in hypertension is unclear. Enigmatically, both inhibitors of monoamine oxidase (which destroys serotonin) and of serotonin lower blood pressure in hypertensive patients and are receiving clinical trials in treatment. There is indirect evidence that monoamine oxidase inhibitors may possess some ganglionic blocking activity.

The above mentioned drugs are usually used in combination, in dosages necessary to reduce the blood pressure to reasonable levels for the patient concerned. Each agent seems to have an additive or potentiating effect on the other so that together smaller doses can be used with fewer side effects or toxic reactions than when either drug is used alone. Although the life of the patient may be prolonged by these agents, there is no definite evidence that the underlying process is reversed.

MALIGNANT HYPERTENSION Malignant or "accelerated" hypertension is a more severe, progressive form of arterial hypertension, characterized by rapidly advancing renal damage, usually, but not always, accompanied by retinal hemorrhages, exudates and papilledema. The papilledema (elevation of the optic disks) has been related to the marked diastolic pressure elevation inducing an increase in cerebrospinal fluid pressure. The clinical course is one of rapid degeneration with early demise due to cerebral, cardiac, or renal complications.

ECLAMPSIA GRAVIDARUM Eclampsia is a state occurring in pregnancy in the last trimester characterized by hypertension, headache, nausea and vomiting, albuminuria, edema, tremors, or convulsions ending in coma. The blood pressure may be extreme and of rapid development. The diastolic pressure shows the more pronounced rise, indicating a generalized vasoconstriction. The cause of the arteriolar spasm is unknown. The blood pressure, as a rule, falls after evacuation of the uterus, which points to the uterine contents being in some way responsible for the symptoms. Since death of the fetus does not result in an abatement of the condition, and it develops in association with a hydatidiform mole, placental tissue is certainly incriminated. Beyond these

facts nothing is known for certain with respect to the causative mechanisms in eclampsia.

Hypotension

Hypotension is usually considered to be present in an adult when the systolic pressure is persistently below 110 mm Hg, although such a definition is arbitrary, since hypotensive symptoms may not be experienced at lower levels. On the other hand, patients with arterial hypertension may develop symptoms at higher systolic pressures.

PRIMARY HYPOTENSION In the absence of an underlying disease, low blood pressure is referred to as "primary" or "essential" hypotension. The subjects with primary hypotension (who are usually emotionally labile, asthenic, young females) often suffer no ill effects beyond fatigue and weakness. The nonspecific symptoms may be more related to the individual's personality than to the hypotension. These patients are more likely to be free from cardiac and renal disease, the condition, for this reason, being said to forecast longevity. Except for a hereditary predisposition, the etiological factors in primary hypotension are unknown.

SECONDARY HYPOTENSION Low blood pressure may occur either as a temporary or persistent phenomenon in numerous disease states, such as hemorrhage, traumatic shock, acute fever, myocardial infarction, tuberculosis, adrenal or pituitary insufficiency and debilitating diseases. The symptoms of secondary hypotension usually result from the underlying disease rather than the low blood pressure. The determining factors are not well understood, but the hypotension is usually due to an inadequate cardiac output, a decreased peripheral resistance or blood volume, or a combination of these factors.

ORTHOSTATIC OR POSTURAL HYPOTENSION In this interesting condition, the reflex mechanisms normally operating to maintain the blood pressure against the effect of gravity are apparently in abeyance, or their sensitivity greatly depressed. A profound fall in blood pressure occurs on assumption of the standing position, the systolic pressure may fall to 40 mm Hg and the diastolic to zero (as determined by the usual auscultatory method). The subject experiences dizziness and/or syncope. This syndrome may occur idiosyncratically with no known underlying disease secondary to various nervous system diseases (diabetes mellitus with neuropathy, tabes dorsalis, myasthenia gravis, syringomyelia), following surgical sympathectomies or during treatment with

adrenergic or ganglionic blocking agents. Idiopathic orthostatic hypotension is believed to be a definite syndrome usually accompanied by anhidrosis and impotence, the male between 40 and 70 years of age is more often affected. Since anhidrosis and failure of a reflex tachycardia on standing accompanies the postural hypotension, the abnormality is believed to be in the sympathetic nervous system. However, indirect evidence also implicates involvement of the parasympathetic system so that the name "primary autonomic insufficiency" has been suggested.

Experimental studies on patients with chronic orthostatic hypotension have shown that they do not pool more blood in the lower extremities on assumption of the erect position than normals, but that there is an abnormal response to the usual shift in blood volume. The abnormality consists in the lack of reflex arteriolar and venous constriction which usually occurs on standing. The drop in blood pressure may be augmented by a fall in cardiac output, but the latter may not decrease excessively (also, a large postural cardiac output fall may occur without a significant change in blood pressure). The demonstration of low plasma or urinary levels of catecholamines in patients with postural hypotension offers direct evidence of an abnormality in the sympathico-adrenal system. It is interesting that vasopressin, which lacks a pressor effect in man, raises the blood pressure in these patients.

Treatment of primary hypotension is usually unnecessary, while correction of the underlying disease should be attempted in secondary hypotension. Abdominal binders, elastic stockings, various sympathomimetic pressor agents, vasopressin, adrenal cortical sodium retaining hormones, or a high salt diet are often, but not always, helpful in chronic orthostatic hypotension. Sodium retaining hormones or a high salt intake are believed to act by increasing the blood volume and, hence, the blood pressure, however, the underlying abnormality is not corrected.

Hyperventilation, Hypoventilation, Hypercapnia, etc

Circulatory adjustments result when the $p\text{CO}_2$ of arterial blood is increased or decreased. A decrease in $p\text{O}_2$ of arterial blood also elicits changes in the cardiovascular system, but a rise in $p\text{O}_2$ above that which is present in normal resting subjects at sea level has little or no effect. The patterns of response which need to be analyzed, therefore, are those related to hypo-

capnia (acapnia), hypercapnia, hypoxia (anoxia) and a combination of hypercapnia and hypoxia (asphyxia).

Hypocapnia can be produced by voluntary hyperventilation or by artificial respiration of anesthetized animals. Carbon dioxide depletion causes a lowering of the tonic activity of the vasoconstrictor center, arteriolar dilation results and the blood pressure falls. The heart rate may be accelerated reflexly from the fall in pressure in the sinoaortic zones. The direct effect of carbon dioxide lack upon the peripheral vessels is to increase their tone, but this effect is not evident in the presence of the reduction in arteriolar tonus related to the central effects.

Dale and Evans found that when cats were severely overventilated the blood pressure fell to around 40 mm Hg within a minute or two and the depressor effect did not occur or was quite evanescent when a mixture of 5 per cent CO_2 in air was substituted for air as the ventilating gas. Depressor effects of hyperventilation with air also were present in decapitated animals thus indicating that the spinal vasomotor centers also are sensitive to changes in carbon dioxide tension. After destruction of the spinal cord hypocapnia caused a rise in blood pressure as would be expected in view of the direct effects on peripheral vessels which in this case are not opposed by the central influences.

In the majority of human subjects in the standing position forced ventilation causes a fall in arterial blood pressure. The fall is attributed in part, at least in some subjects, to interference with the venous return which occurs as a result of the forcible expiratory movements (Vincent and Thompson), since the fall may occur when the subject breathes a mixture containing CO_2 . Severe prolonged hyperventilation in some subjects may cause enough pooling of blood in dependent parts of the body to cause dizziness or even fainting since cerebral blood flow is decreased.

According to earlier views (Y. Henderson) shock could be produced by prolonged hyperventilation, however this does not appear to be the case in experimental animals if a method is used which does not obstruct flow of blood in the lungs. Although arterial pressure is lowered peripheral resistance also is lowered so that blood flow through most organs is maintained or even increased, and blood pressure is restored quickly when the hyperventilation is discontinued.

Hypercapnia causes increased tone of the vasoconstrictor center. Local effects of a rise in

pCO_2 , as when metabolism in the tissues is increased are vasodilator, but this effect is not evident in the presence of moderate increases in pCO_2 achieved by rebreathing or adding CO_2 to the inhaled mixture. Mathison reported that when an animal breathed an air mixture containing 10 per cent CO_2 with an adequate percentage of oxygen the arterial blood pressure rose within less than a minute to double its previous height and intestinal volume fell. Injections of lactic acid or other organic acids into the blood stream produced effects similar to those of carbon dioxide excess.

In a decapitated animal a rise in blood pressure in response to CO_2 occurs when the percentage in respired air is increased to 20, whereas breathing air mixed with 5 per cent CO_2 may be sufficient to excite the medullary vasomotor center.

A moderate degree of hypoxia as produced by ascent to altitude or by breathing at sea level a gas mixture containing about 12 to 15 per cent O_2 causes a moderate increase in heart rate and elevation of the blood pressure. Breathing is stimulated so that a mild decrease in pCO_2 also occurs. A brief severe bout of hypoxia produced by breathing nitrogen for about 30 seconds causes marked cardiac acceleration while changes in blood pressure are somewhat variable. Breathing is stimulated, hence influences related to hypoxemia make the interpretations difficult. Heymans (1950) stated that cardiac acceleration in response to oxygen lack is due mainly 'to reflex stimulation of the sympathetic centers (cardiac and adrenal centers) by way of the chemoreceptors', and that oxygen want effects these centers directly only if very marked. However, in experiments involving perfusion of the carotid bodies a lowering of the pO_2 in the perfused blood failed to elicit cardiac acceleration and this was true when the systemic arterial blood pressure was kept constant by the use of a mechanical compensator (Bernthal). Intravenous injection of sodium cyanide in the smaller doses which stimulate breathing also causes cardiac acceleration, however the effect of cyanide on heart rate is not exerted reflexly from the chemoreceptors (see Heymans, 1953).

In experiments on intact animals subjected to severe anoxia before and after adrenalectomy it is demonstrated that liberation of epinephrine is a factor in the production of cardiac acceleration (Van Loon and associates), however neural acceleration also is concerned. At present it must be con-

cluded that the mechanism which sets off the acceleration in response to hypoxia is not known.

Cardiac output is increased in man as much as 50 per cent while breathing a gas mixture containing 8 per cent oxygen (Doyle and associates, 1952). Also, increases in cardiac output are produced by hypoxia in unanesthetized dogs (Nabas and associates, 1954).

In hypoventilation or asphyxia the combined effects of increased pCO_2 and decreased pO_2 are seen. Blood pressure is elevated, heart rate usually is increased. Cardiac output is elevated. The changes in the blood and the respiratory effects are described elsewhere (ch 32 and 33). As asphyxia is prolonged blood pressure falls as a consequence of decreased strength of cardiac contractions and conduction in the atrioventricular portion of the conducting system may be impaired.

As asphyxia is progressive in an anesthetized dog which is allowed to rebreathe air from a small rubber bag the blood pressure progressively becomes higher until it may reach a level double that in the period before asphyxia. Shortly as rebreathing continues, the blood pressure suddenly falls. This is attributed to a weakening of the cardiac contractions due to asoxemia and not to release of arteriolar tonus. For if the volume of the kidney is recorded at this time, it is found that no change occurs.

As described above, the local effect of a deficiency of O_2 and an excess of CO_2 or rise in cH is to cause vasodilation while the effect of these changes in the vasomotor center is to promote vasoconstriction. In exercise large increases in pCO_2 and cH and decreases in pO_2 occur in the active muscles, and these changes promote a greater blood flow. Changes in pCO_2 and pO_2 in systemic arterial blood during exercise are not prominent since equilibrium with alveolar air of essentially normal composition still occurs (see question of control of pulmonary ventilation during exercise p. 499 and of vasomotor reactions during exercise).

The persistent elevation of the blood pressure which results from a rise in intracranial pressure is attributed to compression of medullary vessels and hence interference with blood supply to the vasomotor centers. The rise in pCO_2 and cH in the vasoconstrictor center causes an increase in vasoconstrictor tonus and therefore a rise in arterial blood pressure to a level sufficient to restore blood flow to the brain. When the rise in intracranial pressure is rapid as in the case of cerebral hemorrhage in man or when it is pro-

duced in experimental animals by introducing fluid, the rise in blood pressure is rapid and a decrease in heart rate is elicited from pressoreceptors. Hence, repeated recording of blood pressure and heart rate provides information concerning whether the rise in intracranial pressure is continuing.

Circulatory Adjustments to Climatic Conditions

Changes in environmental temperature elicit characteristic alterations in circulation. Adjustments in cutaneous blood flow, blood volume and cardiac output occur as a part of the process of heat regulation (see ch. 52). At present there is interest in the use of lowered body temperature to prevent or treat shock and to permit surgery on patients who might not be able to tolerate the stress of anesthesia and operations at normal body temperature. Therefore, it has become necessary to consider the circulatory effects of severely lowered body temperature.

Any mammal if exposed to a sufficiently low temperature will react by conserving its heat and increasing heat production, but if the cold is intense enough for a sufficiently long period the animal begins to cool. At a critical level of body temperature death occurs, but this level is lower for hibernators than for mammals which do not hibernate (Lyman and Chatfield, in *Physiology of Induced Hypothermia*). Species which hibernate evidently undergo adaptations which do not occur, at least in similar degree, in nonhibernators. If a nonhibernator is cooled progressively, death usually occurs due to ventricular fibrillation or asystole when the body temperature has reached the vicinity of 20 to 15° C. The heart of a hibernator (ground squirrel) can beat effectively at rates of 5 to 10 beats per minute at low temperatures and will continue to beat when removed from the animal and placed in cold unoxygenated saline, but the heart of a nonhibernator (white rat), under similar conditions, stops beating within a few minutes (Dawe and Landau, 1960).

As shown by Hook and Stormont (1941), and Heggner and associates (1950), heart rate in the dog decreases almost linearly with decreases in body temperature down to about 20 beats per minute at about 18 to 20° C. Blood pressure showed a progressive decrease but not as much as the decrease in heart rate down to about 24° C. Then as temperature was lowered further, the decrease in blood pressure paralleled the decrease in heart rate. Similar results have been obtained by others. As the heart rate decreases in hypother-

mia the durations of both systole and isometric relaxation as well as duration of diastole increase greatly (as much as 2½ times). When heart rate is decreased comparably by vagal stimulation, most of the lengthening of the cycle is related to prolongation of diastole.

The cardiac output of dogs at a body temperature of 20° C is about 15 per cent of normal due almost entirely to the decrease in heart rate since stroke volume may be normal. The tissues use less oxygen and the coefficient of oxygen utilization is increased. Although coronary blood flow is reduced it is adequate for the needs of the heart in the presence of reduced metabolism (Berne, 1954). During rewarming signs of circulatory inadequacy are noted and have been attributed to the peripheral vasodilation and to adrenal insufficiency related to lack of adrenal response to trauma during hypothermia.

Much attention has been given to the question of what causes ventricular fibrillation in hypothermic animals, and no definite conclusions have been reached. Absolute and relative refractory periods of cardiac muscle are lengthened and conduction is slowed. Excitability changes of the heart in hypothermia are varied. In some cases changes in threshold are not prominent while in others there is an abrupt loss of excitability. It is possible that the latter change is related to failure of repolarization of the fibers of the conducting system which sometimes occurs during cooling. The problem is discussed in detail by Hoffman (Symposium *Physiology of Induced Hypothermia*). Covino (1958) reported that in hypothermic dogs which were about to fibrillate, calcium was shifting into the heart and potassium was leaving. He suggests a cause and effect relationship between these changes and ventricular fibrillation in hypothermic dogs, however several other factors including sympathetic neural activity, by-drogen ion shifts, and type of anesthetic agent also are considered to have an effect on the incidence of fibrillation.

Circulatory Responses to Gravitational Stress

THE EFFECTS OF ACCELERATION A constant speed, however great, has in itself no effect upon the circulation. As pointed out by Armstrong, we are travelling through space quite unaware of a speed of over 18 miles per second caused by the motion of the earth. But acceleration, that is, a change in velocity either in the line of our motion (*linear acceleration and deceleration*), or the movement of the body in a circular or curved

course (*centripetal* or *central acceleration*), may cause profound effects upon the body as a result of the inertia of the blood and viscera. A third type of accelerated movement, known as *angular acceleration*, takes place when the body rotates about its own axis, as when a plane rolls or spins. The rate of angular acceleration is rarely great enough to cause any serious physiological disturbance, but this form of acceleration causes effects on equilibrium and orientation. The development of the modern airplane and maneuvers of military flying have brought prominently to the fore the importance and hazards of acceleration in relation to the circulation. According to Newton's Law, $F = MA$ where F = force, M the mass and A the linear acceleration. Therefore, $A = F/M$.

The effects of *horizontal linear acceleration* upon the body of a pilot are seen in catapulted take offs, or in picking up personnel from the ground or in gliders by high speed planes. Deceleration, i.e., a sudden reduction in velocity, occurs in crash landings, parachute landings, or from parachute opening (especially at very high altitudes), etc. Vertical acceleration, as when the plane falls or pitches, owing to changes in air density, causes motion sickness.

Centripetal acceleration is the type which in military flying causes serious effects upon the circulation. It is defined as the acceleration of a body toward the center of a circle in the circumference of which it is moving at uniform velocity. The central force producing the acceleration (*centripetal force*) is resisted by an equal and opposite, radially acting force, generally called *centrifugal force*. This may be expressed, thus —

$$F = MV^2/r$$

in which M is the mass, V the velocity and r the radius of the circular movement. At a linear or centripetal acceleration equal to that of gravity, namely, 32.2 ft. per second, per second the force exerted is equal to that of gravity. Gravitational force, like centrifugal force, is proportional to mass and is exhibited as weight. The force due to acceleration is, therefore, conveniently expressed in units of gravitational force and designated by the letter G . Thus an acceleration amounting to $2G$ indicates a force double that of gravity, i.e., a body acted upon by such a force would be doubled in weight. The centrifugal force is proportional to the square of the velocity. It can be calculated in G units from equation $G = V^2/32.2r$, where V is the velocity in feet, r the radius in feet of the curved course which the moving

body takes, and G units of gravitational force per pound of mass.² Thus, the weight of a pilot's body subjected to a force of $2G$ is doubled, is tripled at $3G$, and quadrupled at $4G$, and so on.

Acceleration which produces a force acting upon the airman in the long axis of the body from head to seat is called positive (+ G), that acting from seat to head is called negative (- G). A pilot pulling out of a power dive, that is, changing direction at high velocity to a horizontal and upward direction in a banking maneuver has his head directed inward toward the center of the circular movement and is therefore subjected to a positive centripetal acceleration. If the force amounts to from 5 to 6 + G or more, and lasts for longer than 3 or 4 seconds, the phenomenon now generally referred to as 'blackout' results for his blood being acted upon by a force 5 or 6 times that of gravity "falls" or is "thrown" into the lower part of the body (the large vessels it will be recalled, run in the general direction of the long axis of the body), the weight and, consequently, the hydrostatic pressure of the blood is increased (see fig. 27.4). In animal experiments it has been shown that as a result of the very high capillary pressure a marked increase in filtration of fluid from the blood into the extra vascular spaces with hemoconcentration occurs. In man the skin of the lower parts of the legs may show numerous blood extravasations (petechiae). The movement of blood toward the feet reduces the venous return of blood to the heart, and, as a consequence, the pressure of blood in the cerebral and retinal vessels falls. Vision is temporarily lost and the pilot may become unconscious. The abdominal viscera are forced downwards and drawing upon the diaphragm may embarrass respiration. X-ray photography shows elongation of the heart and a reduction in cardiac volume.

"Negative" acceleration as when a turn is made at high velocity with the plane in the inverted position, the pilot's head being directed outward, causes opposite effects upon the circulation and is likely to produce more serious injury, but fortunately, unlike positive acceleration, does not come into play in any necessary maneuver. "Negative" acceleration also occurs in spins resulting from some structural damage to the

² From the following equation the force developed during linear acceleration or deceleration can be calculated.

$G = (V_2^2 - V_1^2)/32.2 \times 2 \times S$
where V_1 is the initial velocity, V_2 the final velocity and S the distance travelled during the period of acceleration.

FIG 27 4 Diagrammatic representation of the hydrostatic pressures in the vascular system of a man in the sitting position at 1 G and at 5 G (Wood and associates)

plane, when the tremendous force created may, through the increased weight of their bodies, prevent the pilot and other occupants of the plane from moving. In a turn with the head directed outward, the blood is driven toward the head resulting in effects sometimes called "red-out." The vessels of the head and neck become engorged, there may be small cutaneous hemorrhages, severe throbbing pain in the head is experienced and the eyes feel as though they were being extruded from their sockets. The abdominal viscera are pushed upwards against the diaphragm. The venous return to the heart is increased and the blood pressure in the cerebral vessels is raised considerably (as much as 65 mm Hg). There may be mental confusion for a time. Cerebral hemorrhage may result, but since the hydrostatic pressure of the cerebrospinal fluid is also increased, it acts as a buffer which, to a large extent, protects the delicate walls of the small cerebral veins and capillaries, which are the most likely to rupture.

Large centrifuge machines have been devised for subjecting the body to positive acceleration and studying the effects produced. Instruments

record blood pressure, cardiac action and blood content of the drum membrane automatically. Thus the tolerance of a pilot to +G can be measured (see fig 27 5).

In order to prevent the physiological effects of positive acceleration, several types of double-walled suits have been designed which, by containing water or air under pressure, oppose a force to resist a rise in the hydrostatic pressure of the blood. The first suit of this kind to be employed in actual air combat was invented by Franks of the Royal Canadian Air Force. It envelops the abdomen and lower limbs; water is introduced into the space between its walls. During the development of centrifugal force a hydrostatic pressure, automatically graded to that exerted upon the blood, is applied through the tissues to the vascular walls. Thus, distension of the vascular bed of the lower part of the body and the accumulation of blood is prevented.

The effects of centripetal acceleration may also be minimized by the pilot assuming a crouching position with the trunk bent well forward and the thighs strongly flexed at the hips. The direc-

FIG. 27.5 Records of pulse rate, blood pressure and blood content of the ear of a normal subject exposed in the human centrifuge for 5 seconds to 5 G. (Drawn in part from graphs kindly furnished by Dr. W. R. Franks.)

tion of the centrifugal force is then across the great vessels of the trunk rather than in line with them, and runs from knee to hip more or less parallel to the vessels of the thigh, the movement of the blood along the veins of the thigh toward the heart is thus actually aided.

MAN UNDER GRAVITY FREE CONDITIONS Gravity is omnipresent and is the only environmental factor which cannot be eliminated experimentally on the earth for any prolonged period of time. This is why our knowledge of the effects of gravity on the circulation is so small. Apart from the few seconds in a free fall, such as in an airplane under going a dive of an almost vertical drop, there is only one way to escape gravity, and that is to leave the earth in a space ship. Such an experiment, once a fantastic dream of the future, has now come close to reality with the travel of dogs into space and their recovery. Man is next.

The acceleration due to take offs and landings of space ships presents no fundamental physiological difficulties, for in test subjects, the limit

of tolerance to centrifugal forces in the direction of chest to back, corresponds to an acceleration of 17 G for 4 minutes, and in the direction of back to chest, to an acceleration of 11 G for 3 minutes. This is compatible with the acceleration due to take offs and landings of space ships. When the interplanetary ship has left the atmosphere of the earth and its propulsion is discontinued, it will behave like a celestial body in its orbit through the solar system. The orbit must lead the ship to its goal following the laws of gravitation. Consequently, during the greater part of the interplanetary flight, a gravity free or a near gravity free state is encountered. Its duration will vary from days (trip to moon) to months (trip to Venus or Mars).

Projection of things to come in space is precarious and must depend more or less on assumptions and conclusions by analogy. Mechanical effects from the surrounding tissues can alter the circulation mildly. The circulatory changes caused by gravity are due to elastic deformation which

body organs and blood vessels undergo. In the weightless state, the organs are without support and, hence, this might lead to mild derangement of body organs as they seek slightly altered positions. Direct disturbances of the circulation, however, by absence of gravity would not be anticipated. The circulation operates by elastic forces delivered by the heart and the elasticity of the blood vessels. Although the blood loses its weight, it retains its mass, inertia, and other properties of a liquid. In general, it is believed it would resemble that of a man at sea level in the horizontal position except that flattening of the veins would not occur and the distribution of the blood would be the same in the horizontal and vertical head up or down position, or indeed, in any position. Finally, it might be expected that absence of gravity would lead to diminution of activity of the vasomotor system and of reflexes that have so much to do with normal compensatory responses of the circulatory system to stress. This is so, since the execution of locomotion takes place under continuous guidance of a complex system of sensory receptors widely distributed over the body. Since the degree of activation of muscle is related to the weight of the body, and since this depends mainly on muscle proprioceptors, one could expect that muscle tonus will be reduced and the limbs relaxed and flaccid. In addition since it will take no more energy to move a large object than a small object, and very little energy, in either case, one might expect a further reduction in skeletal muscle activity with a fall in cardiac output and even atrophy of the heart and skeletal muscle. Some form of standard exercise might be needed to prevent this.

Cardiovascular Effects of Ionizing Radiations

The effects of ionizing radiation upon the circulation of the skin and upon arteries and veins have been recognized and studied intensively over the past 60 years. It has been recognized only recently that whole body radiation produces dysfunction of the entire cardiovascular system and that some form of cardiac failure may be a factor in causing radiation death in some species of animals. What role cardiovascular changes play in causing radiation death in man has not been studied in detail.

Ionizing radiation produces a variety of abnormalities of the cardiovascular system. These are caused by (1) a direct effect of radiation upon the tissues, (2) effects produced by the ionization of water by radiation, (3) effects produced by

products from damaged tissue, (4) effects produced by the autonomic and endocrine reactions to radiation, (5) effects produced by the marked changes in fluid balance of the irradiated animal, and (6) effects produced by other ill-defined but perhaps important abnormalities of the irradiated animal. Insufficient experimental data exist to define with precision the complete sequence of changes in the cardiovascular system or the exact mechanism by which these abnormalities are produced by ionizing radiation.

REACTION OF SKIN TO RADIATION When the skin of man and animals is exposed to a sufficient dose of ionizing radiation (300 to 600r, depending upon the wave length) a characteristic sequence of changes is observed. There is usually an initial erythema during the 1st day which rapidly subsides, followed by a 2nd wave of erythema in the 2nd or 3rd week, a 3rd wave may be seen after 6 weeks. During the later waves of erythema the skin temperature is increased suggesting that a marked vasodilation with increased blood flow has occurred although there is no perceptible change during the latent periods. These changes in cutaneous circulation have been attributed to a combination of the direct effect of irradiation on the component cells of the blood vessels, by modification in the neuromuscular control of the peripheral vascular system (directly or indirectly produced by irradiation) and by the release of histamine and other tissue hormones by the damaged tissue surrounding the blood vessels. The relative importance of each of these in producing damage and dysfunction to the vascular system of the skin remains to be determined.

VASCULAR PHYSIOLOGY Ionizing radiation produces diffuse and irregular damage to the arteries, capillaries, and veins of man and animals. It has been recognized only recently that, in addition to producing obliterative vascular lesions, irradiation produces significant physiological abnormalities of blood vessels. Arteries from irradiated dogs (total body 300r) have an abnormal pressure volume curve, these vessels being more spastic than is normal upon removal from the body. Vessels from irradiated dogs likewise have a decreased vasoconstriction to 1-epinephrine and 1 norepinephrine when compared to control arteries. When a normal artery is irradiated *in vitro* two effects are noted. A slight constriction of the arterial wall occurs immediately upon beginning of irradiation, which is completed in 30 to 45 seconds. This is a direct effect of the radiation. The flow through the vasa vasorum is decreased. This latter effect is secondary to ionization of the solution surrounding the specimen. Alterations

in capillary permeability produced by irradiation play a significant role in producing changes in the red and white cell content of the peripheral blood. These studies have shown that ionizing radiations produce a variety of physiological abnormalities of the peripheral vascular system which are only beginning to be delineated.

CARDIOVASCULAR EFFECTS OF TOTAL-BODY RADIATION. The threshold dose of total body X ray or gamma radiation required to produce significant abnormalities of the cardiovascular system is below 300r and probably above 100r. Because of the tremendous species variation in these responses to irradiation it will be necessary to consider the response of man, when known and other species separately.

Arterial blood pressure. Patients who are receiving x ray therapy may develop a hypotensive episode shortly after irradiation which returns to normotensive levels within an hour or two. Rabbits develop hypotension immediately following total body irradiation of as little as 50r. There is no change in blood pressure, cardiac output or total peripheral resistance of dogs during or for 5 hours following exposure to 1500r of gamma radiation. In the rat an initial hypotensive episode which occurs within the first 2 hours has been described. In both the rat and rabbit there is a rise in plasma histamine which is related in time to the initial hypotensive episodes in these species. This relation may be only fortuitous as there is evidence that the initial hypotension following irradiation is, in part, mediated by reflex mechanisms.

In most species recovery from an initial hypotension is prompt and blood pressure falls again only in the terminal period. VDM and VEM have been found in the blood of rats 6 to 10 days following irradiation.

Cardiac physiology and biochemistry. The isolated hearts of animals tolerate ionizing radiation in doses 10 times greater than the lethal dose for man without showing significant functional abnormalities. These data are strong evidence that irradiation does not directly injure the myocardium and the conduction system of the heart.

However, a series of changes in cardiac biochemistry and function following whole body irradiation (700r) of the rat have been carefully defined by Caster and associates. These are most readily summarized by considering these changes chronologically. 0 to 2 days. During the first 3 to 12 hours there are significant increases both in venous pressure and in the plasma volume of the tissues. By the 2nd day there is a loss in deoxyri-

bonucleic acid (DNA) and lipid from the heart, a decrease in the area of the heart shadow and in the total body plasma volume and the peripheral venous pressure has returned to normal. Electrocardiographic changes begin to appear 3 to 5 days. Both venous pressure and plasma volume drop to a minimum. Four days following radiation shows the beginning of a linear decrease in DNA and actomyosin in the heart 6 to 14 days. By the 6th day the venous pressure increases abruptly and continues high until death. The plasma volume of the heart is increased by 50 per cent. The potassium, DNA and actomyosin concentrations of the heart reach minimum values and the percentage of fluid in the heart and lung increases. Cardiac arrhythmias appear more frequently by the 8th to 10th day and deaths occur frequently. The mechanical action of the heart (as indicated by the heart sounds) changes, and there is a significant shift in the electrical axis of the heart.

Electrocardiographic observations. Abnormalities in the T waves (depression and/or inversion) S-T segments (lowering) and miscellaneous arrhythmias have been observed in most species following total body irradiation. The sequence of changes in the electrocardiogram of the rat following irradiation (700r) have been described by Caster and associates. In these studies the decrease in plasma volume rather than direct damage to the myocardium apparently played a major role in producing these changes.

Postmortem evidence. In many species the terminal findings include a marked pulmonary edema and enlargement of the right side of the heart. Blood vessel walls are diffusely and irregularly damaged.

Effects of Aging on the Circulation

With advancing age significant reductions occur in the functional capacities of many different organ systems. Oftentimes these changes are secondary to alterations in the circulation which result in unpaired blood flow to specific organs and tissues. Because of its increased prevalence among the elderly, the disease process arteriosclerosis plays an important role in the functional impairments which accumulate with age. There are, however, progressive changes in the circulation which occur independently of the development of this disease. These changes will be described in this section.

Heart. Progressive changes take place in the heart which are not related to coronary artery disease, the most frequent cause of death in in

FIG 27.6 Age changes in basal cardiac output in normal males. Each point represents an individual subject.

dividuals over the age of 65. For example, there is a gradual accumulation of insoluble granular material in cardiac muscle fibers (Strehler et al., 1959). These granules make their first appearance at about the age of 20 and increase gradually so that by age 80 they may occupy as much as 5 to 10 per cent of the myocardial volume. Animal experiments have shown that at higher ages the activity of important intracellular enzymes of the myocardium, such as succinoxidase, is significantly reduced (Barrows and associates, 1953).

Although average values for resting heart rate tend to diminish slightly with increasing age (Howell, 1950), the increased incidence of irregularities in rhythm in the aged offers evidence of impairment in the mechanisms regulating rate.

Cardiac output under basal conditions diminishes by approximately 50 per cent between the ages of 20 and 80 years (Brandfonbrener and associates, 1955). Fig. 27.6 illustrates a series of measurements made on normal subjects by the dye injection technique. This curve illustrates the wide individual differences in the effects of age which are also found in observations on many other physiological variables. Thus, there are 80 year-old persons with cardiac outputs as high as the average 40 year-old. Cardiac outputs, calculated by an empirical formula from ballistocardiographic records, also show a significant reduction with age (Tanner, 1949).

Statistical analysis of resting blood pressure measurements in a sample of 79,757 apparently healthy people aged 20 to 106 years indicates a gradual rise in systolic pressure up to the age of

70 (Lasser and Master, 1959). After this age systolic pressure remains constant in men and declines in women. There is only a small rise in diastolic pressure (table 27.3).

In experiments where simultaneous measurements of blood pressure and cardiac output were made it is possible to calculate left ventricular work from the equation $W = 14.3 \bar{p}_s$ stroke volume gm m/beat and stroke power from the equation $P = 1.40 \times 10^{-4} \times \bar{p}_s \times$ stroke volume/t, watts where $\bar{p}_s$ = mean pressure during systole and t_s = duration of systole. Both ventricular work and power or rate of work diminish significantly with age (Landowne and associates, 1955). These observations reflect a decrease in left ventricular work since the calculated pressure increase is not proportional to the decrease in cardiac output. The duration of systole increases results in a decrease in calculated rate of work or power of the heart.

Other evidence of decreased power of the heart in advanced age is found in ballistocardiograph tracings. Starr and Hidreth (1952) recorded a second ballistocardiogram after an interval of 10 to 14 years in 80 normal persons aged 20 to 60+. With increasing age, the I plus J amplitude diminished by roughly 50 per cent over the age span tested. These results are interpreted as a reduction

TABLE 27.3

Mean blood pressure and standard deviation in apparently healthy persons, 20 to 106 years of age

From R. P. Lasser and A. M. Master, *Geriatrics*, 1959, 14, 345

tion in the force of ejection and a slowing of the contractile response of the ventricle. Such an adaptation would permit a weak heart to secure the maximum cardiac output possible.

The speed of circulation of the blood as measured by decholine, or by the mean transit time of dyes injected for the estimation of cardiac output, shows a significant slowing with age. The mean transit time of T 1824 from the antecubital vein to brachial artery increases from 19.0 seconds to 23.7 seconds between the ages of 23 and 82 years (Landowne and associates, 1955).

Age changes are also apparent in the electrocardiogram. The P, Q, R and T intervals show a slight tendency toward prolongation, especially at low frequencies, in elderly subjects. The voltages of P, R and T waves decline after the age of 60. The mean electrical axis of the P wave, which is deviated to the left at birth, becomes vertical by the age of 40 and then shifts progressively to the left as age advances. The mean electrical axis of the QRS complex behaves in an opposite manner indicating a more horizontal position of the heart at advanced ages (Mezzasalma and Morpurgo, 1953; Simonson and Keys, 1952). Vector analysis of conventionally recorded electrocardiograms show similar age changes. Both the QRS and T vector are rotated more anteriorly (larger azimuth angle), are smaller in magnitude and show a smaller angle between the vectors in old than in young men (Simonson and Keys, 1956). At present it is not possible to determine the relative importance of alterations in the electrical activity of the heart and anatomical and positional changes in producing the age changes in the electrocardiogram.

Blood vessels. With advancing age the chemical composition of certain blood vessels changes. Lansing and associates (1951), have shown that the elastin of the aorta undergoes an increase in specific gravity, calcium content and proportion of amino acids containing free carboxyl groups. There is an underlying shift in the amino acid composition of elastin, with an increase in aspartic and glutamic acid and a decrease in glycine, proline and valine. The deposition of collagen increases in the intimal and medial layers of blood vessels. Furthermore, the collagen in old blood vessels increases in resistance to solubilization by chemical treatment. It shows a denser aggregation of strands with increased chemical cross linking. The average circumference of the human aorta increases gradually from 45.0 mm at age 20 to 29 to 81.0 mm at age 80 to 89, whereas the cross sectional area of the media increases from

62.0 mm² to 133.5 mm² over the same age span (Wellman and Edwards, 1950). It is clear, therefore, that, as the aorta ages, some substance is added to the media.

These structural and chemical changes form the basis for the increased rigidity of old blood vessels with an attendant increase in pulse wave velocity. Between the ages of 20 and 70 years the pulse wave velocity in the aorta increases from about 5 m per second to 11 m per second (Hall, 1934; Karnbaum, 1957). At lower intra-arterial pressures (diastolic) the pulse wave velocity in the brachial artery also increases with age, but at higher pressures (systolic) the age difference is much less. Thus, in older subjects the artery behaves as if its fibers were initially more completely extended than in the young (Landowne, 1958).

The peripheral vascular system also shows significant age changes. Flow through a number of vascular beds is significantly reduced in old age. For example, plethysmographic studies of blood flow through the fingers show a fall from 4.77 to 2.76 ml per 10 ml finger volume per minute between the ages of 40 and 60 years (Ring and co-workers, 1959).

There is a rapid fall in the circulation to the brain from childhood through adolescence followed by a more gradual but progressive reduction throughout the remainder of life (Kety, 1956). Between the ages of 25 and 95 years the average fall in blood flow to the brain is approximately 25 per cent of the mean value at age 25.

Kidney blood flow, determined by the clearance of Diodrast or para-aminohippuric acid (PAH) falls by about 60 per cent of the mean value at age 25 between the ages of 25 and 90 (fig. 27.7).

FIG. 27.7 Age changes in resting renal plasma flow in normal males determined by clearance of PAH. Each point represents the mean of three 10 minute clearance periods on an individual.

Although the total amount of blood available for perfusion as indicated by the cardiac output, diminishes with age, there is not a proportional reduction in flow to all organs. As indicated above, the age reduction in blood flow to the kidney is greater than the reduction in cardiac output or flow to the brain. Ideally, we should have simultaneous measurements of cardiac output and flow through different organ systems in subjects of different ages. In the absence of such data, we must rely on average measurements made on different subjects at different times.

The simplest explanation of the differences in blood flow through different organ systems is to assume differences in the degree of structural changes such as arteriosclerosis in the vascular beds involved. However, this hypothesis is not in accord with observations which indicate that the reduction in blood flow in certain vascular beds is produced by a functional vasoconstriction that can be reduced by vasodilating agents. For example the intravenous administration of a vaso dilating agent (pyrogen) produces proportional increases in renal blood flow in both young and old subjects (Shock, 1952). This increase in flow results from a decrease in renal arteriolar constriction. In the aged person, under resting conditions, a functional increase in vascular resistance reduces blood flow to the kidney, which makes a great proportion of the cardiac output available for perfusion of other organs such as the brain.

The response of peripheral blood vessels to both heat and cold shows a reduction with age. However, the primary change is in the speed of response, rather than the final degree of vasodilation or constriction attained.

Thus the marked increase in peripheral resistance calculated from measurement of blood pressure and flow which accompanies aging is due, at least in part, to functional changes in the degree of vasoconstriction of individual vascular beds, and not entirely to the increasing degree of sclerosis of the blood vessels.

Age changes in circulatory response to stress

Age changes in all organ systems become much more apparent when the individual is subjected to a physiological stress. Exercise places extra demands, especially on the circulatory system, which are met less effectively in the old than the young.

One of the factors limiting physical performance in older subjects is their diminished ability to transport oxygen. Robinson (1938) showed that the increase in oxygen uptake during work

proceeds at a slower rate in old than young subjects. He also found that the maximum amount of oxygen transported from the lungs falls from 53 to 26 cc per kg body weight per minute between the ages of 17 and 75. Furthermore, old subjects require more oxygen per kg m of work performed than do young at high or low work rates (Norris and Shock, 1960). There is a greater accumulation of lactic acid in the blood during and after exercise in old subjects than in young which indicates a greater degree of muscular anoxia in old than young.

The rate of recovery of oxygen consumption and carbon dioxide elimination following exercise also diminishes with age. Thus, advancing age places a limitation not only on total performance, but also on the rate of readjustment of physiological displacements produced. One of the characteristics of older subjects is their inability to increase their heart rate after severe exercise to as great an extent as younger people. Young men are able to increase their heart rate to a mean value of 200 beats per minute whereas by the age of 65 the maximum rate attained after exercise is only 160 on the average. Since the increment in cardiac output during exercise is controlled primarily by increase in rate rather than stroke volume, the aged individual is unable to maintain adequate blood flow to exercising muscles. It is therefore not surprising that the arteriovenous oxygen difference increases more in old than young under conditions of heavy exercise.

Performance on the standard Master step test also shows impairment in normal aged subjects. Old subjects increase their systolic blood pressure and heart rate more after exercise and require a longer time to return to pre exercise levels than do young.

Changes in posture also offer a challenge to the cardiovascular system. When subjects are passively tilted from supine to the upright position, older subjects showed a greater decrease and slower recovery of diastolic blood pressure and smaller increase in heart rate than do the young (Norris and associates, 1953).

The stress of a pain stimulus (Hardy Wolf thermal stimulator) results in significant increments in heart rate. However, the variability of heart rate from beat to beat under these circumstances diminishes significantly with increasing age (Malmo and Shagass, 1949). It appears that the factors controlling heart rate are less sensitive to environmental changes in the old than in young.

SUMMARY

In addition to the increased incidence of arteriosclerosis, age imposes gradual impairments in the functional capabilities of the cardiovascular system. Structural and metabolic changes occur in the myocardium. There is a gradual reduction in cardiac output as age advances. The systolic blood pressure rises with age, but there is little change in diastolic pressure. Mechanisms for the control of heart rate are less effective in old than young. In old subjects the duration of systole is lengthened, and there is a decrease in left ventricular work even under resting conditions. There is a reduction in the force of ejection and a slowing of the circulation time.

The peripheral vascular system undergoes changes in structure, chemical composition and function. Large blood vessels become more rigid. The distribution of blood flow among different organs shifts with increasing age. Some organs, such as the kidney, show a functional vasoconstriction that diverts a greater proportion of the falling cardiac output to other organs such as the brain.

The reduced capacity for physical work in the aged is related to their inability to increase their heart rate, and thereby to increase cardiac output to meet the increased tissue demands for oxygen. Light exercise produces greater increments in heart rate and blood pressure in old than young. The rate of recovery of heart rate, oxygen uptake and carbon dioxide elimination after exercise, is slower in old than young subjects. Aging results in a general reduction in the reserve capacities of the cardiovascular system and an impairment in the effectiveness of mechanisms controlling heart rate and vasomotor tone.

REGULATION OF THE CIRCULATION UNDER STATES OF STRESS

Shock and Hemorrhage

BASES AND PRINCIPAL CHARACTERISTICS

The state which commonly develops several hours after a severe tissue injury is referred to either as traumatic, or surgical, or wound, or secondary shock. The last designation contrasts it with primary shock which may supervene immediately following the injury. Primary shock has mainly a neural basis and, therefore, is also called neurogenic shock.

It is believed that the most characteristic feature of traumatic shock is a disparity between the circulating blood volume and the capacity of the circulatory system. When such a disparity develops, for any reason, the pressure in the great veins and right atrium becomes reduced and consequently the filling of the ventricles is inadequate. This leads to a decrease in stroke volume, cardiac output and arterial blood pressure. The fall in blood pressure elicits cardiac acceleration and vasoconstriction. The pale cold skin which is typical of shock is a manifestation of the cutaneous vasoconstriction. Also, the decreased rate of blood flow results in the hypokinetic type of hypoxia and associated cyanosis of the ears and finger tips. The acceleration of the heart rate results in encroachment on time for ventricular filling and thus, along with the lowered venous pressure, contributes to lowering of the stroke volume and pulse pressure. A pulse pressure of less than 20 mm. Hg is not uncommon in shock.

Oliguria or anuria may occur in shock since there is inadequate pressure to maintain the glomerular filtration rate (GFR). Renal blood flow is decreased even more than the reduction in GFR. The nonprotein nitrogen of the blood increases and the alkali reserve falls.

The initiating mechanisms in traumatic shock are those which promote either a decrease in blood volume or an increase in the capacity of the cardiovascular system. Trauma may cause actual blood loss of varying degree, but in addition, it may cause extravasation of fluid into the dam-

aged part. The importance of the loss of blood or plasma volume in the production of the signs and symptoms of shock is made evident by the dramatic improvement in the condition of the patient which occurs when the circulating blood volume is restored early after shock has developed. Later on when circulation has been inadequate for awhile the beneficial effect of transfusions is less or the blood pressure may not be restored by this method.

Early in traumatic shock it appears that there is no serious defect in the heart itself as indicated by the response to transfusions, inadequate cardiac filling is the main problem. In so called cardiogenic shock the circulatory failure is central, i.e., in the heart, and the right atrial pressure is not reduced. Obviously, the problem in this case is quite different than in traumatic shock.

If the essential feature in traumatic shock is the reduction in circulating blood volume then the severity will be related both to the amount of reduction and to the time which has elapsed since the reduction occurred. The production of shock by withdrawal of blood has been studied extensively in experimental animals and it has been demonstrated that removal of a certain fraction of the blood volume for a certain time will result in the appearance of shock and subsequent death even though the blood be reinfused.

STAGES OF SHOCK

Wiggers (1950) differentiates between four stages in the progression of shock to the phase in which treatment is ineffective. In the initial or developing stage circulating blood volume is decreased but not sufficiently to cause serious symptoms. Next is the compensatory stage in which blood volume is reduced further, but blood pressure tends to be maintained within the normal range through vasoconstriction. At this stage blood flow through the skin and, perhaps, the kidneys is decreased while flow to the central nervous system and myocardium tend to be maintained. The volume of the spleen and other blood reservoirs typ-

ically is decreased. The *progressive* stage of shock is characterized by the fact that unfavorable changes are becoming more and more prominent: falling blood pressure, increasing vasoconstriction, accelerated heart rate, decreased pulse pressure, oliguria, etc. Progression indicates that compensatory mechanisms are unable to cope with the reduced blood volume so as to maintain the status quo. When the blood pressure is reduced to the range of 60 to 70 mm Hg myocardial depression, a decrease in heart rate and, perhaps, a decrease in arteriolar tonus may become factors in promoting the hypotension. The last or *irreversible* stage is so designated because treatment no longer is successful in saving the life of the patient. Arterial blood pressure is not restored by the infusion of blood. Apparently, both a loss of arteriolar tonus and myocardial depression are factors in the inability of the circulatory system to respond to transfusions in a beneficial manner. The infused blood tends to remain in the capillary beds.

THEORIES CONCERNING THE CAUSE OF SHOCK

Shock can be produced in experimental animals by mechanical trauma which does not break the skin (e.g., pounding the limb of an anesthetized animal with a mallet) and by bleeding the animal to the extent of 40 to 60 per cent of its calculated blood volume. Blalock, using these methods, concluded that there is no essential difference between the shock induced by the two methods. He favored the view that fluid loss at the site of trauma was sufficient to set off the train of events leading to shock. However, Moon believed that a stage is reached in animals in shock when hypoxia of capillary walls causes increased permeability and thus promotes fluid loss into the tissues at sites remote from the injury. This theory seems to be losing ground.

The results of numerous studies of shock in animals can be summarized by stating that the decrease in blood flow in vital structures such as the myocardium, central nervous system and, perhaps, the liver which occurs when blood volume is inadequate leads to the development of changes which can not be reversed by present methods of treatment. It is possible that in irreversible shock vital cells have become irreparably damaged. However, the possibility remains that if the nature of the changes in the late stages of shock were understood better effective treatment could be achieved. Contrary to earlier theories shock does not appear to be due to hypocapnia (as suggested by Y. Henderson) or to paralysis of the vasomotor

center (Crile) or to adrenal exhaustion (Swingle) or to fat embolism from damaged tissues (Porter). It is true that the adrenal cortex, adrenal medulla and the vasomotor system are subjected to increased demands in a patient in shock, but failure of any of these is not demonstrated to be the basis for irreversibility.

In the period from 1914 to 1921 Dale and Landis, Cannon and Bayliss, and others searched for a toxic factor in the production of shock and gave special attention to histamine. This substance is produced in damaged tissues and causes certain changes in the cardiovascular system similar to those which are found in shock. However, it does not appear that enough histamine is produced over a long enough period in traumatized tissues to cause irreversible shock.

Shorr, Zweifach and associates reported the liberation of a depressor substance from the liver in animals in shock. This substance, initially called VDM (vasodepressor material) and later identified as ferritin, was considered to be responsible for the irreversible stage of shock. However, subsequent studies cast doubt on this interpretation. Injection of ferritin in very large doses does not cause symptoms of shock.

It has been suggested that bacterial toxins are concerned in the irreversibility of traumatic shock. Fine (1954) states that irreversibility to transfusion is present from the onset in septic shock whereas it does not develop until after a long delay in hemorrhagic shock. Even in hemorrhagic shock, according to Fine, a bacterial factor is encountered since antibiotics delay or prevent the development of irreversibility. Therefore he believes that administration of antibiotics is important as a part of the therapy of both traumatic and hemorrhagic shock.

Burn Shock

Secondary shock results from extensive burns. In this case loss of fluid and plasma constituents into the damaged area is considered to be the initiating factor. Since blood cells, for the most part, are retained hemoconcentration is characteristic. Transfusion of plasma is quite beneficial under these conditions. The amount of loss of plasma volume is related to the extent of the burn. The possibility of a toxic factor in burn shock is even greater than in traumatic shock, however no specific substance has been demonstrated to be responsible for development of irreversibility. It seems that considerable amounts of histamine are produced in tissues and liberated following burns.

Barsoum and Gaddum found the histamine content of patients suffering from extensive burns to be several times higher than the normal. Also, it is not uncommon for a patient with extensive burns to develop ulceration of the duodenum (Curling's ulcer) which is attributed to the stimulating effect of histamine on gastric secretion. However, no clear correlation in time was found between the histamine concentration in blood and the onset of shock. Rose and Brown observed that the course of blood histamine concentration following burns could be divided into three stages: (1) an early increase in some cases, (2) a marked decrease during the period of edema and plasma loss, i.e., during the time when shock was evident, and (3) a return to normal or above normal levels as the edema subsided and the patient was improving. These results do not support the view that histamine is the responsible agent in the development of shock following burns.

'Crush Syndrome'

A person who has had a limb compressed for some time, for example by a beam or pile of rubble, may pass into a state resembling shock. In the *crush syndrome* impairment of renal function is a prominent factor. The urine is brownish in color, contains dark granular casts and gives a positive test for myoglobin derived from the damaged muscles. In severe cases anuria develops, and death is due to the failure of renal function. The renal tubules are considered to be damaged by myohematin. The anuria, therefore, would be caused in a manner analogous to that resulting from the transfusion of incompatible blood, the difference being that in one the pigment is liberated from muscle and in the other from erythrocytes.

It appears that the blood flow to the renal cortex becomes reduced in the *crush syndrome* which seems to render the tubules more susceptible to the action of the blood pigment. Trueta and his associates found that the renal cortex had a reduced blood flow in tourniquet shock and stimulation of afferent nerves from the limb also causes renal vasoconstriction.

The renal pathological changes seen in the *crush syndrome* are described as lower nephron nephrosis (ch. 35). This consists of extensive degeneration or necrosis of tubular epithelium and is characteristic of a number of different conditions in which toxic substances reach the kidney in considerable quantities or when the renal

blood flow is decreased severely for a relatively prolonged period.

Anaphylactic Shock

The anaphylactic reaction is one which follows administration of a foreign substance (usually protein in nature) to an animal which has been sensitized to it by a previous dose. The second dose may be quite small as compared with the initial dose. The first dose acts as an antigen, that is, it induces the production of antibody by the animal. Usually about 2 weeks must elapse between doses in order that the second dose may produce maximum effects. The severe form of the anaphylactic reaction is called anaphylactic shock. This shows different manifestations in different species. In the dog the primary change which may cause the death of the animal is constriction of the hepatic veins. This holds the blood back in the splanchnic organs and all of the manifestations of failure of venous return consequently appear. Cardiac output, arterial blood pressure and pulse pressure fall. Heart rate is accelerated. Respiration is stimulated. Salivation and vomiting are induced. In the guinea pig the most serious feature of the anaphylactic reaction is the contraction of bronchiolar smooth muscle. This leads to extreme dyspnea and death from asphyxia. The effect can be demonstrated in the perfused isolated lungs of a sensitized animal by the addition of antigen to the perfusion fluid. Histamine may be concerned at least in part, in this reaction since the amount of this substance in the lungs and blood is increased during the anaphylactic reaction and it has a potent stimulant action on the bronchiolar smooth muscle.

In the rabbit the reaction may be general or purely local. When the foreign substance is injected subcutaneously into a sensitized animal, the skin and subcutaneous tissue at the site of the injection become edematous and swollen, a sterile abscess or slough appears. This was originally described by Arthus and is known as the Arthus phenomenon. When the antigen is administered intravenously, the blood pressure falls abruptly and the respirations become rapid. The bladder and intestine are evacuated. The animal may die within a few minutes from dilation and failure of the right ventricle. The failure of the heart is secondary to the increased resistance in the pulmonary circuit caused by constriction of the arterioles. The arterioles in other parts of the vascular system are also constricted and emboli composed of clumps of leukocytes may be seen blocking the pulmonary and systemic capillaries.

The evidence indicates with little doubt, that, in anaphylactic shock the antibody-antigen reaction takes place in or on the tissue cells and not in the blood plasma. Dale showed for example,

that when the uterus was removed from a sensitized guinea pig and its vessels freed from all traces of blood it gave the typical anaphylactic contraction when the antigen was added to the bath in which it was immersed. Manwaring also found that the blood of the sensitized animal could be replaced by blood from a normal animal without affecting the first animal's sensitivity.

It is now generally accepted that the antigen-antibody reaction in some way brings about the liberation of histamine from the affected tissues and that the action of this amine is responsible for some of the anaphylactic manifestations. Nearly all the features as seen in these three species can be explained upon such a basis. In the dog and guinea pig anaphylactic shock is associated with a rise in the histamine concentration of the blood and although the whole blood of the rabbit shows no increase and is often reduced, the amine passes from the white cells (which contain it in especially large amounts) into the plasma. The species peculiarities of the anaphylactic manifestations can be accounted for largely by the amount of smooth muscle in the reactive tissues of these three species and by its susceptibility to the action of histamine. In the dog the smooth muscle of the hepatic veins is especially well developed. In the guinea pig the bronchioles are particularly susceptible to stimulation by histamine and in the rabbit the pulmonary arterioles show unusually thick muscular coats.

Though histamine liberation appears to be a major factor in the production of the phenomena of anaphylaxis, certain observations indicate that some other factor or factors are involved. Minute doses of histamine for example cause contraction of the isolated rat's uterus, whereas large doses of antigen are required to produce even a weak contraction. Also the isolated guinea pig uterus poisoned by high concentrations of histamine responds to a further dose by relaxation but by contraction to a further dose of antigen.

Peptone solution injected intravenously produces in the dog effects almost identical with those of anaphylactic shock, including incoagulability of the blood due to the liberation of heparin from the liver. Sensitization by a previous dose is not necessary however. Adding peptone to rabbit blood *in vitro* causes the liberation of histamine from the cells into the plasma.

In man fatal anaphylactic shock may follow the injection of horse serum into a person who has been sensitized by a previous administration. Allergic reactions in general show many similarities to anaphylactic reactions and many observations suggest that the two are fundamentally allied although in the case of allergic reactions, sensitization by an earlier exposure cannot always be demonstrated, the reaction appearing upon the first known contact with the foreign substance.

Congestive Heart Failure

Heart failure occurs when the heart muscle is weak or if the heart ceases to pump blood because of arrest or ventricular fibrillation or if cardiac filling is prevented. The heart may fail suddenly as a result of occlusion of a coronary artery or following rapid accumulation of fluid or blood in the pericardial sac or failure may result from sudden overloading of a heart already weakened by chronic disease. In acute heart failure there is a sudden reduction in or cessation of cardiac output. Arterial blood pressure decreases, the pulse weakens or is not palpable and vasoconstrictor reflexes are elicited from the pressoreceptors. The patient is in shock as far as conditions on the arterial side of the systemic circuit are concerned but the venous pressure is not lowered as in shock related to decreased blood volume.

CHRONIC CONGESTIVE HEART FAILURE

A number of chronic diseases eventually lead to weakening of the heart muscle and this results in the development of the syndrome which is known as chronic congestive heart failure. It is important to recognize that heart failure designates a clinical syndrome rather than any specific defect in the heart.

Weakness of the heart is not necessarily expressed as decreased cardiac output since homeostatic mechanisms operate which tend to maintain whatever cardiac output is needed to meet the metabolic requirements of the tissues. Hence in many cases of chronic congestive heart failure a normal cardiac output under resting conditions is observed in the presence of a moderately elevated venous pressure (Espersen, Altschuld, McMichael, 1938 and 1947; Richards, 1949). The weakness of the heart is evident in that it pumps less blood than a normal heart would pump if it were subjected to the same (elevated) filling pressure. It will be noted that the definition of cardiac weakness implied in the preceding statement is that a weak heart is one which will show a lower than normal increase in output in response to a given increase in the venous pressure. Thus if cardiac output at various venous pressures is graphed, a curve would be obtained which lies somewhere below that for a ventricle of normal strength, and the weaker the ventricle, the lower will be this curve (see Youmans and Huckins, 1951).

Another way of thinking about the strength of the heart is in terms of its reserve. Although the moderately weakened heart can achieve a normal

output under resting conditions or during mild exercise it has less reserve. As the level of muscular activity is increased a point would be reached at which cardiac output could not increase further, whereas the normal heart could continue to increase its output well beyond this amount as muscular activity is increased (Niel sen). Thus, the first indication of cardiac weakness is a reduction in the cardiac reserve, as determined by suitable exercise tests, and the severity of cardiac "disability" would be related to the degree of loss of the cardiac reserve.

When the cardiac reserve is diminished as a result of disease cardiovascular adjustments occur to maintain adequate output, and the heart and circulation are said to be in a state of compensation. When such adjustments are inadequate as manifested particularly by a considerable rise in venous pressure, increase in heart size (dilation) and other signs of congestion the condition is referred to as cardiac decompensation.

Congestive heart failure may develop in any person whose heart has been working for a more or less prolonged period against a high peripheral resistance (e.g., essential hypertension) or if the work of the heart has been above normal because of cardiac valvular defects (rheumatic fever) or because of prolonged continuous demands for increased cardiac output (hyperthyroidism, arteriovenous fistula). When the work of the heart is increased chronically, for any reason, a sequence of changes in heart muscle is induced which terminates eventually in its weakening. On the other hand, weakness of the myocardium may result from more specific causes such as inadequate blood supply, damage by certain toxins, etc.

SEQUENCE OF CHANGES IN CONGESTIVE HEART FAILURE

The chief manifestations of chronic congestive heart failure are increased extracellular fluid volume, increased blood volume, elevated venous pressure, dyspnea, cyanosis in some cases, enlargement of the liver and spleen, edema of the dependent parts of the body, and in some cases hydrothorax and ascites. The cardiac output in classical congestive heart failure in the patient at rest is within the normal range or decreased. However, in a group of conditions commonly referred to as "high output" heart failure specific stimuli are present which cause an elevated basal cardiac output.

Until a few years ago most discussions of the mechanisms involved in the development of the

characteristic changes seen in congestive heart failure presented either or both of two theories: the "backward failure" theory, and the "forward failure" theory, however, it no longer seems profitable to describe these theories as such but rather to present the sequence of events now reasonably well established.

One of the most characteristic features of congestive heart failure is the increase in volume and pressure of blood in the pulmonary circuit and in the right atrium and systemic veins (Landis and others, 1946, McMichael, 1947). What causes these changes? According to the earlier theories a decrease in output of the left ventricle would, on purely hemodynamic bases, allow the pulmonary circuit to become congested to the extent that it occurs in congestive heart failure. Likewise, the rise in systemic venous pressure was attributed entirely to failure of the right ventricle to respond to its filling pressure in such a way as to keep the pressure down to normal levels. At the time of the actual onset of failure it was visualized that blood was returning to the corresponding ventricle more rapidly than it was being pumped out, and therefore, the pressure upstream from the ventricle was being permitted to progressively increase until the relatively high levels which occur in congestive heart failure were reached. In some explanations the ventricle was referred to as "damming back" the blood or causing "back pressure." It is apparent, however, that a cardiac ventricle behaves as a force pump and not as a dam (Starr, 1949). The ventricles do not create a back pressure by failing to pump; they allow the pressure to rise as they fail to force the blood on. Therefore, the term "back pressure" does not seem to be suitable to describe any of the hemodynamic changes associated with congestive heart failure. For example, the rise in pressure in a system which occurs as water runs into it faster than it is lifted out by a pump would not be called back pressure.

The concept that venous pressure can increase to very high levels as a consequence of failure of the ventricle to pump the blood which is flowing in by the venous system implies a continuing venous return in the presence of decreased cardiac output. However, the venous return is the same as the cardiac output for any prolonged period except as a shift of volume out of the arterial tree occurs when cardiac output and mean arterial blood pressure decrease. As arterial pressure falls the volume in the systemic arterial tree decreases and this is associated with a slight increase in

pressure in the "low pressure" portions of the cardiovascular system (i.e., the great veins, atria and pulmonary circuit). The maximum increase in pressure which could occur in the atria, on purely hemodynamic bases, when ventricular output decreases is that which would occur following ventricular arrest. When this occurs flow from the arterial tree into the systemic veins and pulmonary system continues until equalization of pressure occurs at the static blood pressure level which is only about 8 to 10 cm. of water. Thus, a rise in venous pressure to the levels which commonly are seen in congestive heart failure is not produced simply by failure of the ventricles to pump the blood returning to them. The large rises in venous pressure are dependent in part upon elevation of the blood volume. Starr (1940) reported that the static blood pressure, i.e., that found throughout the circulatory system shortly after the heart ceases to beat, was considerably higher in patients who had died of heart failure than in those who died from other causes. The elevation of static blood pressure can be attributed to any of three changes: reduced capacity of the cardiovascular system, reduced distensibility or increased volume of blood in the system. There is no reason for considering that either of the first two changes is characteristic of congestive heart failure. Blood volume, on the other hand, has been found to be elevated in congestive heart failure by most investigators who have studied it (Altschule, Borst).

The initial change in the cardiovascular system which leads to the classical syndrome of congestive heart failure must be assumed to be the decrease in left ventricular output related to weakening of the left ventricle or lack of filling of the left ventricle secondary to such changes as right ventricular failure or compression of the left ventricle from without (as from pericardial effusion). Then a series of changes is initiated which in mild or moderate cases leads to restoration of the cardiac output. Hence, when congestive heart failure is diagnosed some of the measurable changes are those which have occurred to counter a decrease in cardiac output. When cardiac output is found to be decreased in the patient at rest this indicates that the condition is so severe that compensatory mechanisms which serve to maintain cardiac output have been overtaxed. In other words a subnormal cardiac output in the patient at rest indicates virtual absence of cardiac reserve.

Patients with congestive heart failure usually have a decreased renal blood flow while the glom-

ular filtration rate is reduced to a lesser degree (Merrill, Bradley and Blake, Davies and Kilpatrick, Mokotoff and others). The load of sodium and chloride filtered at the level of the glomerulus is decreased in direct proportion to the reduction in glomerular filtration. This alone, if sodium reabsorbing capacity of the tubules were unaltered, would lead to a considerable reduction in NaCl excretion. However it appears that tubular reabsorption of sodium also is stimulated. This change has been attributed to the action of aldosterone which is reported to be produced in increased amounts (Parrish, Lasche and others, Singer and Wener). Regardless of the mechanism, the ability of the kidney to excrete NaCl is markedly impaired in patients with congestive heart failure as indicated by the fact that they may show a positive salt and water balance despite a greatly restricted salt intake.

The decreased renal blood flow and glomerular filtration rate in congestive heart failure in the presence of an arterial blood pressure within the normal range indicates that the tonus of renal arterioles is increased. The increased filtration fraction (see ch. 34) may be related to efferent arteriolar constriction since a change of this type causes a lowered renal blood flow without producing a corresponding decrease in glomerular filtration rate.

Patients with congestive heart failure do not show impairment of ability to excrete water in a degree that makes it necessary for them to restrict their water intake. The defect which leads to the increase in the amount of NaCl and water in the body and the corresponding rise in volume of the extracellular fluid compartment is the failure of the kidney to excrete NaCl . As the salt is retained water is held back with it. As a part of this secondary process the increased production of antidiuretic hormone (ADH) may be involved. It has been postulated that the reabsorption of sodium ion from the tubules is the primary change and that the chloride ion moves along with sodium because of its opposite charge. It is significant that the amount of edema in a patient with congestive heart failure can be controlled by directing attention to lowering the total amount of NaCl in the body, by any of several methods, while allowing him to drink water *ad libitum* (Futcher and Schroeder, Schroeder). In the reaction against the severe restriction of water intake, which occurred when it was recognized that there is no physiological basis for such a regimen, it was reported that forcing fluids was of benefit in treating congestive heart failure.

(Schemm, 1942 and 1944) It now appears that a low fluid intake is disadvantageous but that high fluid intake is not of value except to correct the ill effects of dehydration produced by a period during which fluid intake had been severely restricted

HIGH OUTPUT CIRCULATORY FAILURE

Some patients who are diagnosed as having congestive heart failure have a basal cardiac output well above the normal range. Furthermore, effective treatment leads to a lowering of the basal cardiac output to normal levels. It is not reasonable to consider that cardiac weakness as such would lead to an increase in the basal cardiac output, therefore, in patients who have the high output type of circulatory failure it is reasonable to postulate a source of cardiac stimulation which is not present in normal persons.

The similarities between simple congestive failure, described in the preceding section, and high output failure are related to the fact that retention of NaCl and water occurs in both. The increase in extracellular fluid volume leads to many of the signs and symptoms which are common to the two syndromes. The two principal differences between the syndromes are (1) that in high output failure the peripheral resistance typically is low while in simple congestive heart failure it tends to be elevated, and (2) that the level of the basal cardiac output, by definition, is elevated in high output failure. Since a low peripheral resistance, as produced for example by an arteriovenous shunt, will elicit an increase in cardiac output, it is logical to consider that the decreased peripheral resistance is a primary change in the cardiovascular system in patients with high output failure and is the basis for the cardiac stimulation (Youmans and Huckins, 1951, Youmans, 1954 and 1957). Associated with the increased cardiac output there is a shortened circulation time, decreased arteriovenous oxygen difference, increased heart rate in some cases and, commonly, a widening of the pulse pressure.

There are several reasons for postulating that the decrease in peripheral resistance in high output failure is the initial change in the cardiovascular system that leads to the other changes characteristic of the syndrome. (1) In arteriovenous fistula, which may lead to high output failure, perhaps in its purest form (see Elkin and Warren, Holman, Cohen and others), the initial hemodynamic alteration obviously is the reduced resistance to outflow of blood from the systemic arterial tree. (2) Decreased peripheral resistance

occurs in beriberi, severe anemia, hyperthyroidism, Paget's disease, patent ductus arteriosus, hyperthyroidism and certain types of chronic pulmonary disease, all of which may lead to high output failure. (3) The high cardiac output can be explained as a compensatory response to the low peripheral resistance. (4) The renal retention of salt and water may be caused by a shunting of blood away from the kidney by a disproportionately large decrease in resistance in the extra renal portion of the systemic circuit.

In 1937 Wersa and Wilkins emphasized the similarities between the effects of systemic arteriovenous fistula and chronic thiamine deficiency and they observed that circulatory changes produced by large doses of thiamine in patients with beriberi heart disease are similar in important respects to those associated with closure of an arteriovenous fistula. The pattern of cardiovascular changes in beriberi heart disease is the typical high output failure syndrome (Porter and Downs, Weiss and Wilkins, Burwell and Dexter).

Davies and Kilpatrick found renal blood flow and glomerular filtration rate reduced in patients with high output failure due to chronic cor pulmonale. The average for 10 patients was about one half the average for normal individuals. If the renal blood flow in these patients is expressed as the per cent of the cardiac output, the range is 20 to 15 per cent with an average of 7 per cent as compared with an average of around 22 per cent in normal subjects. It is evident that the kidneys do not share in the increased circulation in high output failure associated with beriberi or cor pulmonale. This demonstrates that the extrarenal fraction of the peripheral resistance is disproportionately lowered in these diseases, just as it is in systemic arteriovenous fistula.

It seems probable that chronically increased demands upon the heart caused by a low peripheral resistance would lead eventually to development of cardiac weakness just as when increased cardiac work is related to other types of changes in the circulatory system. If this should occur, the sequence of changes seen in simple congestive heart failure would be expected to be superimposed upon those changes related to low peripheral resistance to produce the final picture in prolonged severe high output failure. In other words, early in high output failure the changes seen could be related entirely to compensation for low peripheral resistance while later the factor of cardiac weakness also probably would be present.

CONSEQUENCES OF HYPERVOLEMIA IN CONGESTIVE HEART FAILURE

It is visualized that hypervolemia to some extent has a compensatory role in simple congestive heart failure and in the high output failure syndrome, however, the increase in blood volume may be great enough to lead to difficulties. The principal dangers in hypervolemia are, first, the possibility that the weakened left ventricle may become dilated to the extent that the dilation per se contributes to an acute decrease in cardiac output, and second, that the pressure in the pulmonary capillary bed may become increased to the point of producing transudation into the alveoli. The dangers of fluid administration to patients with hypervolemia are obvious, but the consequences of administration of vasoconstrictor drugs are less apparent. The ill effects of such drugs in hypervolemia are related to the fact that they promote a shift of blood from the systemic circuit into the already engorged pulmonary circuit, and thus may cause a rise in pulmonary capillary pressure sufficient to produce pulmonary edema.

The degree of pulmonary congestion in a patient with chronic hypervolemia is least in the orthostatic position but is increased when the patient lies down. Immediate transfer of blood from the systemic to the pulmonary circuit occurs as a result of the effects of gravity when the recumbent position is assumed. However, there is also a gradual increase in blood volume while the patient remains recumbent, as edema fluid moves from the interstitial space through the capillary walls, thus the blood volume shows nocturnal increases in patients with chronic hypervolemia and edema. The rise which occurs during the night, and the consequent increase in pulmonary engorgement, perhaps may explain the development of acute dyspnea.

Hemodynamics

The following is a discussion of the effects of arrhythmias, valvular disease, cardiac tamponade, and congenital heart disease on the hemodynamic function of the heart. In less than two decades, tremendous advances have been made in the study of these pathological entities by the development of catheterization techniques (including pressure measuring devices) for use in human. Reference will at times be made to pertinent animal studies, but, mainly, the more important human data will be presented. However,

it must be remembered that large variables are inherent in flow measurements on human subjects even when obtained by cardiac catheterization. In addition to the difficulties in measuring cardiac output by the Fick principle (including dye methods (ch 18), true controls are lacking (except those from a series of catheterized, normal subjects) for the patient cannot be his own control. As an example, an end diastolic ventricular pressure of 4 mm Hg may be elevated since the patient's normal level (before compensation of the heart to the pathological stress) may have been 1 mm Hg. This small pressure elevation could represent a significant diastolic volume increase. Since catheterization may be a frightening experience to most patients, another variable is the failure to attain a resting, steady state. Anesthesia cannot be used because it produces hemodynamic changes such as an increased cardiac output. When variables are measured 'following exercise,' the exertion is performed with the patient in the supine position (with catheter in place), therefore the amount of exercise is usually mild.

Formulas have been derived for the calculation of flow through shunts and stenotic and regurgitant valves. These formulas often use the cardiac output, pulmonary wedge pressure, completely mixed venous blood samples and other measurements or calculations which possess their own error. Clinically the information derived from these catheterizations is very practical and important but physiologically it may represent only directional and semiquantitative hemodynamic changes. Therefore, the precise measurements obtainable in animal experiments are often lacking.

The pulmonary wedge pressure and the extent to which it may or may not represent the events in the pulmonary capillary bed or the left side of the heart, has been discussed. The term "pulmonary circulation pressures" includes the pulmonary venous, wedge, and arterial pressures. The "filling pressure gradient" is the difference in pressure between the atrium and ventricle causing blood to flow from the former to the latter. Often a gradient cannot be measured across a normal or pathological valve by the techniques in present use. Yet a pressure gradient must exist in order for blood to flow. There is evidence that small pressure differences (which may not be measurable by modern equipment) can lead to large blood flows (ch 22). An important technique for measuring these pressure gradients by withdrawal of the catheter from one

chamber to another with continuous measurements of pressures, is being replaced by the use of a double lumen catheter with an opening in each chamber

HEMODYNAMICS IN ARRHYTHMIAS

The investigation by graphic methods, the etiology and the treatment of disorders of the heart beat have already been considered in chapter 23. In this section, the hemodynamic effects of arrhythmias on the circulatory system will be discussed. Stress on the heart is caused by arrhythmias possessing one of the following characteristics: (1) a very rapid rate, (2) an irregular rhythm with disruption of the normal atrial and ventricular coordination, or (3) a very slow rate. Whether the arrhythmia develops in a normal or diseased heart is often very important to the hemodynamic effects produced and, hence, must be considered in determining the actual alterations caused by the heart rhythm. Also, if drugs, like digitalis (inotropic effect on the heart), quinidine (decreased peripheral resistance and increased cardiac output), or procaine amide (decreased blood pressure probably due to peripheral vasodilation) are used to revert the arrhythmia,

the corrected hemodynamic effects cannot be attributed only to reversion of the arrhythmia. A consideration of the role of atrial contraction in the normal functioning of the heart becomes important in those arrhythmias interfering with atrial systole. Atrial systole brings the atrioventricular (A V) valves into closer apposition and may add some blood volume to the ventricles. However, there is no adequate evidence that a normal heart cannot function properly without contraction of its atria. On the other hand, improperly timed atrial systoles, occurring when the atrioventricular valves are closed, can lead to hemodynamic abnormalities.

TACHYCARDIAS The results of animal experiments by Starzl and associates on normal hearts in closed-chest animals showed that electrically induced atrial tachycardias at rates up to 190 per minute for short periods usually caused no alterations in cardiac output, systemic arterial blood pressure or systemic venous pressure, whereas the stroke volume and radiographic size of the heart decreased (fig. 28.1). If on the other hand, the ventricles were electrically stimulated to a tachycardia (made possible with stimulatory rates above the existing sinus rate), the cardiac

FIG. 28.1 The effect of atrial and ventricular tachycardia in the dog. Changes in cardiac output and stroke volume from the initial sinus rate values are shown with increasing rates of atrial and ventricular electrical stimulation. The changes are depicted as percentages of control values. Experiments were performed in closed chest dogs. In contrast to atrial stimulation, ventricular driving irrespective of ventricular stimulation site resulted in a reduction in cardiac output and stroke volume. (From Starzl, T. E. and associates, *Circulation*, 1955, 11, 932)

output, stroke volume, and blood pressure decreased. The resultant atrioventricular asynchronism produced discordant positions of the A V valves at the time of ventricular systole, varying from fully open to fully closed, thereby altering the end-diastolic ventricular volume. The strongest beats (largest stroke volumes) would occur after the longest diastoles (largest end diastolic volumes), whereas shorter diastoles would produce weaker beats. If the atrioventricular conduction pathways were then blocked and the ventricles driven at rates up to 190, the results resembled those described for atrial tachycardia.

Clinically the supraventricular tachycardias (atrial and nodal) cause circulatory disturbances if there is underlying heart disease, or if the tachycardia is prolonged in time. However, heart rates over 200 per minute were tolerated for hours and sometimes days in patients without heart disease. Ferrer and associates studied two patients during paroxysms of nodal tachycardia by right heart catheterization. An unaltered cardiac output with a decreased stroke volume was found. Right atrial pressure was elevated while blood pressure and peripheral resistance were normal. Since atrial systole followed ventricular contraction in these patients, the atrioventricular valves were probably not tightly opposed during ventricular systole. This could lead to tricuspid regurgitation and explain the elevated right atrial pressure.

Patients with atrial flutter have been studied in the same manner as above. Those without underlying heart disease, and one patient with a slow ventricular rate, were found to have normal cardiac outputs. When heart disease was present, atrial flutter with a rapid ventricular rate induced a marked decrease in cardiac output and stroke volume concomitant with a small systemic arterial pulse pressure, prolonged circulation time, dilated heart by roentgenograms, and a raised venous pressure in some patients. In all instances, after reversion to sinus rhythm, the resting cardiac output rose. This was found to be true in 2 patients after all medication had been discontinued. Since this rise in cardiac output occurred without a change in heart rate in 2 patients, and the ventricular diastolic filling time therefore remained constant, it was suggested that atrial flutter contributed to reduced blood flow by the continuous, rapid atrial contractions impeding venous inflow. Pulmonary circulation pressures (pulmonary artery and pulmonary wedge pressures) were normal during atrial flutter in those patients with circulatory insufficiency. It is of interest,

and unexplainable, that patients with atrial flutter and congestive heart failure had a lower pulmonary artery pressure than those with cardiac failure and sinus rhythm.

IRREGULAR RHYTHM Atrial fibrillation contrasts with the above tachycardias by having an irregular ventricular rhythm and absent atrial contractions. The distinguishing characteristics of atrial fibrillation from the regular tachycardias are beat to beat variations of ventricular rate, or ventricular filling and emptying, and of arterial blood pressure (a changing resistance to ventricular ejection). It has been shown in animals and patients that the beat to beat changes were related not only to the previous diastolic filling time and end-diastolic volume, but also to the arterial pressure, end systolic volume and the duration of systole of the preceding beat. In closed-chest dog experiments, acutely induced atrial fibrillation with rapid ventricular rate decreased cardiac output and blood pressure, and increased central venous pressure and the arteriovenous oxygen difference. Dilation of the heart could be seen by roentgenograms. On reversion to sinus rhythm the previous status of the circulatory state returned. In patients, reversion to sinus rhythm is usually beneficial if the ventricular rate is rapid and if drugs that affect the circulatory system are used. Most show an increased cardiac output with shortened circulation time and decreased right atrial pressure. Exercise tolerance is often improved. However, most of the patients studied had underlying heart disease and had evidence of cardiac failure. In 2 patients without heart disease, cardiac output was not changed on reversion to sinus rhythm.

In summary, it can be said that atrial fibrillation with a rapid ventricular rate can lead to circulatory failure in diseased hearts or sometimes in normal hearts. Despite the demonstration of some atrioventricular valvular regurgitation with atrial fibrillation, evidence is lacking that the arrhythmia with a slow ventricular rate is definitely detrimental to the circulatory status of a patient. The effect of the lack of atrial contraction has been discussed above. Since many patients in chronic congestive heart failure are benefited, and since the development of blood clots in the fibrillating atria is dangerous, most cardiologists recommend at least one attempt at reversion to normal rhythm.

BRADYCARDIAS Up to this point, the arrhythmias which cause a rapid heart rate have been considered. Very little hemodynamic data is available concerning sinus bradycardia and par-

tial heart block. A decreased cardiac output but a marked increase in stroke volume was present in one patient studied with sinus bradycardia. It is generally held that when the heart rate slows, there is an increase in end-diastolic volume due to the longer diastolic period. This increases the myocardial fibers' length and leads to a greater stroke volume. In this manner, the cardiac output is maintained at slow heart rates, probably as low as 30 to 40 beats per minute. Slower rates often lead to circulatory insufficiency secondary to a decreased cardiac output.

In experimental dogs, complete heart block can be produced by tying or cutting the atrioventricular conduction pathway. This usually results in average heart rates of 40 to 55. These dogs acutely manifest a decreased cardiac output proportional to the decrease in heart rate, an increased pulse pressure secondary to a decreased diastolic but normal systolic arterial blood pressure, a greater systemic arteriovenous oxygen difference and a rise in right atrial pressure. Within hours each of these factors tends to return toward normal. If the dog's ventricles are electrically stimulated to the preblock heart rate, the cardiac output and other abnormalities return immediately to normal levels. However, these dogs, especially if allowed normal exercise, usually develop severe cardiac failure within 3 months. In this respect they differ from humans who appear to better tolerate complete heart block. (Patients with congenital heart block may have a normal life span.)

Patients with complete heart block have been studied with right heart catheterization and by rapid biplane angiography. In patients without circulatory insufficiency, an elevation is found in right atrial systolic and mean pressure, right ventricular systolic and end diastolic pressure, and pulmonary and systemic artery pressure and pulse pressure. A decreased cardiac output and cardiac index (cardiac output per square meter of body surface) with an increased stroke volume is present. However, the cardiac output (and cardiac index) was reported as normal, despite the above abnormal cardiac pressures, in some patients without underlying heart disease. Angiographic studies with timed electrocardiography have contributed to the understanding of the hemodynamic data in complete heart block. The timing of atrial systole in relation to ventricular systole determines the size of the atria and whether or not reflux of blood occurs into the great or pulmonary veins. When the atria contract against closed valves, or if more than one atrial systole occurs before a ventricular systole empties the

ventricle, the right atrial pressure rises and reflux may occur.

In summary, complete heart block without underlying heart disease is compatible with a long and active life despite the presence of abnormal chamber pressures. Often such patients, especially if the heart block is of congenital origin, have a small increase in heart rate with exercise. If there is underlying heart disease the prognosis is quite poor (despite available treatment) due to eventual circulatory failure from a chronic overload on the heart. Treatment consists of epinephrine, isoproterenol, sodium lactate, methamphetamine or atropine, and more recently the corticosteroids have been recommended. Isoproterenol is the only drug which has been studied and has been shown to augment the cardiac output not only by an increase in heart rate in some patients but also by a direct myocardial effect with an increased stroke volume in others. Recently, platinum electrodes of miniature battery operated, mechanical stimulators have been inserted into the ventricles by percutaneous probe or at open thoracotomy and have met with some favorable success.

HEMODYNAMICS IN VALVULAR HEART DISEASE

Rheumatic endocarditis is the most frequent disease leading to abnormalities of the heart valves. The mitral valve is most commonly affected followed by the aortic, and then the tricuspid valve. The pulmonary valve leaflets are rarely affected. Pulmonic valvular disease will be considered in the following section, Congenital Heart Disease. Other causes of valvular disease include syphilis, bacterial endocarditis, calcification of the valves and trauma.

When the valves become deformed by disease, they impede the flow of blood or allow leakage to occur. If there is narrowing of one of the orifices of the heart the condition is spoken of as "stenosis." Stenosis of the valves is caused by fusion of the leaflets, rigidity of the cusps due to fibrosis and/or shortening and adherence of the chordae tendinae. When the valves are incapable of closing tightly, they are said to be "incompetent," "regurgitant," or "insufficient." They now allow blood to regurgitate in the opposite direction to that of the normal flow. Insufficiency of a valve may be due to deformity, rigidity, retraction, fusion of the cusps or chordae tendinae, or to a dilation of the ring of the valves. If the leaflets are deformed sufficiently to produce stenosis of a particular orifice, they may also be incapable of closing properly and regurgitation will occur as

well. Therefore, stenosis and incompetence of a valve often occur together.

HEART MURMURS When the valves become deformed, abnormal heart sounds appear. Such sounds are spoken of as murmurs or bruits. Presumably, heart murmurs result from the development of turbulence in rapidly flowing blood. The flow of blood through most cavities and channels is silent because the flow is laminar. Turbulence will appear when the Reynolds' number is exceeded (ch 15). Practically speaking, cardiac murmurs appear in the presence of the following conditions, separately or in combination: high rates of flow through normal or abnormal valves, forward flow through a constricted, or an irregular valve or into a dilated vessel, back flow through a valve, septal defect or patent ductus arteriosus, presence of a loose, vibrating structure, such as a chordae tendinae. The impression should not be gained that all murmurs denote underlying cardiac pathology. Early systolic murmurs can be detected in a majority of children, especially those with thin chest walls. These murmurs are called functional and are most often heard at the pulmonary area. Early systolic murmurs are also audible in many normal persons following exercise and, presumably, arise from the increased flow rate. Hemiac murmurs develop in anemic patients as the result of decreased blood viscosity and increased blood velocity in the presence of an augmented cardiac output.

TIME RELATIONS The particular valve involved is determined from the relation of the murmur to the events of the cardiac cycle and from the point upon the chest wall where the sound is transmitted with the greatest intensity. For instance, the aortic valves should open fully during the ejection phase of ventricular systole so as to offer little or no resistance to the outflow of blood at this time. At the end of the period of ejection they should close tightly. If however the orifice is stenosed, the obstruction causes a murmur to be heard during ventricular systole which replaces or modifies the clear first sound. This is referred to as a *systolic*

murmur (fig 282). If, on the other hand, the valves are incompetent and do not come together at the end of the systolic discharge, a rush of blood from the aorta into the ventricle occurs in diastole, and a murmur modifies the normal second sound—diastolic murmur. The murmur may appear in early, mid, or late diastole or may persist throughout almost the entire period. When stenosis and incompetence co-exist a murmur may be produced at the aortic orifice during both systole and diastole, in which event the two normal sounds are replaced by a to and fro blowing sound. A systolic murmur will also be caused by incompetence of the A-V valves (mitral or tricuspid) since the rise in pressure during ventricular systole will drive blood backwards into the atrium and cause abnormal vibrations to be set up.

GALLOP RHYTHM In certain conditions, three distinct sounds are heard which give rise to a rhythm not unlike the gallop or canter of a horse. In addition to the clearly audible first and second heart sounds of each cardiac cycle, a third and even a fourth diastolic sound may be heard. All four sounds are often seen in phonocardiographic tracings. Gallop rhythms appear to be the pathological counterparts of the third and fourth heart sounds.

In some cases the abnormal sound precedes the first sound—the presystolic (atrial) type of gallop rhythm. Two sounds are heard in rapid succession followed by a pause, and then by the second sound (fig 283). This type is associated with depressed atrioventricular conduction (ch 16), bundle branch block, myocardial infarction or, most commonly, hypertensive cardiovascular disease. The extra sound is usually attributed to the actual muscular contraction of the atrium; more recent evidence favors a forceful movement of the ventricular wall apparently resulting from atrial ejection into the partially filled ventricle. Normally, the ventricular contraction follows so closely upon atrial systole, that any sound that may be produced merges into the first heart sound. When, as a result of slowed conduction, the atrial and ventricular systoles are separated by an appreciable interval, the sound resulting from contraction of the atrium may become audible.

In other instances, the abnormal sound follows shortly after the second heart sound—early diastolic (protodiastolic) type of gallop rhythm (fig 284). Most commonly, this gallop rhythm is associated with incipient or actual cardiac failure, therefore, it has a different clinical significance than the presystolic gallop. The cause of

FIG 282 Diagram showing the time relations of heart murmurs to the heart sounds. A, presystolic murmur, B, systolic murmur, C, early diastolic murmur. Numbers refer to normal heart sounds.

FIG 28 3 Phonocardiogram (and electrocardiogram) demonstrating a presystolic gallop (*G*) in a patient with hypertensive heart disease. A systolic murmur is also present between the first (*S*₁) and the second heart sounds (*S*₂) (From Levine and Harvey)

the protodiastolic gallop is unknown. It is not secondary to an asynchronous closure of the pulmonary and aortic valves. The sound occurs at the end of the period of rapid ventricular filling (as shown by correlative studies with intra-cardiac pressure curves). Most likely it is either produced by vibrations set up in the walls of the relaxed dilated ventricle by the shock of blood as it rushes from the atrium or by a temporary reclosure of the atrioventricular valves (Dock).

Two variations of these gallop rhythms may occur. When both gallop sounds are present a quadruple rhythm is produced. When the heart rate becomes very fast a single very loud sound may occur in mid-diastole. This is a result of the fusion of the two gallop waves. It is probably not just an addition of the two sounds but is a new sound produced as a result of atrial contraction actually augmenting the phase of rapid ventricular filling.

In some instances an abnormal sound is heard between the first and second heart sounds—the systolic type of gallop. In contrast to diastolic gallops the systolic gallop is usually of little clinical significance. The origin of the extra sound is uncertain although it may be secondary to vibration set up in a dilated vessel, pleuropenocardial adhesions or to other extracardiac factors.

MITRAL STENOSIS Mitral stenosis is the most common valvular abnormality resulting from rheumatic involvement of the heart. Some degree of mitral regurgitation is also often present. The hemodynamic effects are due to the obstruction to flow between the left atrium and the left ventricle. The normal mitral valvular orifice in man varies between 4 and 6 cm². When this is reduced to about 1.5 cm² hemodynamic abnormalities may be found and at 1 cm² they are severe enough to cause symptoms in most patients.

Mitral stenosis by offering an obstruction to the flow of blood from the atrium into the ventricle may cause a murmur to be heard at any time

FIG 28 4 Phonocardiogram (and electrocardiogram) demonstrating an early diastolic gallop (*G*). Note that the gallop sound occurs in early diastole nearer the second (*S*₂) than the first heart sound (from Levine and Harvey)

between the second and the first heart sounds (fig 28 5). Since intensity of the murmur is dependent on both amount of flow and stenosis, it is not an indication of the degree of stenosis. The duration of the murmur is recognized as correlating better with the size of the stenotic valve since a longer ventricular filling period must be accompanied by a longer murmur. Though the murmur may extend throughout diastole, it tends to be more intense toward the beginning and the end of this phase; it may be heard only during these times or be confined to one or the other of them. The late diastolic murmur (presystolic) disappears when auricular fibrillation supervenes and abolishes the propulsive action of atrial systole.

Braunwald and his associates have defined the hemodynamics of the cardiac cycle in mitral stenosis by catheterization of the left chambers of the heart in patients. Simultaneous inscription of atrial and ventricular pulse pressures (fig 28 6) show that the crossing of the left atrial and ventricular curve and the onset of the atrial c wave are delayed. Since the left atrial pressure at the end of diastole is higher than the ventricular pressure, the mitral valve cannot close until the ventricular pressure reaches that of the left atrium. Presumably isometric contraction may begin while the valve is still open and left ventricular filling continues. When the mitral valve reopens, the left atrial and ventricular curves di-

FIG 285 Phonocardiogram (and electrocardiogram) depicting the murmur of mitral stenosis. Tracing (1) shows an apical diastolic murmur (DM) filling all of diastole with presystolic accentuation. The systolic interval between the first (S_1) and second (S_2) heart sounds demonstrates no murmur. Tracing (2) also is a diastolic murmur recorded at the apex and pulmonic areas from a patient with mitral stenosis. S_4 denotes the "opening snap" of the mitral valves which is often heard in mitral stenosis. (From Levine and Harvey.)

verge (instead of normally coinciding) for a pressure gradient is maintained to force blood across the stenotic valve. This pressure gradient results in a slight shortening of the isometric relaxation period and allows an early onset of mitral valve opening. Thus, the time for left ventricular filling may be increased by small amounts at either end of the ventricular filling period. The period of diastasis is usually absent and the atrial pressure curve shows a continuous decline in pressure during diastole until atrial contraction occurs. In the normal heart, left ventricular filling takes place early in diastole for the most part, but in mitral stenosis it is believed that filling continues throughout diastole.

Although little is understood concerning the sequence of hemodynamic events which may occur in any one patient, much data has been accumulated from animal experiments and from catheterization studies in patients with mitral stenosis in different phases of the disease. Such data cannot take into account the effects of a concomitant, unmeasurable amount of mitral

FIG 286 The cardiac cycle of the left side of the heart in mitral stenosis. See text for explanation. (from E Braunwald and associates, *Circulation*, 1955)

insufficiency, other valvular disease or myocardial insufficiency which are often present in the patients studied. In general, the asymptomatic patients show a normal cardiac output, a normal pulmonary artery and pulmonary wedge pressure and a normal pulmonary resistance at rest. The filling pressure gradient between the left atrium and the left ventricle is the only consistent abnormality in those patients that have had left heart catheterization. Often there is an abnormal response to exercise by an inadequate increase in cardiac output and a rise in pulmonary artery pressure. Since filling of the ventricle may take place during the entire period of diastole when a stenotic valve is present, an increased heart rate could decrease the cardiac output by shortening the period of diastole. Exercise results in an increased venous return to the right side of the heart. The increased right ventricular work load in pumping the blood through the raised pulmonary resistance may lead to decompensation and a decrease in cardiac output.

Most patients with severe, symptomatic mitral

stenosis show the following abnormalities at catheterization: a decreased cardiac output, stroke volume and vital capacity, an increased left atrial, pulmonary wedge, and pulmonary artery pressure, an increased left ventricular filling pressure gradient and an increased pulmonary arteriolar resistance. The right atrial mean, and the right and left ventricular end-diastolic pressures are normal unless myocardial failure has supervened. With exercise, the abnormalities in these patients are usually further intensified.

From the above data, a scheme can be postulated for the hemodynamics in a patient with gradually increasing mitral stenosis. It has been shown by Gorlin and his associates that the dynamic effect of mitral stenosis is not linearly proportional to its degree but tends to be curvilinear. As the stenosis becomes tighter, a more than proportional rise in pressure is necessary to produce equivalent increases in flow across the valve. The left atrial pressure rises in order to produce the necessary pressure gradient that forces blood into the left ventricle across the resistance created by the stenotic valve. There must be a corresponding increase in pulmonary vein, capillary, and finally, pulmonary artery and right ventricular systolic pressure to maintain the flow of blood to the left atrium from the right side of the heart. As the mitral valve narrows further, blood flow into the normal sized left ventricle is decreased despite a large pressure gradient from the enlarged left atrium, and cardiac output diminishes. The tissues of the body compensate for the decreased cardiac output by extracting more oxygen from each cubic centimeter of blood, creating an increased arteriovenous oxygen difference. When the hydrostatic pressure in the pulmonary capillaries exceeds that of the plasma osmotic pressure, there will be transudation of fluid into the alveoli from the capillaries producing pulmonary edema.

The increased pulmonary artery pressure is not entirely due to the mitral valve obstruction. Parker and Weiss described a thickening of the pulmonary arterioles secondary to intimal proliferation. Necrotizing arteriolitis was also present along with pulmonary capillary elongation, dilation and basement membrane thickening. Whether these findings are related to the increased pressure and congestive phenomena of long standing mitral stenosis or represent changes from rheumatic involvement of the lung has not been settled. Curti and associates found no consistent correlation between the calculated pulmonary arteriolar resistance and the degree of disease of the pulmo-

nary arterioles in lung biopsies. They postulated that active vasoconstriction may play a large role in the pulmonary resistance present in cases of mitral stenosis. Whatever the cause of the lung pathology, the changes add another obstruction to the circuit in addition to the stenotic valve.

With the pulmonary artery pressure rise, the systolic pressure, and thus the work of the right ventricle, increases. When the right ventricle can no longer maintain its output against the increased pulmonary resistance, its end diastolic pressure rises, leading to right atrial and eventual systemic venous pressure elevations. Then signs and symptoms of right heart failure appear.

Enlargement of the mitral orifice in mitral stenosis by finger fracture or incision has been performed in thousands of patients. Hemodynamic studies before and after operation have demonstrated dramatic changes in some patients from such commissurotomy while others have been unimproved. The symptomatic improvement is often more impressive than the hemodynamic changes. The pulmonary vascular resistance has been reported to decrease over a period of 6 months to a year in many patients. Evaluation of this operation is difficult for the knowledge of the natural history of mitral stenosis in untreated and medically treated patients is inadequate. Also, a prolonged follow up of the operated patients is needed.

MITRAL INSUFFICIENCY Mitral insufficiency often coexists with a stenotic mitral valve but may occur in the "pure" form. The magnitude of the regurgitant stream is not only determined by the mitral valve area but also by the pressure relationships on both sides of the valve. Rodbard and Williams have suggested that contraction of the muscular ring at the base of the mitral valve decreases the size of the mitral leak during ventricular systole. The fact that simultaneous flow through two orifices favors the larger orifice also lessens the amount of mitral regurgitation. However, since the pressure gradient from the left ventricle to the left atrium is much less than from the left ventricle to the aorta, regurgitation is favored. The amount of reflux into the left atrium has been calculated in patients to sometimes exceed the aortic flow and, in animal experiments, with the production of acute mitral insufficiency, the heart has been able to compensate for large amounts of regurgitant flow. Wiggers and Feil demonstrated that reflux may occur during the entire period of systole including isometric contraction, continuing into protodiastole.

in dog hearts with surgically produced acute mitral insufficiency. This explains why the murmur of mitral incompetence is pansystolic in time and often obscures the second heart sound (fig 287). However, sometimes the murmur is maximal late in systole and may even be confined to late systole. The mechanism of this late systolic crescendo murmur is not understood.

Ross and associates studied the dynamics of the cardiac cycle in patients with mitral insufficiency by left heart catheterization. Left atrial pressure (fig 288) rises little during isometric contraction followed by a rapid increase to a peak ("v" wave) during late ejection by the ventricle. The left atrial pressure slightly exceeds the left ventricular pressure during the "y" descent. An abnormally rapid fall in ventricular pressure during late ejection is coincident with the atrial "v"

FIG 287 Phonocardiogram (and electrocardiogram) demonstrating the murmur of mitral insufficiency. These 4 tracings show loud systolic murmurs (SM) at the apex in patients with mitral insufficiency. S_1 and S_2 denote the first and second heart sounds. The diastolic interval (S_2 to S_1) is clear (from Levine and Harvey).

FIG 288 Simultaneous left atrial and left ventricular pressures recorded at operation in a patient with mitral insufficiency. The atrial pressure curve rises to a high peak during ventricular ejection secondary to the regurgitation. An abnormally rapid fall in ventricular pressure (indicated by the brackets) is noted during late ventricular ejection. End diastolic pressures are elevated in both chambers; there is no diastolic pressure gradient across the mitral valve (from Ross, Braunwald and Morrow).

wave. The rapid fall is evidently due to the inability of the ventricle to maintain its ejection pressure when regurgitant flow is maximal. Reflux of blood most likely begins during isometric contraction. The forward aortic output cannot begin until the intraventricular pressure exceeds the aortic pressure. It should be mentioned that the large "v" wave is not characteristic of mitral regurgitation; for it has also been seen in predominant mitral stenosis. The "v" wave is responsible for a systolic atrial pulsation often seen in mitral insufficiency by fluoroscopy.

Patients with mitral insufficiency usually show a decreased cardiac output but some are normal or low normal. Since the left ventricle pumps blood into the left atrium and aorta, the total left ventricular stroke volume must increase or the aortic output will fall. The left ventricular tension and systolic pressure are increased by a greater diastolic volume leading to an elevated stroke output. Large regurgitant flows may exist without measurable increase in left ventricular end diastolic pressure. Braunwald and associates shunted blood from the left ventricle to the left atrium in dogs and suggested that the increased stroke volume was related to a more complete emptying of the ventricle; however, normal dog hearts are quite different from the hypertrophied, dilated, left atrium and ventricle seen in patients with diseased mitral valves.

The greater left ventricular diastolic volume

may be brought about by a considerable increase in left atrial pressure. The left atrial pressure rises during ventricular systole but may be normal during diastole; the mean pressure is usually elevated. There may or may not be abnormal pulmonary circulation pressures. When present they are of less severe intensity than seen in mitral stenosis and may be secondary to left ventricular failure, pathological pulmonary changes (as described for mitral stenosis) or to an elevated left atrial pressure (to maintain sufficient diastolic blood flow through the mitral valve).

When the left ventricular end diastolic pressure rises to maintain the cardiac output in the presence of mitral incompetence it may be due only to the inability of the ventricle to maintain its stroke volume through the two orifices or also to intrinsic myocardial disease with impaired contractility. Whichever mechanism predominates the end result is a further rise in left atrial pressure eventually reflecting back to increase the peripheral venous pressure as described for mitral stenosis.

Operative procedures to correct mitral insufficiency have consisted of suturing of the valves, insertion of prostheses or of decreasing the size of the atrioventricular annulus with a circumferential suture. That no one procedure has been widely accepted is evidence of the lack of success with these techniques.

AORTIC STENOSIS Stenosis of the aortic valves may be classified as noncalcific or calcific. The former is predominantly due to rheumatic fever but the etiology of the latter remains in doubt. Although the general opinion favors rheumatic endocarditis, atherosclerosis of the valves and even brucellosis have been incriminated. The clinical picture and hemodynamic abnormalities of aortic stenosis may be imitated by a congenital circular narrowing of the aorta just above the valves called supravalvular stenosis or by a subaortic stenosis due to a fibrous ridge attached to the myocardium below the aortic valve. Brock has described an entity which causes functional subvalvular stenosis and pathologically shows only an enormous hypertrophy of the outflow tract of the ventricle. Recently the latter has been found to have a high familial incidence. The normal area of the aortic valve is about 3 cm^2 . Gorlin and associates estimated the critical orifice (below which significant hemodynamic changes take place) to be 0.5 cm^2 . Aortic stenosis produces a small orifice through which blood is ejected at high velocity during systole, presumably resulting in turbulent flow. The

murmur (fig. 28.9) is usually mid systolic for there is an interval between the first heart sound and the onset of the murmur determined by the time needed by the ventricle to raise its pressure sufficiently to open the aortic valve. The murmur increases to a maximum about midsystole and then diminishes to cease before the second heart sound. It is usually heard loudest over the aortic area and is transmitted into the neck vessels but can also be loud at the apex.

Those patients with aortic stenosis who are asymptomatic usually have a normal cardiac output and stroke volume. The systolic gradient of pressure between the left ventricle and aorta (by left heart catheterization) is the diagnostic feature present in all cases (fig. 28.10). This gradient may reach as high as 150 mm Hg so that the brachial artery pressure is much lower than the ventricular systolic pressure. The left ventricular end diastolic pressure is usually normal. Mueser and associates found an elevated left ventricular end diastolic pressure in patients who were thought not to be clinically in failure. They postulated that the concentric hypertrophy of the

FIG. 28.9 Phonocardiogram (and electrocardiogram) showing the systolic murmur of aortic stenosis. The systolic murmur with a midsystolic accentuation (often called diamond shaped) was recorded in three areas (aortic left sternal border in the 3rd interspace and apical). Note absence of diastolic murmur (from Levine and Harvey).

chamber decreased its capacity and perhaps small volume changes then led to large pressure changes. The workload of the left ventricle in patients with aortic stenosis has been calculated to be usually twice that of normals but may reach six times normal. Gorlin and coworkers found that although the ventricular filling pressure rose in their patients there was no change in effective or total stroke work or cardiac output with exercise. They suggested that this was secondary to the hydraulic obstruction rather than myocardial failure and that the hearts were on the plateau of their ventricular function curves.

The brachial artery pressure curve (which is similar to the aorta curve shown in fig. 28 10) in patients with aortic stenosis shows a prolongation of the systolic upstroke time (end of diastole to peak of systole). There is an incisura on the ascending limb referred to as the anacrotic notch. The latter has been shown by Katz and associates to be present in the central aortic pressure curve. They postulated that the vibration created by the suction action on the aortic walls of the suddenly produced rapid axial stream beyond the constriction was its cause.

With the above data in mind a hemodynamic picture can be postulated for aortic stenosis. Because of the obstruction between the left ventricle and aorta the left ventricular systolic pressure must rise to force blood through the stenosed

valves. The period of ejection is prolonged and blood is expelled at a high velocity. The percentage of the left ventricular work spent in giving velocity to the blood rises sharply. An increased diastolic volume causes a more forceful systolic contraction with restoration of normal cardiac output. Left ventricular hypertrophy develops to compensate for the increased workload and may be the reason the left ventricle is able to sustain such high systolic pressures without failure.

The left ventricular systolic pressure may rise very high but finally the end diastolic ventricular pressure must increase in an attempt to maintain cardiac output. One of the reasons for failure of the left ventricle may be a decreased coronary supply. Animal experiments have demonstrated a significant reduction in coronary blood flow during ventricular systole which was due to increased coronary bed resistance associated with a very high intraventricular pressure. Also since the aortic stenotic heart cannot usually increase its cardiac output with exercise there would probably not be an increase in coronary flow. Elevation of the left ventricular diastolic pressure may eventually lead through the increased left atrial pressure to a rise in the pulmonary circulation pressures, an increased workload for the right ventricle and right sided heart failure.

Patients with aortic stenosis may have their valves opened by a surgical approach through the ventricle or aorta, often with the help of an extracorporeal pump-oxygenator. A dilator finger or knife is used as in mitral stenosis. Clinical improvement has been excellent in many patients and a reduction in the left ventricular to aortic systolic pressure gradient has been found immediately after operation.

AORTIC REGURGITATION Incompetent aortic valves most often result from rheumatic fever or syphilis; rarer causes are bacterial endocarditis, trauma, dissecting aneurysm of the aorta or congenital defects of the valves. The murmur (fig. 28 11) of aortic regurgitation is pansystolic, beginning early after closure of the aortic valves, swelling quickly to a crescendo and then diminishing with the falling diastolic pressure. It is continuous throughout diastole because of a persistent pressure difference between the aorta and ventricle. This murmur is high pitched and usually of a very low intensity; it is often very difficult to hear. An apical presystolic murmur is sometimes heard in aortic incompetence resembling that of mitral stenosis. This murmur was described originally by Austin Flint and bears his name. According to the most generally ac-

FIG. 28 10. Simultaneous pressure recordings in the left ventricle (LV) and aorta in a patient with aortic valvular stenosis. Catheterization of the left heart was via the transbronchial route. The electrocardiogram is shown above the pressure tracings. Note the very high left ventricular systolic pressure and systolic pressure gradient (hatched area) across the aortic valve. The aortic curve shows a small pulse pressure, prolonged systolic upstroke time and an anacrotic notch. See text for further explanation (courtesy of E. Braunwald, Section of Cardiology, Clinic of Surgery, National Heart Institute).

cepted explanation, it is due to vibrations set up in the anterior leaflet of the mitral valve as blood regurgitates through the aortic orifice into the path of the stream entering from the left atrium.

The hemodynamic effects of aortic incompetence are due to the regurgitation of blood from the aorta into the left ventricle. Wiggers and Maltby, in animal experiments, demonstrated that the magnitude of backflow varied with the size of the leak and could be 50 per cent or more when the cusps were totally deficient. The pressure gradient existing in diastole between the left ventricle and the aorta, and the duration of the diastolic filling period are also important factors determining the amount of regurgitation. The left ventricle is called upon to accommodate, in diastole, not only the blood from the atrium, but that regurgitated as well. This leads to a high initial tension at the end of diastole and a greater stroke volume during systole, in time, dilation and hypertrophy develop to give a very large left ventricle. Welch and associates in dog experiments, have produced aortic regurgitation by a shunt from the aorta to the ventricle. Since the left ventricular end-diastolic pressure rose to higher levels than the left atrial pressure, they postulated that the mitral valve protected the pulmonary circulation and allowed a high left ventricular end-diastolic pressure to produce a more forceful contraction.

The left ventricle with aortic reflux demonstrates a much shorter isometric period and its pressure curve (fig. 28 12) rises abruptly. As the semilunar valves open, an 'explosive' ejection of the large volume of blood into the unfilled aorta causes the abrupt increase in systolic pressure. A much greater proportion than usual of the ventricular contents is discharged during the first half of systole, and a much smaller proportion during the period of reduced ejection. It is at this time—the period of reduced ejection—that the sharp fall in pressure occurs and not during diastole. The pressure fall continues steeply into the period of isometric relaxation. Little further decline during the remainder of diastole occurs. Other factors contributing to the low diastolic pressure are the regurgitation itself and a peripheral dilation causing a rapid run-off of the blood. Gorlin and coworkers claim that peripheral vasodilation is a basic characteristic of aortic insufficiency which disappears when congestive heart failure develops with its usual systemic vasoconstriction. The pulsation in the capillaries seen in aortic regurgitation has been attributed by Lewis and Drury to dilation of the arterioles. Wiggers found

that peripheral signs of aortic insufficiency could be produced in an artificial model when central regurgitation was produced and the peripheral resistance kept constant. He, therefore, considered that it was due primarily to the low diastolic pressure and high pulse pressure. However, Myerson and associates have been able to produce all the peripheral phenomena of aortic insufficiency in a single extremity by the intra arterial injection of mecholyl to cause vasodilation. Most cardiologists agree that peripheral vasodilation is a characteristic of aortic insufficiency.

The sudden ejection of a large volume of blood in early systole and the peripheral vasodilation

FIG 28 11 Phonocardiogram (and electrocardiogram) demonstrating the murmur of aortic insufficiency. S_1 and S_2 denote the first and second heart sounds. An early, decrescendo diastolic murmur (DM) is recorded at the aortic area. A systolic murmur (SM) is also present (from Levine and Harvey).

FIG 28 12 Simultaneous recordings of the pressures in the left ventricle (LV) and femoral artery in a patient with aortic valvular insufficiency. The electrocardiogram is shown at the top of the figure. The calibration of the pressure for the left ventricle is on the left side and for the femoral artery on the right side. Note that the systolic pressures of the left ventricle and femoral artery are similar. The catheter has been withdrawn into the left atrium to obtain its pressure curve. The transbronchial route for left heart catheterization was used. See text for description of pressure curves (courtesy of E Braunwald, Section of Cardiology, Clinic of Surgery, National Heart Institute).

also provide an explanation for the high peaked character of the pulse tracing, and for the low position or absence of the dicrotic wave on the catacrotic limb (fig 28 12). Also, the collapsing or water hammer, character of the radial pulse (Corrigan's pulse), and the sound resembling a pistol shot, heard when a stethoscope is applied over an artery, are attributed to these phenomena because of the very wide peripheral pulse pressure.

Catheterization studies show the effective cardiac output (aortic blood flow) to be normal in most patients studied and usually to rise with exercise. The latter is in contrast to patients with aortic stenosis. Exercise may decrease the magnitude of the regurgitation by increasing the heart rate. In animal experiments, after production of acute aortic insufficiency, an increase in heart rate reduced the regurgitant flow probably by a decrease in the diastolic filling time. The work of the left ventricle in patients with aortic valve incompetence is increased two to three times, and the left ventricular systolic pressure rises, as does stroke work, with exercise, again contrasting with aortic stenosis. Left heart catheterization usually reveals a normal left ventricular end-diastolic pressure but an increased left atrial pressure. Pulmonary wedge pressures, however, are normal in some patients but rise on exercise. No gradient of pressure is found across the aortic valve when aortic stenosis is absent. Patients have lived normal lives for years with aortic insufficiency. The reason for left ventricular failure occurring after a long asymptomatic period (except for those related to the wide pulse pressure and peripheral vasodilation) is not clear, but may be secondary to many factors, such as overstretching of the myocardial fibers, associated degenerative disease, or any added stress calling for an increased cardiac output. At this point, the left ventricular end-diastolic pressure rises and a pressure increase gradually occurs back through the pulmonary circulation to the right ventricle. Stretching of the mitral ring (with resultant regurgitation) by a greatly dilated left ventricle may play a large role in the final picture.

Hufnagel and associates have devised an operative approach to this disease by insertion of a rigid prosthetic plastic ball valve in the descending aorta. Clinical improvement has been satisfactory in many of the operated patients, but emboli often form in the aorta, seeding to various parts of the body. The valve is also a noise nuisance to the patient. Bailey and coworkers have inserted a nylon ball in the aorta, at the valve

level, and have reported success in several patients.

TRICUSPID STENOSIS Stenosis of the tricuspid valve is usually the result of rheumatic involvement but may also be congenital in origin. As an isolated lesion, it is rare, mitral stenosis is most often associated with it and, also, some degree of tricuspid insufficiency usually occurs through the stenotic valve. The murmur of a stenotic tricuspid valve resembles that of mitral stenosis, but is located parasternally in the 4th or 5th intercostal space. It is low pitched, rumbling, and is like the mitral stenotic murmur in its diastolic timing. Distinguishing features of the tricuspid murmur from a mitral stenotic murmur are its increase with inspiration and a soft or normal pulmonary component of the second heart sound.

Right heart catheterization studies on patients with tricuspid stenosis have helped to define the hemodynamics of the lesion. It must be remembered that few of the cases studied had 'pure' tricuspid stenosis and that mitral disease often complicated the picture by raising the pulmonary circulation pressures. As in mitral stenosis, the main hemodynamic abnormality is that the atrium does not empty its contents normally into the ventricle. The increased resistance at the stenotic valve leads to an increased diastolic volume in the right atrium, the latter becoming dilated and hypertrophied. In order to propel the blood into the right ventricle, the pressure in the right atrium must be elevated. In patients, a high right atrial pressure is observed which exceeds the right ventricular pressure throughout diastole and, thus, creates a diastolic filling gradient across the tricuspid valve (fig 28 13). The right atrial pressure is higher than the ventricular diastolic pressure even at the end of diastole. The latter chamber must raise its pressure to atrial level before the valve can close, causing a prolonged isometric contraction period. Because of the increased right atrial pressure, the peripheral venous pressure rises and, eventually, signs of right-sided heart failure (edema, hepatomegaly, and ascites) appear.

With exercise, patients show an increased right atrial pressure and an increase in the diastolic filling gradient. The right ventricular diastolic pressure would most likely be normal at rest and with exercise, but is usually elevated because of an associated mitral lesion in these patients. The cardiac output and stroke volume are decreased and, with exercise, a subnormal increase occurs. The low cardiac output is usually explained by the inability of the thin walled, dilated right

atrium to adequately fill the right ventricle. The lack of a normal increase in cardiac output during exercise may be secondary to a decreased diastolic filling time with an increased heart rate.

In tricuspid stenosis the atrial pulse pressure (fig 28 14) exhibits a very large "a" wave due to the contraction of a hypertrophied atrium dilated by a large diastolic residual volume against a narrowed outlet. These giant "a" waves propagate retrogradely through the venous system causing a presystolic, pulsating liver, and can often be seen clearly in the jugular veins of the neck. Such giant "a" waves are not diagnostic of tricuspid stenosis for they may also be seen in other diseases, such as severe pulmonary hypertension. The peak atrial systolic pressure wave is thus very high and falls very rapidly with atrial relaxation. The "v" wave is usually small while the "c" wave may be absent. The right atrial pressure does not decrease greatly when the tricuspid valves reopen, indicating impaired emptying of the right atrium, and ventricular filling probably takes place throughout diastole as described for mitral stenosis.

The accentuation of the tricuspid stenosis murmur with inspiration is usually explained by the increased venous return to the right atrium secondary to the fall in intrathoracic pressure. The right

FIG 28 14 Pressure tracings of the right atrium (RA) and brachial artery (BA) in a patient with tricuspid stenosis (upper tracing) and in a patient with tricuspid insufficiency (lower tracing). The electrocardiogram is shown in the lower section of each tracing. The arrows indicate the onset of ventricular systole and the letter A marks the peak of atrial systole. For discussion of atrial curves see text (from Ferrer and associates 1953)

FIG 28 13 Simultaneous pressure curves from the right atrium (RA) and right ventricle in a patient with tricuspid stenosis. The electrocardiogram is shown at the top of the tracing. Note that the right atrial pressure exceeds the right ventricular pressure throughout diastole creating the pressure gradient depicted by the hatched area. The right ventricular systolic pressure is elevated secondary to pulmonary hypertension from a concomitant mitral stenosis. For discussion of the pressure curves see text (courtesy of E Braunwald, Section of Cardiology, Clinic of Surgery, National Heart Institute)

ventricular pressure also falls with the decrease in intrathoracic pressure, and an increased pressure gradient and flow occur across the valve.

Tricuspid commissurotomy is now performed in this disease as in mitral stenosis. If the latter disease is also present both valves may be opened at the same operation but the mitral should be done first to avoid pulmonary congestion from a suddenly increased right ventricular output as the tricuspid stenosis is relieved.

TRICUSPID INSUFFICIENCY Organic tricuspid insufficiency is predominantly functional or rheumatic in origin but trauma and bacterial endocarditis are rarer etiologies. It is sometimes present congenitally or in the syndrome associated with malignant carcinoid tumors. Functional tricuspid incompetence may occur whenever there is dilation of the right ventricle, and it is usually

reversible. The murmur of an incompetent tricuspid valve resembles that of mitral regurgitation, being pansystolic. It is often accentuated early in systole and is heard loudest at the lower, left, sternal edge.

The pulse pressures of the right atrium and ventricle have been simultaneously and separately studied in patients by right heart catheterization. The mean right atrial pressure is elevated. The right ventricular systolic pressure is usually very high while the end diastolic pressure may or may not be elevated depending on the presence of right ventricular failure, often from concomitant mitral disease. The atrial pressure curve (fig. 28 14) often shows a sharp spike at the onset of ventricular systole, probably due to the force of the contracting ventricle. Next a plateau elevated curve, representing regurgitation of blood from the ventricle, occurs, the 'x' wave is usually absent. This plateau curve may so resemble the ventricular pressure curve in severe insufficiency that it is spoken of as "ventricularization" of the atrial curve. The atrial pressure during the ventricular systolic period is higher than that of the presystolic period and is sustained to the end of isometric relaxation. The ventricular pressure then falls below the atrial level and the A V valves open. The pressure in the relaxing ventricle continues to drop while the atrial pressure decreases at a slower rate and reaches its lowest value after the right ventricular pressure is minimal. Emptying of the right atrium reverses the decreasing ventricular pressure and the two chambers equalize their pressures, rising rapidly to complete the early diastolic dip. The diastolic dip, which is not always present in tricuspid insufficiency, is also seen in right ventricular failure and constrictive pericarditis but not with the characteristic plateau pressure curve of the right atrium.

The cardiac output is decreased in most patients with tricuspid insufficiency and rises, although subnormally, with exercise. The peripheral arteriovenous oxygen difference is usually abnormal and increases further with exercise as the tissues extract more oxygen per unit of blood to compensate for the decreased blood flow. Patients with tricuspid insufficiency are often said to have a lower cardiac output than those with mitral incompetence because there is no ventricular pump to compensate for the tricuspid regurgitation of blood.

The enlarged right atrium, with its increased pressure, may never completely empty in tricuspid insufficiency and eventually cannot compen-

sate despite the presence of hypertrophy and dilation. This leads to a high peripheral venous pressure with the development of edema, hepatomegaly, and ascites. In contrast to tricuspid stenosis, the enlarged, congested liver pulsates during systole. The usual explanation for the pulsating liver is that the reflux of blood into the atrium transmits a pulse wave to the organ, but Bloomfield and associates have measured in some patients a pressure gradient from the right atrium to the peripheral veins suggesting there may actually be a reflux of blood into the inferior vena cava and into the liver. The right atrium may reach gigantic size in tricuspid insufficiency, as in stenosis, but, in contrast to the latter, the right ventricle also hypertrophies and/or dilates because of the increased workload imposed by pumping blood into both the right atrium and pulmonary artery.

HEMODYNAMICS IN CARDIAC TAMPONADE

Pericardial effusions may develop during the course of an inflammation of the pericardium (pericarditis) due to a multitude of etiologies. Large amounts of fluid, up to a liter or more, accumulating slowly may not embarrass the heart while acute effusions of much smaller amounts may compress the myocardium and interfere with its function (often referred to as tamponade'). Chronic constrictive pericarditis is a fibrous, sometimes calcified thickening of the pericardium which adheres to the epicardium. Both conditions interfere with the normal cardiac action by restricting the ventricles, one by an increased intrapericardial pressure (effusion), the other by a stiffened pericardium (constrictive pericarditis). They produce a clinical syndrome characterized by systemic and pulmonary venous congestion with signs and symptoms of left and right sided heart failure. There is an absence of cardiac murmurs but a prominent heart sound may be heard early in diastole. According to McKusick, this protodiastolic sound is probably related to the rapid ventricular filling and/or the abrupt halt in ventricle filling.

The hemodynamic abnormalities of cardiac tamponade have been studied in both animal experiments and in patients. Pericardial effusion in dogs has been produced by infusion of air or saline into the pericardium while irritative substances such as cellophane, have been used to incite chronic constrictive pericarditis. The syndrome produced in the dog is very similar to that seen in man. Metcalfe and associates, and Isaacs and co-workers, have shown that the main hemo-

dynamic abnormality is a hindrance to the diastolic expansion of the heart and not a restriction of blood flow into the right atrium secondary to constriction of the venae cavae at their orifices. As successive amounts of saline or air were injected into the pericardium to raise the intrapericardial pressure, the systemic and pulmonary venous, the mean atrial, and the pulmonary wedge pressures increased while peripheral blood pressure fell slowly at first and then precipitously. The cardiac output decreased secondary to a progressive fall in stroke volume and was insufficiently maintained by a concomitant rise in heart rate. The intravascular pressures (pulmonary and systemic, venous and arterial) tended to approach each other as the intrapericardial pressure increased. Isaacs and colleagues explained the restricted cardiac output by the pressure-volume curve of the pericardium which showed that large volume changes gave small increases in pressure when pressures and volumes were small, but as the curve rose, small volume increases caused large pressure increases (fig. 28-15). Thus, the circulatory effect would be due to a limitation of space available for expansion of the ventricle. Isaacs and associates also produced generalized and localized constrictive pericarditis in dogs by placing plastic casts in the pericardium. Hemodynamic changes were identical to those described for tamponade from effusion only when one or both ventricles were constricted. Isolated atrial involvement proved to be unimportant.

Catheterization studies in patients with chronic constrictive pericarditis and/or effusion have produced data comparable to that in the animal experiments. The mean atrial, systemic, pulmonary wedge, pulmonary artery diastolic and right ventricular end diastolic pressures tend to be similarly elevated in severe cases. Hemodynamic events are the same for both sides of the heart, and the right mean atrial pressure is approximately equal to that of the left atrium showing that the distensibility of the heart is determined by the thickened pericardium.

The ventricular pulse pressure curve is of low amplitude with a slightly elevated, normal or decreased systolic pressure. After the systolic pressure rise, there is a rapid fall almost to or even below the baseline (zero pressure), for the ventricle empties normally creating a steep pressure gradient between the high atrial mean pressure and the ventricle. As a result, blood rushes into the ventricle causing a steep rise of the pressure curve to a higher than normal plateau for the remainder of diastole. This sharp fall and rise is

FIG. 28-15. Volume elasticity curves of right and left ventricles before and after total pericardial constriction. These are volume pressure curves obtained immediately after death from the right (RV) and left (LV) ventricles of the dog's heart within a normal pericardium (before) and from right and left ventricles within a generalized pericardial constriction (after). Increments of 10 cc of saline were injected via the pulmonary artery or aorta into the closed ventricles while intraventricular pressures were recorded. It can be seen that if the pericardium is thickened by scar so that it offers more resistance than usual as the right ventricle volume increases against this increased resistance greater than usual corresponding pressures are required (from Isaacs, Carter, and Haller).

called the diastolic "dip" (p 244). Since the ventricular end diastolic (and mean diastolic) pressure approximates the mean atrial pressure (for the ventricle is prevented from distending by the thickened pericardium), filling of the ventricle occurs during the first part ("dip") of diastole with little further increase during the plateau phase. The atrial pressure curve shows two sharp drops to give a characteristic "M" shape: a large pressure decrease during the rapid ventricular filling which coincides with the "dip" of the ventricular curve in time, amplitude and shape, and a smaller drop associated with ventricular ejection ("X" wave). Atrial systole is of high amplitude for the atrium is contracting against a nearly completely filled ventricle. Cardiac output and stroke volume have been normal in some patients but are usually decreased. With exercise, all elevated pressures rise further. In those that show some increase in cardiac output with exertion, the stroke volume did not increase indicating that the rise

in cardiac output was secondary to an increased heart rate

From the data presented above, hemodynamic sequelae can be postulated for both pericardial effusion and chronic constrictive pericarditis. The thickened pericardium or effusion interferes with diastolic filling of the ventricle so that greater than normal diastolic filling pressure gradients are needed to maintain cardiac output. As explained before (pp 146 and 309), dilation of the ventricle normally leads to an increase in stroke output by increasing the myocardial fiber length resulting in a greater force of contraction. Presumably, such dilation is prevented by a constricting scar. Systemic and pulmonary venous pressure rise by unknown mechanisms to increase the venous return to the heart and maintain cardiac output. The increased venous pressures lead to serous cavity effusions, anasarca, hepatomegaly and pulmonary congestion. The compensatory mechanisms probably become inadequate as scarring progresses, and cardiac output and stroke volume fall.

The treatment of pericardial effusion is drainage of the fluid by needle tapping or surgery to create a pleuropericardial window. In chronic constrictive pericarditis, the two ventricles are decorticated of their thickened pericardium, the atria may be left alone. Following the surgical procedures, all pressures may return to near normal with a disappearance of the diastolic 'dip', but most patients continue to show abnormal hemodynamics despite clinical improvement. The failure to attain normality is postulated to be due to incomplete decortication of the ventricles, persistent abnormalities of the lungs or myocardial fibrosis. It should also be mentioned that the entire clinical and hemodynamic picture of chronic constrictive pericarditis and pericardial effusion can be produced by other conditions, the most common of which is diffuse myocardial fibrosis.

HEMODYNAMICS IN CONGENITAL HEART DISEASE

The development of intracardiac catheterization to measure the pressures and oxygen contents of the various chambers of the heart has led to a better understanding of the hemodynamic effects of congenital lesions upon the heart. Various formulas have been developed for measurement of cardiac output, and systemic, pulmonary and shunt flows from the data obtained. It must be borne in mind in this section that many assumptions must be made in these formulas and

that adequately mixed blood is often difficult to obtain when a shunt is present. Only the more common congenital entities involving the heart will be discussed. It is hoped that from the data presented, the main hemodynamic effects of the less common anomalies can be surmised.

PULMONIC STENOSIS Cardiac catheterization studies have shown that isolated pulmonary stenosis is a much more common congenital heart lesion than it was formerly considered. Acquired stenosis, due to rheumatic fever, bacterial endocarditis, or carcinoid tumors, is quite rare. The obstruction to right ventricular outflow usually occurs at the valves but is not uncommon in the outflow tract of the right ventricle (infundibular stenosis), and even occurs in the pulmonary artery or one of its main branches. The outflow tract may be narrowed by muscular hypertrophy, but often, a diaphragmatic stenosis is also present. The murmur of pulmonary valvular stenosis is located in the second or third left costal inter

FIG 28-16 Phonocardiogram (and electrocardiogram) showing the murmur of pulmonic stenosis. Upper tracing recorded in the 3rd left inter space at the sternal border, middle tracing at aortic area, and lower tracing, at apical area. The systolic murmur (SM) is loudest at the pulmonic area and fills all of systole. The diastolic interval shows no murmur (from Levine and Harvey)

Fig 28-17 Simultaneous pressure recordings in the right ventricle (RV) and pulmonary artery (PA) in a patient with valvular pulmonic stenosis. The electrocardiogram is shown above each pressure tracing. Upper tracing is preoperative and lower tracing is postoperative. The mean pulmonic valve systolic gradient is shown by the stippled area and fell from 45 to 19 mm Hg postoperatively. Note the elevated right ventricular systolic pressure which decreased, but not to normal following surgery (from Tanenbaum, Braunwald, and Morrow).

space, parasternally. It is often loud and rough with a pansystolic duration (fig 28-16). Infundibular stenosis most often produces the same type of murmur over one or two lower interspaces. Multiple catheterization studies of patients with the various forms of pulmonic stenosis have been reported (fig 28-17). The characteristic finding is an increased systolic pressure gradient across the stenotic area. Usually, there is little or no measurable gradient in this area. The right ventricular systolic pressure and work are elevated, presumably depending on the degree of stenosis. Right ventricular and diastolic pressure is normal until failure intervenes. The right atrial mean pressure is normal to high.¹ The pulmonary

¹ The mean right atrial pressure may be high because of a large atrial pulse pressure (giant "a" wave) with an elevated systolic but normal diastolic level. The giant "a" wave is related to the contraction of the normal sized or enlarged atrium against the increased resistance to filling offered by the right ventricle.

artery pressure is normal or decreased while pulmonary wedge pressure and vascular resistance are normal. The pulmonary blood flow is less than normal, but this has been shown not to cause arterial desaturation since saturation of pulmonary venous blood is within the normal range. Cardiac output is normal or low, although increases are found in the presence of minimal stenosis. Oxygen consumption increases with mild exercise showing that pulmonary artery flow can increase.

The pathophysiology of pulmonic stenosis is due to the obstruction to flow from the right ventricle to the pulmonary artery (fig 28-18) leading to an increased volume of blood retained in the former. This increases the myocardial fiber length, the systolic pressure, and the work of the right ventricle, resulting in a compensatory increase in output to maintain the pulmonary blood flow and venous return to the left heart.

FIG. 28-18. Pulmonic Stenosis. Figures within vessels or chambers denote the blood oxygen content in cubic centimeters per liter of blood. Circled figures indicate the blood pressure, systolic over diastolic and mean pressures are shown. The black shadow shows the area of pulmonic stenosis infundibular in this patient. The pressure changes from the pulmonary artery to the right ventricle were determined by catheterization and localized the area of stenosis. The pulmonary artery is dilated as often seen in cases of pulmonic stenosis. Notice the marked degree of systolic hypertension in the right ventricle with a normal pulmonary artery pressure (from Courmand, Baldwin, and Himmelstein).

Such dynamic changes lead to right ventricular hypertrophy, the work of the left ventricle is not increased. The right atrial pressure rises in order to maintain a filling pressure for its ventricle. With increasing degrees of stenosis the right ventricular output falls and its end diastolic volume and pressure rise. The latter is reflected in the peripheral venous system by the development of right heart failure signs. Animal experiments and data from patients suggest that the presence of an atrial septal defect or patent foramen ovale in pulmonic stenosis acts as an escape valve for the increased load on the right heart by allowing a shunting of blood to the left atrium. Such cases, of course, may develop cyanosis.

The surgical approach to correction of pulmonary stenotic valves is an incision or excision of the valves by means of a transarterial or transventricular approach. Extracorporeal pump oxygenators are now used more frequently in

order to view the valve directly. Infundibular stenosis may be corrected by excision of the stenotic area or by an actual reaming out of the hypertrophied muscle. Following the operation the chamber pressure may return to normal but often remains elevated. Most patients have improved markedly whether their pressures returned to normal levels or not.

PULMONIC INSUFFICIENCY Insufficiency of the pulmonic valves, acquired or congenital, is a very rare lesion. Functional incompetence from dilation of the valvular ring is often seen in pulmonary hypertension secondary to mitral stenosis or pulmonary disease. A soft, blowing diastolic decrescendo murmur, which can sometimes be loud and harsh, is located in the second or third left costal interspace parasternally, and may be transmitted to the apex. When present in mitral stenosis, it has been named the 'Graham Steell murmur'.

Several series of dog experiments with partial or complete pulmonic valveectomy or bypassing the pulmonic valve (shunting of the total right ventricular output into the pulmonary artery) did not produce myocardial decompensation, even with strenuous exercise, for periods up to 18 months. The pulmonary artery diastolic and systolic pressures were found to approximate those of the right ventricle in these dogs. Changes in cardiac output were not consistent. The right ventricle was dilated (by fluoroscopy or at autopsy) or sometimes hypertrophied (at autopsy by heart weight to body weight ratios).

A few patients with isolated pulmonic insufficiency were studied by catheterization of the right heart. The right ventricular and pulmonary artery systolic and diastolic pressures were approximately equal (fig 23 19). Mean right atrial pressures were normal. No evidence of right ventricular decompensation was shown unless pulmonary hypertension or another lesion co existed. The pulmonary artery pulse pressure curve resembled the tracing seen in aortic insufficiency.

According to the above clinical and experimental data, pulmonic insufficiency evidently is easily compensated by the right ventricle. Usually there is not sufficient functional disturbance to produce symptoms or signs as evidenced by the few clinical reports. The patients, whose catheterization data are reported above, were asymptomatic for many years despite their incompetent pulmonic valves. However, insufficiency of pulmonic valve may become significant if pulmonary hypertension is present. The increased diastolic pulmonary artery pressure in the latter condition would lead to larger regurgitant flow. Right ventricular volume, stroke output and work would increase. Right ventricular hypertrophy was found in patients showing a combination of pulmonic insufficiency and hypertension.

ATRIAL SEPTAL DEFECT Often referred to as the most frequent congenital heart lesion, atrial septal defect most often involves the foramen ovale and includes part of the septum secundum. Defects in the septum primum are less common and usually lie in the caudal part of the septum, involving the valvular rings. A patent foramen ovale (called "probe patent") is often found at autopsy, consisting of only a slit-like aperture which is functionally closed during life by the left to right atrial pressure gradient. Defects less than 0.5 cm in diameter are usually hemodynamically insignificant, while those greater than 2 cm almost always produce signs and symptoms. A loud systolic murmur, usually heard in the second or third

FIG 23 19 Simultaneous pulmonary artery (PA) and right ventricular (RV) pressures obtained at right heart catheterization in a patient with congenital pulmonic valvular insufficiency. The pressures in the right ventricle and pulmonary artery are identical (28/7 mm Hg). A diastolic pressure gradient is not present across the pulmonic valve indicating the absence of pulmonary stenosis (from Collins, Braunwald and Morrow).

FIG 23 20 Simultaneously recorded left and right atrial pressures in the open chest dog. Vertical intercepts at A, C, F beginning of atrial systole, onset of ventricular isometric contraction, period closure of aortic and pulmonary valves respectively. For discussion, see text (from Opdyke and associates).

costal interspace, but also present in other areas, is the common finding and is felt to be caused by the large right ventricular outflow. An apical or pulmonic diastolic murmur may also be audible, presumably due to the large blood flow through the tricuspid valves or pulmonic insufficiency.

Opdyke, Little and associates, have studied the hemodynamic effects of the normal atria in dogs with and without an atrial septal defect. They found that during the cardiac cycle, the left consistently surpassed the right atrial pressure by a small but significant, difference except for an occasional brief period before atrial systole (fig 23 20). When intravenous infusions were given, the pressure differential between the two atria was maintained. In another group of dogs, after

FIG 28.21 Semi-volume elastic curves of right and left atrioventricular cavities at various points of the atrial cycle (A, B, E, atrial aystole). For discussion, see text (Slightly modified from Opdyke and associates.)

creation of an atrial septal defect the same left to right pressure differential existed. By tying the veins entering both atria, it was demonstrated that the left atriovenous system was less distensible than the right, more blood could be added to the right atrial chamber before a pressure rise occurred (fig 28 21). This difference in distensibility could account for the pressure differential between the two atria. It was concluded that the pressure differential was solely a dynamic event since an equalization of pressures in the two atria occurred when ventricular asystole was produced; the gradient was then reestablished with the resumption of ventricular action. Two other reasons have been postulated for the differ-

ence in atrial pressures: (1) right atrial contraction slightly earlier than left atrial systole may transmit pressure to the left chamber; (2) an increased resistance to filling by the thicker left ventricle as compared to the right ventricle may result in a higher left atrial pressure.

Catheterization studies in patients have agreed with the above animal findings. When the catheter passes through the atrial septal defect, left and right atrial pressures can be compared. Findings vary of course with the size of the defect and with the presence or absence of pulmonary hypertension, which will be discussed below. In the absence of the latter, catheterization studies show (fig 28 22): (1) the left exceeds the right

FIG 28 22 Atrial septal defect. Numerical figures within vessels or chambers denote the blood oxygen content in cubic centimeters per liter of blood. Circled figures indicate the blood pressure, systolic over diastolic and mean pressures are shown. The presence of a shunt of well oxygenated blood into the right atrium is diagnosed by the large difference in oxygen content between the blood samples from the vena cavae and the right atrium. Since the findings do not differentiate between an atrial septal defect and anomalous drainage of pulmonary veins into the right atrium, the shunt (denoted by the arrow) is depicted in an intermediate position. The pulmonary flow was calculated to be over twice the systemic flow. Pulmonary hypertension and an elevated right ventricular end diastolic pressure are also present (from Cournaud, Baldwin, and Himmelstein).

atrial mean pressure, the actual pressures being normal or elevated, (2) right atrial and ventricular oxygen saturations are higher than that of the superior vena caval blood due to the left to right shunt, (3) a left to right shunt flow which often is 3 times the systemic flow, (4) a normal or increased right ventricular systolic pressure, the latter may be due to a functional pulmonic stenosis from the excessive pulmonary blood flow in addition to the increased stroke volume of the right ventricle, (5) an increased workload of the right ventricle, especially in imparting velocity to the increased flow, (6) a markedly increased pulmonary blood flow which may be 2 to 4 times the systemic flow, but a normal or slightly elevated pulmonary artery pressure, and a normal or low pulmonary vascular resistance, (7) a normal, but sometimes decreased, systemic flow, (8) an increased oxygen consumption with mild exercise, and (9) a normal peripheral arterial saturation.

From the above data a hemodynamic picture can be postulated for atrial septal defect. Since the left exceeds the right atrial pressure the shunt of blood is predominantly to the right atrium although some reverse flow may occur. The right atrial pressure may rise to increase the filling pressure of the ventricle for the latter must eject not only the systemic venous return but also the large amount of shunted blood. The increased volume of blood stretches the myocardial fibers of the right ventricle to give an increased stroke output; this leads to an increased right ventricular workload and to a very large pulmonary blood flow. Large defects therefore, may be associated with dilation of the right atrium, ventricle and pulmonary artery and right ventricular hypertrophy. The normal lung is a low pressure, highly distensible system which can accommodate the large excess flow with little change in pressure and a decrease in resistance. The increased venous return to the left heart is divided between the shunt and the systemic blood flow, which may be normal or decreased. With large shunts right ventricular output is augmented, but may not continue proportional to the increase in right atrial pressure, the right ventricle becomes less efficient at the higher filling pressures as the end diastolic pressure rises. This can eventually lead to the signs and symptoms of right heart failure since the peripheral venous pressure reflects the right chamber pressure elevations.

Pulmonary hypertension usually does not develop until the third decade in patients with atrial septal defects. The increased pulmonary

vascular resistance is due to narrowed arterioles by medial hypertrophy and endothelial proliferation, and probably, in some patients, to an increased vascular tone. The etiology of the development of these changes has not been elucidated despite much investigation. They appear earlier in ventricular septal defect but evidently are not only secondary to an increased pressure in the pulmonary vessels, for this would not explain their development in atrial septal defects. In dogs, similar pulmonary vascular changes can be produced by end to end anastomosis of a systemic arterial vessel to a pulmonary artery. This is more effective than a side to end anastomosis and could be explained by the lack of direct pressure thrusts in the latter. Fetal lungs show highly muscular, small, pulmonary vessels in ventricular septal defect; it is postulated that the increased pressure in the pulmonary artery does not allow normal regression of this fetal state. This is not of course, an adequate explanation for the development of pulmonary hypertension in patients with atrial septal defects.

Whatever the cause, once pulmonary vascular resistance begins to increase in septal defects, it is progressive. The resistance raises the pulmonary artery pressure and decreases the pulmonary blood flow. The right ventricle has a further increase in its workload against pressure and shows a rise in systolic, and later, in end diastolic volume and pressure. The latter is reflected in the right atrium which must then raise its pressure to fill the ventricle. The elevated right atrial pressure decreases the pressure gradient and, thus, the shunt from the left atrium. This cycle may progress to a point where the shunt flow reverses, causing a decreased peripheral arterial saturation and cyanosis.

Atrial septal defects are also seen in combination with other congenital lesions, such as pulmonic stenosis, mitral stenosis (usually acquired and called Lutembacher's syndrome), Ebstein's disease, tricuspid atresia and many others. These all affect the hemodynamic findings but, because of their rarity, will not be discussed.

The surgical correction of an atrial septal defect is performed by a closed or open technique, the latter with the aid of an extracorporeal pump-oxygenator. The defect is closed by direct suturing. After complete closure, a shunt flow is not measurable, systemic blood flow often increases, pulmonary blood flow is markedly reduced, and right ventricular work and pressures are reduced. The pulmonary vascular resistance often increases in the postoperative

period along with the decreased pulmonary flow. If severe pulmonary hypertension was present, results are not so good, for the pulmonary vascular changes usually do not regress and right heart failure may develop. Patients with high pulmonary vascular resistance are refused operation for this reason. An idea of the reversibility of the pulmonary hypertension may be gained by having the patient breathe pure oxygen or by administration of a pulmonary vasodilator agent, although such a correlation with postoperative results has not been extensively studied.

VENTRICULAR SEPTAL DEFECT. Ventricular septal defect is probably the second most common congenital heart lesion. Approximately 90 per cent of the defects occur in the membranous septum lying in the outflow tract of the left ventricle beneath the base of the aortic valve separated usually from the latter by a band of connective tissue. Less common are defects of the muscular septum which are often multiple perforations, not usually functionally open because of the contraction of the musculature during systole. A pansystolic, loud, often coarse murmur is heard in the third to fourth costal interspace parasternally. A mid-diastolic apical murmur may also be present, resulting either from a functional mitral stenosis or from rapid ventricular filling.

The hemodynamic effects of a ventricular septal defect are determined by the size of the defect, the pressure gradient across the valve, and the relative resistances to flow of the pulmonary and systemic circulations. Small defects are usually asymptomatic with the murmur as the only sign present, such uncomplicated cases are called Roger's disease, after the man who first described the murmur. Because of the pressure differential, which may be over 100 mm Hg between the left and right ventricle, large defects have much more profound hemodynamic effects than those seen in atrial septal defects.

Catheterization findings in patients with ventricular septal defect depend on the size of the opening and on the presence or absence of pulmonary hypertension. Pulmonary hypertension is often present from birth in these patients, or may develop later and progress in severity. Small to medium defects (fig. 28-23) (less than 1 cm per M^2 of body surface) show a pressure gradient across the defect, an elevated right ventricular systolic pressure, an increased oxygen content of right ventricular blood compared to right atrial blood, a shunt flow which may reach several liters per minute, and a large pulmonary blood flow with a normal or slightly elevated pulmonary

artery pressure. The left and, also, the right heart have an increased workload and are usually hypertrophied. The left ventricle must pump blood into both the right ventricle and the aorta, it increases its output in order to maintain systemic blood flow. Mean right atrial and pulmonary wedge pressure are normal, while pulmonary vascular resistance may be normal or low in the absence of pulmonary hypertension.

With very large ventricular septal defects, the systolic pressures tend to equalize between the right and left ventricle. The shunted blood flow into the low resistance right ventricular system is enormous in amount. There is a very large pulmonary blood flow and decreased pulmonary vascular resistance. Such defects usually lead to early failure of one or both ventricles unless pulmonary hypertension develops to decrease the amount of shunted blood. In patients with pulmonary hypertension (fig. 28-24) the pulmonary artery pressure is increased but the pulmonary wedge pressure is normal (in the absence of left ventricular failure) demonstrating that it is an arteriolar resistance. There is a decreased pulmonary blood flow and an increased pressure workload of the right ventricle, leading to pressure elevations in this chamber which tend to decrease the shunt flow. As this cycle progresses, the shunt flow may be reversed causing a decreased peripheral arterial saturation and cyanosis. The latter syndrome is indistinguishable from that described below as Eisenmenger's complex.

In summary, the amount of flow through a ventricular septal defect depends on the size of the defect and the resistances of the systemic and pulmonary circulation. Small defects present a large resistance to flow, meaning that a high pressure differential continues to exist between the two ventricles. Large defects allow a very large shunt flow which is decreased only by the development of increased pulmonary vascular resistance. However, the latter increases the workload of the right ventricle so that now both ventricles are severely hemodynamically involved.

Eisenmenger's complex, consisting of a ventricular septal defect, an aorta which overrides the ventricular septum and is therefore open to both ventricles, and right ventricular hypertrophy, will be briefly discussed, for it is often considered to be a severe form of ventricular septal defect. Substituting the word "syndrome" for "complex," Wood and others list any reversed shunt flow due to pulmonary hypertension (such as occurs in patent ductus arteriosus, ventricular and atrial septal defects) under this classification. Since the

FIG 28-23 Interventricular septal defect. Figures within vessels or chambers denote the blood oxygen content in cubic centimeters per liter of blood. Circled figures indicate the blood pressure, systolic over diastolic and mean pressures are shown. The increase in oxygen content to the right ventricle (compared to the right atrium) indicates a shunt of oxygenated blood (shown by the arrow) from the left ventricle. The estimated systemic and pulmonary blood flows were 3.57 and 6.14 liters per minute respectively. This indicated a shunt flow of 2.57 liters per minute. Note the moderate elevation of right ventricular and pulmonary artery systolic pressures secondary to the shunt flow (from Cournaud, Baldwin and Himmelstein).

upper portion of the ventricular septum has a spiral course whereby the aortic root may come in contact with both ventricular cavities, a large ventricular septal defect located below the aortic valve may cause an apparent overriding of the aorta, i.e., the second component of the Eisenmenger's complex. The right to left shunt in this cyanotic disorder is probably not related to the dextroposition of the aorta but to the pulmonary hypertension which is always present. The aorta, unless it rises almost directly from the right ventricle, would receive little blood from the right side as long as the right ventricular systolic pressure remained well below that of the left ventricle. In patients with a large ventricular septal defect and an overriding aorta, catheterization studies show a tremendous increase in pulmonary vascular resistance, an elevated right ventricular

and pulmonary systolic pressure equal to the systemic systolic pressure, evidence of a right to left shunt by decreased arterial oxygen saturation, and a normal or low pulmonary blood flow. The oxygen saturation of the right ventricular blood is higher than that of the right atrial blood indicating that an admixture occurs through the septal defect. The right ventricular work is markedly increased; this is reflected in the hypertrophy of this chamber. There is an increased oxygen consumption with mild exercise, although the cyanosis may deepen due to increased right to left shunting of blood.

The surgical correction of ventricular septal defect has been greatly enhanced by the use of extracorporeal pump-oxygenators and/or hypothermia. Under direct vision, the defect is sutured closed with or without the use of a synthetic

Fig. 28-24 Interventricular septal defect with marked pulmonary hypertension. Figures within vessels or chambers denote the blood oxygen content in cubic centimeters per liter of blood. Circled figures indicate the blood pressure: systolic over diastolic and mean pressures are shown. The increase in oxygen content in the right ventricle (compared to the right atrium) indicates a shunt of oxygenated blood (shown by the arrow) from the left ventricle. The lack of a systolic pressure gradient across the pulmonic valve rules out pulmonic stenosis. The high pressure in the pulmonary artery must be secondary to pathological changes in the pulmonary vasculature causing an increased resistance to flow. Note that the end diastolic right ventricular pressure is elevated slightly, indicating the presence of decompensation. The estimated systemic blood flow is 3.7 liters per minute and the pulmonary flow 6.9 liters per minute, giving an estimated shunt flow of 3.2 liters per minute (from Cournand, Baldwin and Himmelstein).

patch. The ideal candidate for surgery would have a large shunt volume with a high pulmonary blood flow but normal or only slightly increased pulmonary vascular resistance. Small defects with minor hemodynamic changes are usually not corrected because of the surgical risk. Cyanotic patients with right to left shunts from severe pulmonary hypertension including Eisenmenger's complex do not benefit from closure of the defect. Following operation patients who had an elevated pulmonary vascular resistance show little decrease when catheterized several months later. Patients with severe pulmonary hypertension who have undergone surgery have fared very poorly.

TETRALOGY OF FALLOT The tetralogy of Fallot is the most common of the cyanotic congenital

heart diseases. Classically it has been described as a combination of pulmonary stenosis, ventricular septal defect, right ventricular hypertrophy, and dextroposition of the aorta, the latter overriding the ventricular septum. A right-sided aortic arch is also present in about a quarter of the cases. The pulmonary stenosis is most commonly of the infundibular type. Since the advent of cardiac catheterization studies the concept of tetralogy as a single entity has been undermined. It is now considered that a spectrum of patients exists ranging from severe tetralogy, with a large ventricular septal defect and severe pulmonic stenosis, to patients with either a large ventricular septal defect or a severe pulmonic stenosis as the dominant lesion. Between these two ex-

trems are mulder combinations of the two lesions. The dextroposition of the aorta is not considered as an important determinant in the hemodynamic picture (see ventricular septal defect). The right ventricular hypertrophy is not congenital in origin but results from the stress imposed on this chamber. There is usually a loud, harsh, systolic murmur in the second or third costal interspace parasternally, presumably due to the pulmonary stenosis, but it is not pansystolic, ending before the aortic second sound.

Patients with large ventricular septal defects, but mild pulmonic stenosis, show a left to right shunt without cyanosis and the reader is referred to the above discussion of ventricular septal defects for the hemodynamic abnormalities. Similarly,

patients with a severe pulmonic stenosis and a small ventricular septal defect behave hemodynamically as discussed under pulmonic stenosis but, in addition, have a right to left shunt with cyanosis.

When both the ventricular septal defect and the pulmonic stenosis are significant, the following catheterization data and calculations are found (fig 28 25): (1) the pulmonary artery pressure is reduced as is the pulmonary blood flow, (2) the pulmonary capillary flow is often greater than the pulmonary artery flow from collateral circulation to the lungs, however, the effective pulmonary flow is still below normal; (3) the right ventricular systolic pressure is elevated, but the end diastolic pressure is usually normal.

FIG 28 25 Tetralogy of Fallot. Numerical figures within vessels or chambers denote the blood oxygen content in cubic centimeters per liter of blood. Circled figures indicate the blood pressure, systolic over diastolic and mean pressures are shown. Dark areas represent very low blood saturation as compared to white areas denoting high blood saturation. The large systolic gradient of the right ventricle to the pulmonary artery indicates a marked degree of stenosis. The systolic pressures in the right ventricle, aorta and brachial artery are almost identical. From analysis of the oxygen data, it can be calculated that the left to right ventricular shunt is small, but the right to left ventricular shunt is large (indicated by arrows). Calculation of the systemic blood flow shows it to be somewhat reduced; the pulmonary blood flow is about half the systemic flow. Note that the aorta overrides both ventricles (from Courvoisier and Baldwin, and Himmelstein).

the right ventricular systolic pressure approximates the aortic systolic pressure, (4) right and left mean atrial pressures are similar, (5) the arterial oxygen saturation is decreased, left atrial samples of blood are usually more saturated than left ventricular samples showing that the shunt is mostly interventricular and not from the right ventricle into the aorta, and (7) the oxygen consumption with mild exercise does not rise but decreases, as does the peripheral arterial saturation, deepening the cyanosis.

In summary, a hemodynamic picture can be postulated for tetralogy of Fallot. The resistance offered by pulmonic stenosis causes the right ventricle to shunt blood mostly through the ventricular septal defect and somewhat into the dextropositioned aorta. The right ventricle hypertrophies in response to the increased workload but rarely dilates, for it can easily empty into the left ventricle or aorta. The systolic pressure of the right ventricle rises to the level of that in the left ventricle in order to eject its blood into the systemic circulation through the least resistant available opening, i.e., the aortic valve via the septal defect. The aortic blood is desaturated by the shunted venous blood. The pulmonary artery pressure and blood flow are markedly decreased because of the pulmonic stenosis, but the pulmonary capillary circulation may be augmented by a collateral flow from systemic arteries. The fact that some reversed shunt also occurs is established by the higher blood oxygen content of the right ventricle compared to that in the atrium. These patients cannot increase their oxygen consumption during mild exercise probably because of the limited, circulating volume of mixed venous blood that can be propelled across the stenosed valve in to the lungs.

The surgical correction of tetralogy of Fallot has grown through three stages. The Blalock-Taussig operation, creating a channel similar to a patent ductus arteriosus between the aorta (subclavian artery) and the pulmonary artery, supplies more blood to the lungs, but the results, although often good, are not excellent. The next procedure attempted was an indirect correction of the pulmonic stenosis (see p. 430). This produced slightly better results but with a higher operative mortality. The use of the extracorporeal pump-oxygenator has recently made a direct open approach possible to correct both the ventricular septal defect and the pulmonic stenosis. Since these patients do well without a correction of the dextropositioned aorta, this is further proof

that it is probably not a significant hemodynamic determinant in this anomaly.

PATENT DUCTUS ARTERIOSUS Patent ductus arteriosus is next in frequency, after the septal defects, among congenital heart diseases. It is the persistence of a patent channel joining the left pulmonary artery to the aorta (distal to the subclavian artery), which is normally found in the fetus and which closes within a few weeks after birth. The exact mechanism of the normal obliteration of the ductus is not understood although it has been shown that the duct constricts, when perfused with oxygenated blood, and dilates if nitrogen replaces the oxygen, another theory asserts that high pressures maintain the ductus patent while low pressures lead to its closure. Classically a 'machinery' murmur (fig. 28-26) is heard throughout systole and diastole due to the continuous shunting of blood and is located in the second or third costal interspace, parasternally. This murmur is harsh in quality increasing toward the end of systole, and waning during diastole.

The hemodynamic effects of a patent ductus arteriosus are secondary to the shunting of blood from the high pressure system of the aorta to the low pressure circulation of the pulmonary artery (fig. 28-27). The amount of blood shunted depends upon the size of the ductus and the pressure difference between the aorta and the pulmo-

FIG. 28-26 Phonocardiogram (and electrocardiogram) demonstrating the machinery murmur of patent ductus arteriosus. Upper tracing (recorded preoperatively) at the pulmonic area shows loud systolic (SM) and diastolic (DM) components of the continuous murmur. S_1 and S_2 denote the first and second heart sounds. Lower tracing (recorded after ligation of the ductus) shows persistence of a soft pulmonic systolic murmur (from Levine and Harvey).

FIG. 28-27. Patent ductus arteriosus. Figures within vessels or chambers denote the blood oxygen content in cubic centimeters per liter of blood. Circled figures indicate the blood pressure, systolic over diastolic and mean pressures are shown. The large increase in oxygen content in the pulmonary artery demonstrates a shunt of oxygenated blood (indicated by the arrow) from the aorta. The estimated pulmonary blood flow as calculated from the oxygen content of the left pulmonary artery, was 4.93 liters per minute and the systemic cardiac output was 2.38 liters per minute. This means a shunt flow of 2.6 liters per minute existed. The slight increase in pulmonary artery pressures indicates the presence of a mild degree of pulmonary hypertension (from Cournaud, Baldwin, and Himmelstein).

nary artery. Eppinger, Burwell, and Gross studied the hemodynamic changes in patients and dogs with patent ducti. In dogs the left subclavian artery was sutured to the pulmonary artery to simulate the clinical situation. Such animals showed an increased left but a decreased right ventricular output. The shunted blood from the aorta to the pulmonary artery was calculated to be more than 50 per cent of the left ventricular output. Two of three dogs showed an increased mean pulmonary artery pressure, probably from the large pulmonary blood flow rather than an increased pulmonary resistance. Patients with patent ductus were studied while under anesthesia and during thoracotomy, before the ductus was tied. The oxygen content of the pulmonary artery was greater than that of the right ventricle. Blood flows through the shunt varied from 4 to 19 liters per minute, which was 45 to 75 per cent

of the left ventricular output. The total pulmonary blood flow (right ventricular plus shunt flow) was 10 to 20 liters per minute. The left was 2 to 4 times the right ventricular output. Arterial blood pressure showed a low diastolic level with a wide pulse pressure. Studies in unanesthetized subjects by other groups have demonstrated similar findings. The mean right atrial pressure was normal while the right ventricular and pulmonary artery systolic pressures were normal or elevated. The pulmonary vascular resistance was increased when pulmonary hypertension was present.

In summary, the higher aortic pressure shunts blood through a patent ductus arteriosus to the low pressure pulmonary circuit during the entire cardiac cycle. Depending on its size, some shunts have been calculated to deliver up to 30 liters per minute to the pulmonary artery. This leads to an

excess pulmonary blood flow and venous return to the left side of the heart. The increased volume return to the left ventricle results in a stretch of the myocardial fibers, whereby the left ventricle increases its output in order to maintain systemic blood flow at or near normal levels. This increased workload of the left ventricle may lead to its hypertrophy. The escape of blood from the aorta to the pulmonary artery causes a sharp fall in diastolic pressure, producing an increased pulse pressure and most of the peripheral signs of aortic insufficiency.

Patients with a patent ductus arteriosus may develop pulmonary hypertension, for unknown reasons, as discussed under atrial septal defect. As the pulmonary vascular resistance increases the pulmonary artery and right ventricular systolic pressures rise. This causes a decrease in the pressure differential between the aorta and pulmonary artery and a decrease in the shunt flow. When the pulmonary hypertension is more severe, the shunt flow may become partial, and then completely reversed, producing a hemodynamic picture similar to Eisenmenger's complex, except that the cyanosis is limited to the lower body. Such patients usually have a very large ductus, right ventricular hypertrophy, secondary to the increased work of the right ventricle, and an atypical or absent murmur.

The surgical treatment of patent ductus arteriosus consists of cutting the ductus and suturing the aortic and pulmonary ends closed. After operation, the arterial diastolic pressure rises, the left ventricular output decreases and, in the majority of patients, the murmur disappears. Operation is usually not recommended for patients with severe pulmonary hypertension and reversal of ductal flow, since the ductus serves as an escape valve for the excess right ventricular pressure and output. Delayed closure, in such cases by partial ligation or by a two-stage shunting operation has been suggested, but not tested in a sufficient number of patients.

COARCTATION OF THE AORTA. Coarctation of the aorta is a congenital defect which is usually subdivided into an "infantile" and "adult" form. In infantile coarctation consists of a long segment of narrowing in the distal aortic arch, from the left subclavian artery to the ductus arteriosus insertion while the adult form is a shorter, more localized constriction at or distal to the ductus attachment. Since these two variations are often seen in different age groups than their label implies it has been suggested that such a classification be discarded because it serves no useful purpose to the surgeon who is attempting to cor-

rect the defect. A loud systolic murmur, due probably to the turbulence at the constricted area, extends from early systole slightly into diastole. It is most often loudest at the base of the heart but is also heard in the left interscapular area.

The hemodynamics of coarctation of the aorta involve an increased pressure workload on the left ventricle which has to pump its output through the narrowed area. This strain, which often leads to left ventricular hypertrophy, is somewhat relieved by the development of an extensive collateral circulation between the subclavian artery and its branches above the constriction, and the branches of the descending aorta below (fig. 28-23). In patients studied by catheterization techniques, the cardiac output is normal or increased. The blood flow to the upper body is normal or elevated and, due to the extensive collateral circulation, normal to the lower body. An elevated blood pressure occurs above the coarctation. There is a delay in onset of the femoral pulse (fig. 28-20) which normally precedes the radial pulse slightly. This delayed onset may not be palpable but the late systolic peak of the femoral pulse as compared to the radial, is very noticeable. The femoral pulse curve shows a slow rise and fall with a decreased pulse pressure and an absent dicrotic notch.

Patient and animal studies purport to show that the upper body hypertension can be explained on a purely mechanical basis related to the degree of aortic constriction. Gupta and Wiggers thoroughly studied, in dogs, the hemodynamics of aortic constriction just beyond the left subclavian artery. As the degree of constriction was increased, systolic, diastolic and pulse pressures increased in the aorta above the constriction and decreased in the femoral artery. They postulated that the hypertension above the constriction was not only secondary to the increased resistance but also to the reduced capacity and distensibility of the aortic compression chamber, into which the left ventricle empties, and to the physiological reactions of the left ventricle, whereby its systolic discharge is increased. They explained the slow rise and fall and the maintenance of diastolic pressure of the femoral pulse to the damping effect on the aortic pressure wave in its passage through the constricted area. In dogs with a constricted aorta, but with a subclavian to aorta shunt imitating the collaterals found in man, the systolic and diastolic pressures of the aorta above the constriction were decreased, while those of the femoral artery were increased when compared to the findings in coarcted dogs without such a

FIG. 28-28 Diagrammatic representation of routes of collateral circulation in coarctation of the aorta. The extensive collateral circulation between the subclavian arteries and their branches above the constriction and the branches of the descending aorta below the coarctation is shown. (From Edwards and associates: *An atlas of congenital anomalies of the heart and great vessels*. Charles C. Thomas, Publisher, Springfield, Illinois, 1954.)

shunt. The pulse pressure increased but the contour of the femoral pulse wave did not return to normal. Thus, an artificial collateral circulation reduced the workload on the left ventricle and the elevated blood pressure of the upper body while increasing the blood flow to the lower extremities.

Experimentation on dogs has produced evidence for and against renal ischemia being a factor in the upper body hypertension. Also Painter and associates have demonstrated hypertrophy of the media and endothelial proliferation of arterioles in organs of patients above and below

the constricted aorta. The fact that hypertension does not exist in the lower body was explained by the metabolic need for blood dilating its narrowed arterioles. This increased peripheral resistance could explain the finding of normal or even increased femoral artery diastolic pressures in many coarctation patients.

Coarctation of the aorta has been corrected in hundreds of patients by excision of the involved area and anastomosis of the proximal to the distal end. If a long area of the aorta is involved a graft is inserted. Following operation the upper extremity hypertension may either decrease to nor-

FIG 23.29 Tracings of the intraradial and intrafemoral arterial pressures from a patient with coarctation of the aorta. The following points should be noticed (1) the elevation of the systolic and diastolic pressures in the radial artery, (2) the smaller femoral systolic and pulse pressures, (3) the slight delay in onset of the femoral pulse wave compared to that of the radial pulse wave, and (4) the late peak of the femoral pulse as compared to that of the radial pulse (from Brown, Clagett, Burchell, and Wood)

mal levels or remain elevated. The persistence of this hypertension after removal of the constricted aortic area would argue for a renal etiology except that the increased pressure may have induced permanent arteriolar changes, thereby increasing the peripheral resistance

SECTION THREE

Respiration

29

UPTAKE AND DELIVERY OF THE RESPIRATORY GASES

The Physical Principles Governing the Respiratory Exchanges

The cells of higher animals continually use oxygen and produce carbon dioxide as a waste product. Movement of oxygen into the lungs of mammals is promoted by breathing movements. Oxygen diffuses into the blood in the pulmonary capillaries to be carried to all parts of the body where it diffuses from the capillary blood into the interstitial fluid and on to the cells. Carbon dioxide diffuses from the cells to the interstitial fluid and then to the blood in the systemic capillaries to be carried to the lungs where it diffuses into the alveolar air.

The major problems to be considered under the heading of respiratory physiology are 1) the uptake of oxygen from alveolar air and its delivery to the tissues, 2) the uptake of carbon dioxide from tissues and its delivery to the alveolar air, 3) the mechanism of rhythmic inspiration and expiration, and 4) the mechanisms by means of which the amount of air breathed per minute is adjusted to the needs of the body. The actual chemical processes by which the oxygen is utilized in the cells (cellular respiration) will not be discussed. This subject is considered in detail in texts in biochemistry. Some of the derangements of respiration are considered under the appropriate major headings, while others which are of a more general nature are described in the final chapter of the section.

It is assumed that the reader already will have knowledge of elementary biochemistry and human anatomy. Further, it is essential that the relation of carbon dioxide to the acid base balance (ch. 13), the physiology of nerve muscle and reflex action (ch. 63) and the physiology of the autonomic nervous system (ch. 71) should

be studied in advance in order to understand the chemical and neural control of respiration.

The Kinetic Theory of Gases—Diffusion, Partial Pressures, Absorption Coefficients

Any quantity of a gas when placed in a container of whatever size expands its volume until limited by the boundaries of the confining vessel. This fact is explained upon the theory that the gas molecules are in continuous motion, moving through space at high velocity and being deflected from their course only upon coming into collision with other gas molecules or with the boundaries of the space itself which they strike and from which they rebound repeatedly. Such movements constitute a bombardment upon the confining walls which is responsible for what is called the pressure or tension of the gas. The greater the number of molecules in any given space the more frequent obviously will be the bombardments. So if the capacity of the space is reduced the molecules are brought closer together. The rate of bombardment upon a unit of surface will increase and the pressure of the gas will rise (see *Boyle's Law* below). A rise in temperature increases the velocity of the molecular movements, increases the rate of bombardment and the force of the impacts. The pressure in consequence increases (*Charles' Law*).

In all circumstances the gas molecules as a result of their movements will in time distribute themselves evenly throughout the space in which they are confined and consequently the pressure will be the same upon all parts of the limiting

TABLE 29 1

Absorption coefficients of various gases in distilled water at different temperatures

Temperature	Oxygen	Carbon Dioxide	Carbon Monoxide	Nitrogen
0	0.049	1.71	0.035	0.024
20	0.031	0.87	0.023	0.016
40	0.023	0.53	0.018	0.012

surface. In other words although at the start the molecules may be in greater concentration in one part of the space than in another, even distribution is soon brought about, and the pressure throughout all parts of the space becomes equal. This behavior of a gas whereby the equalization of its molecular concentration occurs is spoken of as *diffusion*. If we should deal with a mixture of two or more different gases instead of with a single gas it would be found that each component in the mixture behaved as though present alone. Its molecules would become distributed evenly throughout the mixture, and its pressure would depend upon its concentration without regard to the concentrations of the other component gases (*Law of partial pressures*).

If two samples of a gas of different concentrations, be placed one on each side of a membrane permeable to that gas, diffusion also occurs until the tensions on the two sides of the membrane are equal, as in the case of a gas mixture each gas behaves as though present alone.

When a gas or a mixture of gases lies in contact with the surface of a liquid, the molecules of each gas penetrate the liquid and become dissolved in it until the tensions of that particular gas within and without the liquid are equal. The gas is then said to be equilibrated with the liquid (*Law of solubility of gases*). On the other hand, if the liquid be now exposed to a lower pressure of the gas the molecules which had undergone solution at the higher pressure escape until equilibrium is restored at the lower level. Soda water, for example, is water which has been equilibrated with carbon dioxide at a high pressure. When the cork is removed from the bottle containing the surcharged liquid, effervescence occurs. Molecules of carbon dioxide are given off until the pressure of the dissolved gas equals that of the carbon dioxide in the atmosphere. A gas at different tensions in two liquids also comes into equilibrium whether the liquids are in direct contact or are separated by a membrane permeable to the gas. Also the actual amount of gas which will undergo solution at a given pressure varies with the particular gas and

with the liquid. If distilled water for example be exposed to oxygen at a pressure of 760 mm. and a temperature of 0°C. each 100 cc. will take up 4.9 cc. of the gas. Oil, on the other hand, under the same conditions of pressure and temperature will absorb a great deal more. Therefore, if samples of water and oil are exposed to the atmosphere though the gas pressures in the three media are identical, the volumes of the atmospheric gases in 100 cc. (volumes per cent) of each medium will be widely different.

The quantity of a gas (measured at standard temperature and pressure) which can be absorbed by 1 cc. of a liquid at 760 mm. Hg is called the *absorption coefficient* of the gas for that particular liquid. Thus the absorption coefficient of oxygen in water at 0°C. is 0.049 and of carbon dioxide 1.71, the coefficient varies inversely with the temperature (see table 29 1). The presence of dissolved solid substances in the water will reduce the absorption coefficient of these gases. The values for the body fluids are, therefore, slightly less than those given above. Thus the coefficient of absorption of oxygen in plasma at body temperature (37°C.) is 0.024 and of carbon dioxide 0.510.

The rate of diffusion of a gas through a liquid is in direct proportion to the absorption coefficient of the gas in that liquid and inversely proportional to the square root of its molecular weight. The diffusion rate of carbon dioxide through a wet membrane is about 30 times greater than that of oxygen when the two gases are under identical conditions. For general physiological work the *diffusion coefficient* of oxygen has been defined by Krogh as the number of cubic centimeters of the gas which will diffuse 0.001 mm. distance over a square centimeter of surface, per minute, at a pressure of 1 atmosphere. It varies for different tissues and body fluids and increases 1 per cent per degree Centigrade.

The diffusion coefficients for oxygen through the following materials at body temperature were found:

Water	0.51
Gelatin 15 per cent	0.45
Muscle	0.31
Connective tissue	0.18

Certain diseases that cause thickening of the pulmonary membrane, destroy lung capillaries, or interfere with diffusion within the blood itself, will reduce the rate of gas diffusion between the blood and the alveolar air. Among such conditions are edema of the lung, emphysema, pulmonary fibrosis, mitral stenosis, and congestive heart failure.

Summary of the Gas Laws

(1) *Boyle's Law* When the volume of a gas is altered, the temperature remaining constant, the pressure varies inversely, i.e., the product of the pressure and the volume remains constant. If the space wherein a certain gas is confined be reduced by half, the gas pressure is doubled and vice versa.

(2) *Law of Charles (or Gay Lussac)* For each rise in temperature of 1°C a gas kept at constant pressure expands by $\frac{1}{273}$ of its volume at 0°C . The volume of a gas at constant pressure is therefore proportional to its absolute temperature (-273°C).

(3) *The Law of Partial Pressure (Dalton's Law)* The pressure exerted by a gas in a mixture of gases is equal to the pressure which the same quantity of that gas would exert were no other gases present. It follows that the total pressure of a mixture of gases is equal to the sum of the pressures of its component gases. For example, the atmosphere (dry) exerts a pressure of 760 mm Hg. The gases of which it is composed—oxygen, nitrogen (including other inert gases), and carbon dioxide are present in the proportions of 20.96 per cent, 79 per cent and 0.04 per cent respectively. The partial pressure exerted by oxygen is therefore $(20.96/100) \times 760 = 159.2$ mm Hg and of carbon dioxide $(0.04/100) \times 760 = 0.30$ mm Hg.

Air in contact with water is continually receiving water molecules from the surface of the liquid. This water vapor follows Dalton's Law exerting a pressure independently of the other gases, and proportional to the quantity present in the air. The higher the temperature the greater is the quantity of water which the air will hold before becoming saturated and the greater consequently will be the tension of aqueous vapor.

The air in the lungs has a temperature of about 37°C and is usually stated to be fully saturated with water vapor, the latter, therefore, exerts a pressure of 47 mm Hg.¹ The air after leaving the lungs falls in temperature, some of the water vapor condenses and the latter in consequence is much less. The tension of water vapor in room air (18°C) would be no more than 15.5 mm Hg even though the air were fully saturated, and is usually around 4 or 5 mm Hg. The aqueous tensions of air (saturated) at various temperatures are given in table 29.2.

In the measurement of the respiratory gases the volumes are expressed dry (i.e. less the aqueous vapor, though actually no correction for this is

¹ Christie and Loomis from direct measurements have obtained a lower value for the aqueous tension of alveolar air than the usually accepted one of 47 mm Hg (namely 45 mm Hg). They claim that the alveolar air is not fully saturated and that the temperature of the lung is lower than has been assumed. Hyperpnea they found reduced the aqueous tension by as much as 7 mm Hg. Holding the breath increased it by 0.5 mm Hg.

TABLE 29.2

Tension of aqueous vapor and water in grams in moisture saturated air at different temperatures

Temperature	Tension of Aqueous Vapor	Water per Cubic Meter of Air
$^{\circ}\text{C}$	mm Hg	grams
0	4.6	4.9
5	6.5	6.8
10	9.1	9.4
15	12.7	12.8
20	17.4	17.2
30	31.6	30.1
37	47.1	

required) and at standard temperature and pressure (STP)—760 mm Hg and 0°C . The individual gases carbon dioxide or oxygen are then expressed as percentages of this dry volume.

In order to arrive at the tension of one or other gas from its percentage in dry air the figure for the barometric pressure less the aqueous tension must of course be used as the basis for calculation. For example if the carbon dioxide percentage in a sample of alveolar air (dry) is 5.6 per cent and the barometric pressure, (and so of course the total gas pressure of the alveolar air) is 760 mm Hg, then the tension of carbon dioxide in the alveolar air must be

$$(5.6/100) \times (760 - 47) = 39.9 \text{ mm Hg}$$

Similarly when the O_2 percentage in dry alveolar air is 14.2 the oxygen tension is

$$(14.2/100) \times (760 - 47) = 101.2 \text{ mm Hg}$$

(4) *Henry's Law of the Solution of Gases* If the temperature remains constant, then the quantity of a gas which goes into solution in any given liquid is proportional to the partial pressure of the gas.

The Exchange of Gases in the Lungs

THE PARTIAL PRESSURES OF THE GASES IN THE LUNG AIR

In table 29.3 are given average figures for the partial pressures of oxygen, carbon dioxide and nitrogen including argon and other inert gases in inspired, expired and alveolar airs. The fall in oxygen pressure from inspired to alveolar air and in the reverse direction for carbon dioxide will quite evidently promote the free interchange of these gases across the pulmonary epithelium. The interchange of gases between inspired and alveolar airs is reflected in the intermediate values shown for the gas pressures in the expired air.

The alveolar oxygen and carbon dioxide tensions tend to vary with the minute volume

TABLE 29 3

Composition of atmospheric air, inspired air, and alveolar air at pressure of 1 atmosphere

Gas	Partial Pressure*		
	Inspired air	Expired air	Alveolar air
	mm Hg	mm Hg	mm Hg
Oxygen	158.25	116	100
Carbon dioxide	0.30	28	40
Nitrogen, argon etc	596.45	569	573
Aqueous vapor	5.00	47	47
Totals	760.00	760	760

* These are general figures. There is considerable variation between individuals and under different conditions. The range of gas pressures in the alveolar air for man at rest is from 97 to 108 mm Hg of oxygen, and from 35 to 45 mm Hg for carbon dioxide.

Minute amounts of argon, helium, neon and other rare gases are present in the atmosphere and are included in the figure given for nitrogen. They are inert in so far as respiration is concerned, nor do they appear to be essential for any physiological process.

During voluntary hyperpnea the CO_2 tension falls and the O_2 tension rises. When the breath is held or during periods of apnea, changes of a reverse order occur.

Nitrogen, so far as respiration is concerned is inert. Argon and other inert gases are included along with nitrogen and all of these together or dinarily are designated as "nitrogen", since no distinction needs to be made in discussions of respiratory physiology.

A small but constant amount (about 0.83 vol. per cent) of nitrogen is taken up and dissolved in the plasma but it is neither used nor produced within the body, hence, the quantities in arterial and in venous blood are identical. It will be noted, however, that the *percentage* of this gas is higher in alveolar and expired air than in inspired air. This is due not to any absolute increase in the quantity of nitrogen but to the reduction of the total volume of the respiratory gases resulting from the greater quantity of oxygen absorbed than of carbon dioxide put out.

PARTIAL PRESSURES OF OXYGEN AND CARBON DIOXIDE IN BLOOD

In table 29 4 are given the tensions of oxygen and carbon dioxide in arterial and in venous blood. The venous blood, it will be seen, has a lower tension of oxygen (by 60 mm) than the alveolar air but a higher tension of carbon dioxide

TABLE 29 4

Gas tensions in arterial and in venous blood

	Tension	
	Venous blood	Arterial blood
	mm Hg	mm Hg
Oxygen	37	100 ¹
Carbon dioxide	46	40
Nitrogen	573	573
Water vapor	47	47
Totals	703	760

(by 6 mm). It is to be remembered that the pulmonary capillaries and the air in the alveoli are separated by delicate membranes freely permeable to these gases. The pressure gradients are favorable to a rapid inward diffusion of oxygen (from alveolar air to blood) and an outward diffusion of carbon dioxide (from blood to alveolar air). Equilibrium is quickly established between the respiratory gases in the alveolar air and in the blood of the pulmonary capillaries. Since the diffusion coefficient of carbon dioxide through the pulmonary membrane is much higher than that of oxygen, the pressure gradient of the former gas need not be so high for this to occur. It will be seen from tables 29 3 and 29 4 that the tension of carbon dioxide in the blood leaving the lungs, i.e., in the mixed arterial blood, is the same as that in the alveolar air. Indeed it is the usual practice when one wishes to know the arterial CO_2 tension to determine that of the alveolar air and assume that the two are identical. It has been shown, however, by Bock and associates that a slight difference (0.5 mm Hg) does exist.

The oxygen tension of the mixed arterial blood returned from the lungs of man is only slightly lower than that of the alveolar air. Comroe and Dripps, in a series of normal human subjects, obtained a value of 97.4 Hg for the alveolar air and 97.1 Hg for the arterial blood²—an *alveolar-arterial difference* of only 0.3 Hg. Comparable values for man were obtained by Lilenthal and associates.

Gaseous equilibrium is attained not instantaneously but progressively along the course of the pulmonary capillary. Diffusion is rapid at the venous end but as blood and alveolar air approach equilibrium the diffusion process necessarily be-

² Since virtually no oxygen is released from the blood in the arterial system, a sample taken from an artery will have the same O_2 tension as that in a pulmonary vein.

FIG 29-1 Krogh's microtonometer *A* is an enlarged view of an equilibration chamber constituting the lower part of *B(1)* but which is shown only in part in the latter drawing. *A* is filled with saline solution through the side tube 1, a narrow tube into which the specimen of blood is introduced, 2, an air bubble. The lower end of 1 is connected by rubber tubing to a cannula inserted into a blood vessel, the blood issues from a narrow opening at the upper end of the tube 1 in a fine jet and plays upon the bubble. After the gases in blood and bubble have come into equilibrium the latter is drawn into the graduated capillary tube shown in *B*, by means of the screw plunger (4) and analyzed according to the following procedure. The volume of the bubble is first measured, it is next drawn into a solution of KOH which absorbs the CO_2 , then returned to the graduated tube and measured again, the difference between the two measurements gives the amount of CO_2 which it contained. The bubble is then passed through a solution of potassium pyrogallate to absorb the O_2 , and its volume measured a third time. *C* is a model with an attached cannula which can be inserted directly into a blood vessel.

comes slower. The length of the capillary and the rate of the blood flow through it are factors which must determine the extent to which equilibrium occurs. Roughton obtained a figure of 0.75 seconds for the time of passage of the blood through the pulmonary capillaries for normal men at rest, this was shortened to 0.34 seconds during heavy work. The total volume of blood in the pulmonary capillaries at any moment is also, owing to their distension, much greater than during rest, during arduous exercise the quantity of blood in the lungs may be double that during rest.

The tensions of oxygen and carbon dioxide in human arterial blood may be determined by bringing a small bubble of air into contact with a sample of the blood obtained by arterial puncture. The method employed for the purpose is an adaptation to man (Barcroft and Nagahashi) of a method originally invented by Krogh for animals (see fig 29-1). After the gases in the air have come into equilibrium with those dissolved in the blood, the small bubble is analyzed and its composition determined. The gas tensions are then calculated from their percentages. Since no gaseous exchanges occur across the walls of the arteries, the tensions so determined are those of the blood leaving the pulmonary capillaries. It has already been mentioned that the arterial carbon dioxide tension is usually obtained from an analysis of alveolar air. The gas tensions of the blood coming to the lungs—the mixed venous blood—may be determined in man by direct or indirect methods. In animals mixed venous blood may be obtained from the right ventricle by puncturing the chest wall with a hollow needle attached to a syringe.

The Volumes of Oxygen and Carbon Dioxide in Blood

Knowing the respective absorption coefficients for oxygen and carbon dioxide in plasma, and the gas pressures, the volume of each gas in simple solution in 100 cc of plasma can be readily calculated (table 29-5). For example, the absorption coefficient of oxygen in plasma is 0.023 at body temperature and at a pressure of 760 mm Hg. At the partial pressure of oxygen in arterial blood the plasma should hold in solution $(100/760) \times 0.023 = 0.003$ cc of oxygen per cubic centimeter or 0.3 volume per cent. The absorption coefficient of carbon dioxide in plasma (0.51) or of whole blood (0.48) is higher than that of oxygen, but the partial pressure of carbon dioxide to which arterial blood is exposed in the lung is lower (40 mm

TABLE 29-5

Volumes per cent (cubic centimeters of gas per 100 cc blood) of oxygen and carbon dioxide in arterial and in venous blood

Gas	Venous Blood		Arterial Blood	
	Total	In simple solution	Total	In simple solution
Oxygen	12-14	0.1	19.5	0.3
Carbon dioxide	58	3.0	48	2.5

Hg) than that of oxygen. The quantity of the former gas in simple solution in whole blood is therefore $(40/760) \times 48 = 2.5$ volumes per cent.

About 19.5 volumes per cent of oxygen and from 40 to 50 volumes per cent of carbon dioxide can be removed from arterial blood. The proportions of these gases present in simple solution are, therefore, only a small fraction of the quantities held in the blood in other ways. They are present in chemical combination—oxygen with hemoglobin and carbon dioxide mainly as bicarbonate (see p. 459).

Blood normally contains about 15 grams of hemoglobin per 100 cc. Since 1 gram of hemoglobin carries a maximum of 1.34 cc. of oxygen, arterial blood would, therefore, when saturated to its full capacity, contain about 20 cc. of oxygen. Blood as it leaves the lungs is about 97.5 per cent saturated with oxygen so that the hemoglobin holds at this degree of saturation about 19.5 cc. of oxygen per 100 cc. of blood.²

The photoelectrical determination of the oxygen saturation. In man, the oxygen saturation can be determined in the blood as it circulates through a translucent part such as the pinna of the ear, by means of the *oximeter*. This instrument originally suggested by the work of Squires has been developed by Ooldie and by Millikin. The method is

² Since the blood in passing through the capillaries of an air sac comes into equilibrium with the air of that air sac as described previously the statement that the arterial blood has a tension less than that of the alveolar air and is only from 91 to 96 per cent saturated requires explanation. The discrepancy is explained as follows: The air sacs are not all ventilated to the same extent; in some the O_2 tension is higher, in some lower than that of the alveolar air as determined upon a sample. In other words the O_2 tension of a sample of alveolar air is an average of the O_2 tensions of the air in all the air sacs. But when we come to consider the blood coming not from a single air sac but from the lung as a whole—i.e. the *mixed arterial blood*—it becomes evident that while an under-ventilated air sac will lower the oxygen tension and so the oxygen saturation of the hemoglobin, an overventilated one cannot compensate this effect to any significant extent. The O_2 in solution (upon which the O_2 tension directly depends) is in equilibrium with that combined in hemoglobin, and it is evident from the shape of the O_2 dissociation curve of hemoglobin that a rise in oxygen tension above 100 mm. Hg will saturate the blood very little more, whereas a fall of 20 mm. Hg or so will reduce the saturation very materially.

The variation between individuals in the O_2 saturation of the arterial blood is attributed to the different degrees to which uneven ventilation of the air sacs occurs and also to slight differences in the shapes of the dissociation curves. It was first shown by Barcroft that the O_2 dissociation curve is not precisely the same for all persons. The dissimilarities are due apparently to slight differences in the chemical constitution of the globin part of the hemoglobin molecule.

based upon the fact that red light (wave length 600 to 7500 m μ) is transmitted readily by oxyhemoglobin, but only slightly by reduced hemoglobin. The apparatus consists of an electric light bulb and a photoelectric cell placed, respectively, at the front and back of the pinna. The heat of the bulb dilates the vessels so that the oxygen saturation of the blood in the capillaries becomes that of the arterial blood. The light transilluminates the tissue and after passing through suitable filters is received by the photoelectric cell. The electric current set up is measured galvanometrically and the actual percentage of oxygen saturation is calculated by means of the calibrations of the instrument with values established by the Van Slyke method. This method has proved of great value in determining the oxygen saturation of the blood drawn by catheter from the right auricle, ventricle and pulmonary artery in the diagnosis of congenital cardiac defects (p. 522). Groom and his associates have devised a more convenient apparatus for this purpose. The blood is transilluminated by passing it through a tube composed of polythene attached to the catheter on the opposite side. The transmitted light is registered by photoelectric cells placed respectively behind red and near infrared (wave length 750 to 900 m μ) filters. The oxyhemoglobin concentration is calculated from the value registered by the first cell, the total hemoglobin from that given by the second cell. From the ratio of these values the oxygen saturation is estimated.

The quantity of oxygen or of carbon dioxide contained in a given sample of blood (*oxygen or carbon dioxide content*) is determined by transferring the sample to a blood gas apparatus (Haldan or Van Slyke) and then freeing all the oxygen from the hemoglobin by the addition of potassium ferricyanide, or all carbon dioxide from combination by the addition of acid. Precaution must be taken not to permit the sample to come in contact with air. Since the cell wall is not freely permeable to $K_2Fe(CN)_6$, the corpuscles should be first lysed by ammonia or saponin solution. Haldane showed that all the oxygen in blood is liberated by this procedure and the oxyhemoglobin is turned into methemoglobin (p. 57). The *oxygen capacity* of a sample of blood is calculated by exposing it to air or oxygen and determining the amount which it then contains, that is when the hemoglobin is completely saturated. The ratio of oxygen content to oxygen capacity $\times 100$ gives the percentage saturation of the blood with oxygen. Since the quantity of oxygen (1.34 cc.) which will combine with 1 gram of hemoglobin is known, the hemoglobin content of a specimen of blood

may be calculated from the quantity of O_2 in the blood when fully saturated, i.e., from its oxygen capacity. For example, if a sample of blood has an

oxygen capacity of 10 volumes per cent, its hemoglobin content is $(10/1.34 =) 7.5$ grams per cent or about 50 per cent of the normal

The Transport and Delivery of Oxygen to the Tissues

The small amount of oxygen in simple solution (about 1 per cent of the total) is negligible when one considers the oxygen requirements of the tissues even during rest (250 cc per minute). If the blood could hold no more than this it would be necessary for some 120 liters to circulate through the tissues each minute, even assuming that all the oxygen were given up during each circulation. Nevertheless, the gas in simple solution is of the utmost importance since it is in equilibrium with the alveolar air on the one hand and on the other determines the quantity of oxygen which shall be held in combination with the hemoglobin. This will be made clear from a study of the oxygen dissociation curve for hemoglobin.

The Dissociation Curve of Hemoglobin

Oxygen enters into chemical combination with the iron of the hemoglobin molecule (see ch. 6) to form *oxyhemoglobin*. Each atom of the metal unites with two atoms of oxygen. The remarkable feature of the union of oxygen with hemoglobin is the readiness with which the gas is released from combination when its tension in the surrounding medium is reduced. Hemoglobin from which the oxygen has dissociated is called *reduced hemoglobin*. The relationship between the partial pressure of oxygen and the percentage saturation of the hemoglobin with the gas—i.e., the proportion of oxyhemoglobin to reduced hemoglobin—can be shown in the form of a curve—the *oxygen dissociation curve of hemoglobin*. The curve for a solution of hemoglobin in distilled water is obtained in the following manner. Several samples of the hemoglobin solution are placed each in a separate closed vessel known as a tonometer (fig. 29.2). The respective samples are then exposed to known oxygen tensions 0, 10, 20, 40 and 100 mm Hg. The tonometers are rotated continuously in a water bath at body temperature. The solution is thus spread out as a thin film over the interior surface of the vessel. After equilibrium has been attained, the proportion of oxy to reduced hemoglobin is determined. When 100 per cent saturated—that is, when the hemoglobin has taken up oxygen to its full capacity—the solution contains about 20 volumes per cent of oxygen. When a quarter or half saturated it therefore contains 5 or 10 volumes respectively. The results are plotted on a chart with the oxygen tensions along the

abscissae and the percentage saturation along the ordinates as shown in figure 29.3

Huffner obtained such a curve for hemoglobin from calculations based upon the law of mass action (see below).

If the foregoing procedures are carried out with blood instead of with a hemoglobin solution a different type of curve is obtained as shown in figure 29.4. It is S-shaped.

The dependence of the oxygen saturation of hemoglobin in an aqueous solution upon the partial pressure of the gas is in accordance with the law of mass action which states that "the velocity of chemical change is proportional to the product of the concentrations of the reacting substances." In this case the reacting substances are reduced hemoglobin and oxygen. The reaction is reversible and is represented thus

It is evident that in the foregoing procedures the tension of oxygen in the hemoglobin solution, or in the plasma in the case of whole blood, came into equilibrium with the oxygen pressure of the atmosphere introduced into the tonometer. Then, the concentration of the dissolved oxygen must be proportional to the partial pressure of the gas to which the solution was exposed. So, if C_a = concentration of O_2 , C_R = concentration of reduced hemoglobin and C_H = concentration of oxyhemoglobin, then the velocity of the reaction of Hb with O_2 to form HbO_2 will be proportional to the product of C_a and C_R multiplied by

FIG. 29.2 Series of tonometers. The numbers denote the pressure of oxygen in mm. (After Barcroft.)

FIG. 29.3 Oxygen dissociation curve of a solution of pure hemoglobin (After Barcroft)

FIG. 29.4 Composite curve to show the degree of variation in the oxygen dissociation curve of human blood as determined upon a number of persons. In each case the blood was exposed to an atmosphere containing the same percentage of CO_2 as that of the alveolar air of the individual examined. Ordinates, percentage saturation, abscissae, oxygen pressure (After Barcroft)

a constant k , and the reverse reaction, the dissociation of oxyhemoglobin (HbO_2) to reduce hemoglobin (Hb) and oxygen, will be proportional to C_n multiplied by another constant k_1 . Thus

$$k(C_s \times C_R) = k_1(C_n)$$

At any given tension of oxygen in the opposed reactions, the formation of oxyhemoglobin and its dissociation proceed simultaneously until equilibrium becomes established. A simple reaction of this nature will explain the dissociation curve of a hemoglobin solution but the S-shaped curve of blood is thought to be due to a series of reactions

It will be recalled that natural hemoglobin has a molecular weight (about 64,000) four times greater than was previously supposed. It may therefore be given the symbol Hb_4 . It is thought that each molecule of hemoglobin combines with four molecules of oxygen, $\text{Hb}_4 + 4\text{O}_2 \rightarrow \text{Hb}_4\text{O}_8$. The oxygen dissociation curve calculated by the application of the law of mass action to this equation has a more pronounced S shape than any actually observed for blood. On the other hand, the curve calculated from the equation $\text{Hb}_4 + \text{O}_2$ is hyperbolic (fig. 29.3). It is believed, therefore, that in the combination of oxygen with hemoglobin under physiological conditions, four separate but simultaneous reactions take place

The combination of all these reactions, it has been suggested, is responsible for the special S-shape of the oxygen dissociation curve (figs. 29.4 and 29.5).

Certain features associated with the shape of the dissociation curve of whole blood as shown in figure 29.4 are of the utmost physiological importance. It will be seen that with the partial pressure of oxygen in arterial blood (97 mm Hg) the hemoglobin is already nearly (93 per cent) saturated with the gas. Exposing the hemoglobin to a higher oxygen tension, therefore,

FIG. 29.5 Dissociation curves of human blood, exposed to 0, 3, 20, 40 and 90 mm CO_2 . Ordinates, percentage saturation. Abscissae, oxygen pressure (After Barcroft)

will cause a negligible increase in the total quantity of oxygen taken up by the blood, and to gain even the ultimate 2 or 3 per cent the oxygen pressure would require to be raised to over 300 mm Hg. The flattening out of the upper part of the curve means that relatively little reduction in the percentage saturation of the hemoglobin occurs until the oxygen pressure falls to about half its normal value. At pressures above 60 mm Hg relatively wide variations in alveolar oxygen pressure can occur with minimal changes in the total oxygen load of the blood. At an oxygen tension of 70 mm Hg the hemoglobin is still about 90 per cent saturated. The slope of the lower part of the curve is such that a given fall in oxygen pressure causes a much greater desaturation of the hemoglobin. The behavior of hemoglobin as indicated by the shape of the curve therefore favors a nearly maximum uptake of oxygen in the lungs so long as the oxygen pressure is above 80 mm Hg and a rapid release of the gas at the lower oxygen pressures which prevail in the tissues (1 mm or less to 60 mm Hg). It will be realized from a glance at the hyperbolic curve shown in figure 29.3 how unsuitable hemoglobin would be as a carrier of oxygen if it behaved in the manner indicated by such a curve. The hemoglobin would show a great avidity for oxygen in the lungs but would not yield up its oxygen load until the partial pressure in the tissues had fallen to a very low level. At the pressures which exist in the tissues the rate of dissociation of oxyhemoglobin would be many times slower than the rate of its formation. Hemoglobin would thus be worthless as an oxygen carrier. As it is the oxygenation of hemoglobin in the lungs and its reduction in the tissues proceed at practically equal rates

The Effects of Reaction and of Temperature upon the Shape of the Oxygen Dissociation Curve

A change in the reaction of the blood toward the acid side causes the dissociation curve to flatten toward the right, i.e., the affinity of hemoglobin for oxygen is reduced. Carbon dioxide and lactic acid liberated during tissue activity will exert this effect. The influence exerted by CO_2 was discovered by Bohr and is usually referred to as the Bohr effect⁴ (see fig. 29.5).

⁴The oxygen dissociation curve of hemoglobin is so sensitive to acid that it has been used by Barcroft and his associates as a basis of a method for measuring changes in blood reaction. A shift of the curve to the right i.e. when the blood absorbs less oxygen at a given O_2 pressure would

FIG. 29.6. Oxygen dissociation curves of goats blood fetal two curves on left maternal two curves on right. Bended lines about 10th week of pregnancy interrupted lines about 18th week (Drawn from data of Barcroft and associates.)

Temperature exerts a similar effect upon the dissociation curve. These agencies therefore, cause the hemoglobin to liberate its oxygen more readily at the lower oxygen tensions but exert little effect upon the uptake of oxygen at the higher tensions. They cause the reactions involved in the breakdown of oxyhemoglobin to be speeded up, the equilibria shown on page 456 being shifted to the left. Alkalies and a fall in temperature will of course have the reverse effect.

The oxygen dissociation curve of fetal hemoglobin differs from that of postnatal hemoglobin in being steeper as shown in figure 29.6, that is, at a given oxygen tension it takes up more oxygen than does adult blood. Yet since the passage of oxygen from mother to fetus is simply a matter of diffusion the tension of oxygen in the blood of the umbilical vein is the same as that in the maternal venous blood of the placenta

indicate an increase in H^+ ion concentration and a shift to the left the reverse change

As gestation proceeds the fetal curve moves farther to the left and due to increased H ion concentration the maternal curve moves to ward the right (See Fetal Circulation p 521)

The Unloading of Oxygen in the Tissues

It is now possible to give a summary of the manner in which oxygen is taken up from the lungs by the blood and supplied to the tissues. The absorption of oxygen from the alveolar air is the result simply of diffusion. The oxygen tension in the arterial blood is lower (never higher) than that of the alveolar air. This is so even at high altitudes where the alveolar oxygen tension is greatly reduced (ch 33). There is no reason therefore to believe that the pulmonary epithelium actually secretes oxygen into the blood.⁵ The percentage saturation of the hemoglobin is dependent upon the oxygen tension of the blood i.e. the amount of the gas in simple solution which as just mentioned is governed in turn by the oxygen pressure in the alveolar air. We have seen that the hemoglobin in the blood leaving the lungs is about 98 per cent in the form of oxyhemoglobin (i.e. it is 98 per cent saturated with oxygen).

Practically no oxygen is lost from the arterial blood until the capillaries have been reached so the blood reaches the periphery with a high pressure head of oxygen. The oxygen tension of the tissue fluids and cells is relatively low but varies with the functional activity at the moment between 1 and 60 mm Hg. a flow of oxygen from the plasma across the capillary membrane results. This of course will tend to lower the oxygen tension of the capillary blood plasma and upset the equilibrium between it and the oxyhemoglobin. Dissociation of the latter occurs to sustain the partial pressure of the plasma oxygen. In other words a steady flow of oxygen from red cell to tissue cell is maintained as a result of the slope in partial pressure of the gas. The rise in temperature and liberation of carbon dioxide and lactic acid in the tissues as we have seen shifts the oxygen dissociation curve to the right and so accelerates the decomposition of the oxyhemoglobin.

Coefficient of Oxygen Utilization

Depending upon the particular tissue and its activity at the moment the blood in its passage

⁵ The view that the pulmonary epithelium does not always play the role of a passive membrane but is capable of actively secreting oxygen into the arterial blood was advanced by Bohr and later elaborated by Haldane.

through the capillaries loses from a fifth to nearly all of its oxygen load. The mixed blood coming to the lungs i.e. blood from all organs of the body, during rest is somewhat more than 75 per cent saturated with oxygen containing about 4.5 volumes per cent less than does the arterial blood. The figure used to express the proportion of the total oxygen content of the blood which is given up to the tissue is called the *coefficient of oxygen utilization*. Thus if the oxygen content of the arterial blood is 19.5 volumes per cent and that of the venous blood 15 volumes per cent (i.e. an arteriovenous oxygen difference of 4.5 volumes per cent) the coefficient is $[(4.5)/(19.5)] = 0.23$. As indicated above the coefficient varies considerably for different tissues and for the same tissue in accordance with the degree of its activity.

THE RESPIRATORY QUOTIENT

The ratio of the volume of carbon dioxide produced by a tissue to the volume of oxygen absorbed

$$\frac{\text{Volumes CO}_2 \text{ produced}}{\text{Volumes O}_2 \text{ absorbed}}$$

is called the respiratory quotient of that particular tissue. The ratio of these volumes as determined from the expired air will be the respiratory quotient of the body as a whole.

The Manner in Which the Call of the Tissues for Oxygen is Met

Increased activity of any tissue always entails an increased oxygen consumption which may be several times the resting value. Increase in the oxygen supply to the tissue above its requirement on the other hand does not increase the oxygen usage. The tissue takes what oxygen its activity at the moment demands but no more.

There are two ways in which a greater demand of the tissues for oxygen may be met. By (1) increasing the total blood flow through the tissue and maintaining a high intracapillary oxygen pressure and (2) raising the coefficient of oxygen utilization i.e. increasing the quantity of oxygen abstracted from a given volume of blood.

Both these factors come into play but the extent to which each operates is not the same for different tissues. The coefficient of oxygen utilization is increased by establishing a steep oxygen pressure gradient between the plasma within the capillaries and the tissue cells. That is the quantity of oxygen used (Q) with other things being

equal, be proportional to the difference in intra capillary and intracellular pressures (P_c and P_t respectively), thus

$$Q \propto P_c - P_t$$

The pressure gradient of oxygen from blood to tissue cells acts in a sense as a force to drive oxygen through the tissues. The farther the cells are from the source of supply—the blood—the lower the oxygen pressure will be and the less oxygen will they receive. During activity or any pronounced fall in oxygen tension of the blood, the cells most distant from the source of supply may suffer anoxia unless more capillaries open up, and thus reduce the radius along which oxygen diffuses. Some tissues, however, such as cardiac muscle, take up oxygen at a pressure as low as 5 mm Hg (Keilin). An increase in the pressure gradient is brought about, (a) by the action of acids (carbonic and lactic) and a rise in temperature both of which accelerate the decomposition of oxyhemoglobin and so maintain a high intracapillary oxygen pressure, (b) by lowering the oxygen tension within the tissue cells, and (c) by shortening the distance through which the oxygen must diffuse, i.e., by opening up more capillaries and so reducing the radius of the cylinder of tissue supplied by each capillary.

During activity more oxygen is consumed and the oxygen tension in the tissues tends to fall, thus increasing the pressure gradient from blood to tissue cells.

The Carriage of Carbon Dioxide by the Blood

Dr. PROSSER J. H. W. FENNELL

The total carbon dioxide content of blood means the amount of CO_2 which can be extracted from a given volume of blood by exposure to a vacuum after the addition of acid. The results are usually expressed as volumes per cent (v p c) by which is meant cc of CO_2 (measured at STP) per 100 cc of blood. The methods of Van Slyke and his coworkers are now most commonly used for the measurement of CO_2 in blood and other fluids. In Van Slyke's manometric apparatus a known volume of blood is acidified and subjected to a partial vacuum in which CO_2 and other gases are rapidly extracted. The gases are then compressed to a known volume and their pressure measured. The CO_2 is removed by introducing NaOH , and the pressure at the same volume is again measured. From the change in pressure the amount of CO_2 can be calculated. By such a method then, it is found that human blood normally contains 50 to 60 v p c of CO_2 , the venous

As mentioned above, during arduous work the coefficient of oxygen utilization is much increased, and, since the blood flow through the muscles is greatly increased, as well, the oxygen supply to the contracting muscles is augmented several fold. In man the oxygen consumption of the muscles may actually be increased by from twenty to thirty times or in an athlete even fifty times. The increase in oxygen consumption is brought about in part by the removal of more oxygen from each unit of blood.

The circulation rate (ch 25) in man may increase tenfold or more during muscular exercise. It is certain however, that there is also a redistribution of the blood, that is a greater proportion of the total blood volume is driven through the muscles than during rest. The actual blood flow through the active muscles may, for this reason, be twenty times or more greater than the flow during rest. Nevertheless, though the red cell has a shorter stay in the capillary it unloads more of its oxygen, as indicated by the increase in the coefficient of oxygen utilization. The actual speed of the red cell through the capillary is not, however, as great as might be thought from the increased volume of blood flowing through the muscles, for the opening up of more capillary channels and the consequent increase in the total cross section of the blood stream tends to prevent excessive acceleration of the red cell's passage.

blood actually containing 5 to 10 v p c more than the arterial.

It was first shown by Pflüger (1864) that, if whole blood were very thoroughly evacuated, all the CO_2 could be removed without the addition of acid. On the other hand, all the CO_2 in plasma could not be removed by vacuum alone. After very thorough evacuation the addition of acid or of red blood corpuscles allowed the liberation of more CO_2 . These facts suggested that, in plasma, CO_2 is present mainly as bicarbonate, for on exposure to a vacuum NaHCO_3 loses a part of its CO_2 according to the equation,

To liberate the CO_2 in Na_2CO_3 it is necessary to add acid. These results suggested, too, that the red cells contain something which can act as an acid.

* At a given temperature (H_2CO_3) is a constant fraction of the dissolved CO_2 , and hence does not require separate representation in the formula.

Solubility of CO₂ in physiological fluids at body temperature

Fluid	Absorption Coefficient ²
Water	0.545
Plasma	0.510
Red cells	0.44
Whole blood	0.48

The amount of dissolved CO₂ in blood can be calculated from its solubility coefficient in blood (table 29 6), when the pressure of carbon dioxide with which the blood is in equilibrium is known (p CO₂). The dissolved CO₂ consists in part of carbonic acid (H₂CO₃). Although the actual amount of H₂CO₃ is extremely small (being only about 0.1 per cent of the dissolved CO₂) it is of great importance. When H₂CO₃ enters the blood which is a slightly alkaline solution, it combines with base to form bicarbonate (BHCO₃) until an equilibrium is reached between the three forms of CO₂:

The relative amounts of these three forms at equilibrium depend upon the pH of the solution and can be calculated from the Henderson Hasselbalch equation

$$(C) \quad \text{pH} = \text{pK}_1 + \log \frac{(\text{BHCO}_3)}{(\text{CO}_2) \text{ dissolved}^2}$$

pK₁ is a composite constant which in normal plasma has a value of about 6.1. The pH of plasma is normally about 7.4. Hence we may write

$$(D) \quad 7.4 = 6.1 + \log \frac{\text{Bicarbonate CO}_2}{\text{Dissolved CO}_2}$$

or

$$\frac{\text{Bicarbonate CO}_2}{\text{Dissolved CO}_2} = \frac{20}{1}$$

If the pH of the plasma is abnormal this ratio will, of course, be different.

The interior of the red cell is more acid than the plasma. Consequently, the ratio of bicarbonate to dissolved CO₂ will be smaller. Further more, since the water content of the red cell is less than that of plasma, the amount of dissolved CO₂ will be less too. For these two reasons then,

² Cubic centimeters CO₂ (measured at STP) dissolved in 1 cc fluid at a pressure of CO₂ of 760 mm Hg

at the same tension of CO₂, the cell contains less total carbon dioxide than the plasma. Yet, as we shall soon see, the red cells play the dominant role in the transport of carbon dioxide.

THE ROLE OF HEMOGLOBIN IN CARBON DIOXIDE TRANSPORT

When carbon dioxide enters the blood from the tissues it combines with water to form H₂CO₃. This reaction is relatively slow in most solutions with a pH close to neutrality. In the blood, however, the reaction is catalyzed by an enzyme carbonic anhydrase, which is found in the red cell but not in the plasma. The H₂CO₃ is thus formed within the cells. Nearly all of the H₂CO₃ thus formed then combines with base to form bicarbonate. The base available for combination is that which is already combined with weaker acids, mainly proteins, which are displaced by carbonic acid according to the equation,

Hemoglobin is used as the example in this equation because it does, in fact, furnish directly and indirectly, the greater part of the base used. It does so for a number of reasons. In the first place, it comprises about three quarters of the total protein in blood. Secondly, it holds in combination an even greater proportion of the base held by weak acids in the blood, because it has so many weak acid groups in its molecule. Thirdly, it has the remarkable property of changing its acid strength with its degree of oxygenation. When the blood is in the tissues, it loses its oxygen, and the hemoglobin becomes a weaker acid and able to yield more base to carbonic acid. *In the lungs the hemoglobin is oxygenated and becomes a stronger acid.* This assists in displacing carbonic acid from combination with base and in turning it out of the blood. Figure 29 7 shows the titration curves of oxyhemoglobin and hemoglobin. It will be seen that at the same pH oxyhemoglobin is combined with more base than is hemoglobin, i.e., oxyhemoglobin is the stronger acid.

That hemoglobin behaved in this peculiar way was first suggested by Christiansen, Douglas and Haldane (1914), who investigated the carbon dioxide dissociation curve of reduced and oxygenated whole blood. As in the construction of an oxygen dissociation curve, samples of oxygenated or reduced whole blood are brought into equilibrium in a series of saturating vessels called tonometers, with different pressures of

CO_2 . The CO_2 contents of the equilibrated bloods are then determined by analysis and plotted against the corresponding gas tensions. Christiansen, Douglas, and Haldane found that the curve for oxygenated blood was lower than that for reduced blood. In other words reduced blood could carry more CO_2 at the same tension of CO_2 than oxygenated blood (fig. 298). For many years it was thought that this phenomenon was due entirely to the change in acid strength of hemoglobin on oxygenation. Reduced hemoglobin being a weaker acid would yield more base to carbonic acid and hence, at equal pressures of CO_2 , more bicarbonate would be formed. It now appears however that 50 per cent or more of this greater CO_2 -combining power of reduced blood is due to the greater power of reduced hemoglobin to combine directly with CO_2 .

Leaving aside the question of how the greater CO_2 -combining power of reduced blood is effected let us consider the physiological importance of the phenomenon. By examining figure 298 it will be seen that if the blood represented by point A on the curve took up 5 v p c of CO_2 , from the tissues and no reduction of the hemoglobin occurred the tension of CO_2 in the blood would rise by about 14 mm Hg. If however, about 6 v p c of O are lost from the capillary

FIG. 297. Curves to show the amounts of base (in equiv. valents) bound by oxygenated and reduced hemoglobin at varying pH. The slopes of the curves represent the buffer values in terms of the equivalent of base required to cause unit pH increase (from Peters and Van Slyke, *Quantitative Clinical Chemistry*, Vol. 1, 1932, from data of Hastings, Van Slyke, Neill, Heidelberger and Harrington).

FIG. 298. Carbon dioxide dissociation curves of fully reduced human blood (upper solid line) in presence of hydrogen and fully oxygenated human blood (lower solid line) in presence of air. Volumes of CO_2 along the ordinates. CO_2 tension along the abscissae. Line A-V is the so-called physiological dissociation curve of CO_2 , i.e. as a result of the reduction of hemoglobin the relation of volumes of CO_2 to CO_2 tension is indicated at points along this line and not along the lower curve for oxygenated blood. At 1 (arterial point) are indicated the volume and tension of CO_2 in arterial blood. Point B indicates the conditions in fully reduced blood. Point V (venous point) represents the degree of reduction of hemoglobin which normally occurs in the body during the passage of the blood through the systemic capillaries. The position of the line A-V varies with the respiratory quotient moving to the right or left respectively with a rise or fall in the R.Q. Its position in the figure corresponds to a respiratory quotient of about 0.8. The interrupted line below is the CO_2 dissociation curve for oxygenated dog's blood (Modified from Christiansen, Douglas and Haldane).

blood (as indicated by point V) the extra CO_2 can be taken on with a rise of only 7 mm Hg in the CO_2 tension. As the change in CO_2 tension is minimized so too is the change in the pH of the plasma because at the lower pressure of CO_2 less free carbonic acid is present. In the lungs the reverse reactions occur. Here oxygenation of the hemoglobin reduces the CO_2 -combining power of the blood and a smaller fall in CO_2 pressure is effective in removing the excess CO_2 .

The dominant role of the red cells in CO_2 transport can be further demonstrated by contrasting the CO_2 dissociation curves of separated plasma and true plasma. The latter is constructed by exposing whole blood to different pressures

FIG. 29.9 Comparison between the CO_2 dissociation curves of blood and of separated and true plasma from the same blood (After Evans, redrawn from data by Joffe and Poulton)

of CO_2 and then separating the plasma and analyzing it for CO_2 , the former by equilibrating plasma in the absence of red cells (fig. 29.9)

It is apparent that the curve for *separated* plasma is much flatter than that of *true* plasma which signifies that much larger changes in CO_2 pressure and pH accompany a given change in CO_2 content in *separated* plasma. Evidently separated plasma is not as well buffered as true plasma. The greater buffer power of true plasma must be due to the red cells. We know, however, that base ions, e.g., K^+ and Na^+ cannot pass from the red cell into the plasma, because the red cell membrane is impermeable to cations with the exception of H^+ . Consequently, the red cells must increase the buffer power of the plasma indirectly. They do so by means of the chloride shift or Hamburger phenomenon.

If CO_2 is added to whole blood and the corpuscles and plasma are analyzed separately, it will be found that

- (1) The bicarbonate content of both plasma and corpuscles has increased
- (2) The chloride content of the corpuscles has increased
- (3) The chloride content of the plasma has decreased
- (4) The metallic cation content of the corpuscles and plasma has not changed
- (5) The water content and volume of the corpuscles has increased

The reverse changes occur when CO_2 is removed from blood by evacuation. Evidently, there is a transfer of the chloride from plasma to cells when CO_2 enters the blood, and the reverse process when CO_2 leaves the blood, hence the name, chloride shift. A simple qualitative ex-

planation of this phenomenon can be given. When CO_2 enters the blood, more HCO_3^- is formed in the corpuscles than in the plasma, because they contain more available base for neutralizing H_2CO_3 . These excess HCO_3^- ions tend to diffuse out into the plasma, but, owing to the electrostatic attraction of the cations within the cells, can only do so if an equal number of Cl^- ions enter to take their place. Thus HCO_3^- from the cells enters the plasma in exchange for Cl^- which enters the corpuscles. This process will continue until an equilibrium is reached which has been found to agree (very nearly) with the distribution required by Donnan's theory of membrane equilibria (p.) This requires the following relations *

$$(F) \quad \frac{[\text{H}^+]}{\text{cells}} \times \frac{[\text{Cl}^-]}{\text{cells}} = \frac{[\text{H}^+]}{\text{plasma}} \times \frac{[\text{Cl}^-]}{\text{plasma}}$$

$$\frac{[\text{H}^+]}{\text{cells}} \times \frac{[\text{HCO}_3^-]}{\text{cells}} = \frac{[\text{H}^+]}{\text{plasma}} \times \frac{[\text{HCO}_3^-]}{\text{plasma}}$$

or

$$\frac{[\text{H}^+]}{\text{plasma}} = \frac{[\text{Cl}^-]}{[\text{HCO}_3^-]} \times \frac{[\text{HCO}_3^-]}{\text{cells}} = \frac{[\text{HCO}_3^-]}{[\text{Cl}^-]} \times \frac{[\text{H}^+]}{\text{cells}}$$

The phenomenon can, in fact, be explained very precisely in terms of the Donnan theory. When CO_2 enters the blood the ratio $(\text{HCO}_3^-)_{\text{cells}} / (\text{HCO}_3^-)_{\text{plasma}}$ increases because more base is available in the cells. Similarly because the buffer power of plasma is less than that of the cells $(\text{H}^+)_{\text{plasma}} / (\text{H}^+)_{\text{cells}}$ increases. The Cl^- of the plasma must now pass into the cells in exchange for HCO_3^- until the ratios are again equalized at a new level. Since the new ratio is a higher one, the number of osmotically active particles in the cells must now be higher than in the plasma. Consequently, water enters the corpuscles to equalize the osmotic pressures of the corpuscles and plasma and the volume of the corpuscles increases. If stasis of blood occurs during the withdrawal of blood from a vein, an abnormal amount of CO_2 may accumulate and the relative volumes of corpuscles and plasma may be appreciably altered. Hence stasis is undesirable when the blood is required for purposes where the relative volumes of corpuscles and plasma must be measured, e.g., in the estimation of blood volume.

* In applying the Donnan equilibrium to the red cell, the only cation which can be regarded as diffusible through the red cell membrane is the H^+ ion.

THE EVOLUTION OF CARBON DIOXIDE IN THE LUNGS

The pressure of CO_2 in the alveoli is kept by respiratory activity at a lower level than it is in venous blood, hence CO_2 diffuses from the blood into the alveoli. This disturbs the equilibrium between the three forms of CO_2 and causes reactions to proceed in the direction indicated below

It has been known for a long time that the reaction $\text{H}_2\text{CO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O}$ is inherently a slow one. It is known too that the blood spends only about one second in the capillaries of the lung and about the same time in the capillaries of most tissues. The velocity constants of these reactions in solutions other than blood are known too, and it can be calculated that if blood had not certain peculiar properties, the time which it spends in the lungs would scarcely allow the escape of 10 per cent of the CO_2 which we know does escape. Rapid loading and unloading of CO_2 by the blood is accomplished in two ways. The first, which has been mentioned already, is the action of the enzyme, carbonic anhydrase, which accelerates enormously, in either direction, the reversible reaction $\text{H}_2\text{CO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O}$. As the carbonic anhydrase of the blood is found only in the red cells and not in the plasma, we may deduce that the rapid changes in CO_2 content occur primarily in the red cells while the plasma comes more slowly into equilibrium with the cells, perhaps after the blood has left the capillaries.

Carbonic anhydrase is present in a number of other animal tissues besides the erythrocytes, e.g., in gastric mucosa and the mucosa of the small intestine as well as in the renal cortex, pancreas, lens and retina, brain, spleen, red muscle, liver, testes, in the oviducts of hens, where its function appears to be concerned in the deposition of calcium in the eggshell, and in saliva. Its physiological significance in most of these situations is unknown. Carbonic anhydrase is a protein, and zinc, as shown by Keilin and Mann, is an important constituent of its molecule. The action of the enzyme is destroyed by an inhibitor in plasma, which has been identified as a pseudoglobulin. It is also inhibited by sulfanilamide, cyanide, sulfocyanate, and by heavy metals. Different sulfonamide drugs differ in their ability to inhibit carbonic anhydrase. The

ones most commonly used therapeutically are weak inhibitors of this enzyme. Some, however, have been developed for this special purpose, such as, acetazolamide (Diamox). It is used particularly as a diuretic in cardiac failure. It acts on the kidney to increase the excretion of sodium and potassium, an action which seems to depend on the inhibition of carbonic anhydrase.

The other mechanism for the rapid combination and dissociation of CO_2 in blood is the direct combination of CO_2 with hemoglobin. This reaction does not go through the stage of carbonic acid and is very rapid. For many years past the existence of such a compound has been generally denied. It is now accepted however. About 25 per cent of the CO_2 liberated in the lungs under normal resting conditions is carried in the blood in direct combination with hemoglobin. Nevertheless, the total amount of CO_2 in the blood combined in this way is small, probably it never amounts to more than from 8 to 10 per cent of the total CO_2 . But the fact that reduced hemoglobin combines with more CO_2 than does oxyhemoglobin gives the compound an enhanced importance in the transport of CO_2 , it accounts for from 20 to 25 per cent of the gas freed in the lungs.

Carbon dioxide does not combine with the hemoglobin molecule in the same way that O_2 and CO do. It apparently combines with an NH_2 group to form a so-called carbamino acid. Hence, one name suggested for this compound is hemoglobocarbamate acid (HbNHCOOH). Another name less descriptive but possessing the virtue of brevity is carbhemoglobin.

Carbamino compounds of CO_2 with amino acids are well known and the technique of estimating these simpler compounds has been adapted for determining carbhemoglobin. Other forms of combined CO_2 , such as NaHCO_3 , can be precipitated as BaCO_3 by the addition of alkaline BaCl_2 . The barium salts of the carbamino acids are soluble and remain in the supernatant fluid after centrifuging. The affinity of Hb for CO_2 diminishes with pH, and with strong acidification all the CO_2 dissociates off. Consequently, the Van Slyke technique for estimating total CO_2 can be applied to the supernatant fluid to measure the carbhemoglobin.

An increase in the CO_2 pressure of the blood should, *per se*, cause the formation of a greater amount of carbhemoglobin, but since an increase in CO_2 pressure is always accompanied by an increased acidity, which lowers the affinity of

FIG. 29.10 Upper curves showing the proportions of the difference in CO_2 capacity of reduced and of oxyhemoglobin which is due to the higher carbamino content of reduced hemoglobin. The shaded area represents the proportion due to carbamino CO_2 . Lower curves showing the negligible effect of a rise in CO_2 tension upon the carbhemoglobin content of blood. (After Ferguson and Roughton modified.)

Hb for CO_2 variations in CO_2 pressure over physiological ranges have actually little effect on the carbhemoglobin content of the blood. That is to say the dissociation curve of carbhemoglobin is practically flat over physiological ranges of CO_2 pressure. The main factor of physiological importance in displacing CO_2 from Hb is oxygenation of the Hb (fig. 29.10).

SUMMARY

About 5 per cent of the total CO_2 in blood is physically dissolved. Two to ten per cent depending on the degree of oxygenation of the hemoglobin is combined directly with hemoglobin (carbhemoglobin). The remainder is present as bicarbonate and as such is combined with base which has been yielded to H_2CO_3 by the weak acids of the blood, the most important of these is hemoglobin.

The CO_2 -combining power of reduced blood is greater than that of oxygenated blood (1) because reduced hemoglobin is a weaker acid than oxyhemoglobin and (2) because reduced hemoglobin can combine directly with more CO_2 to form carbhemoglobin than can oxygenated hemoglobin.

Base yielded by hemoglobin participates in directly in the carriage of CO_2 by the plasma by means of the *chloride shift*. Base within the cells neutralizes the Cl^- ions which enter the red cells thereby leaving base in the plasma free to neutralize HCO_3^- ions.

As the blood passes through the lungs it loses a small part of its total CO_2 (i.e. about 10 per cent). The elimination of CO_2 is accomplished with minimal change in pH and in CO_2 tension by the concurrent oxygenation of the blood which decreases the CO_2 -combining power of the blood in the two ways mentioned above.

The transfer of CO_2 to and from the blood while it is in the capillaries can be accomplished

FIG. 29.11 Showing main processes occurring in the blood during the output of carbon dioxide and uptake of oxygen in the lung (after Roughton).

in less than one second, because (1) carbonic anhydrase catalyzes the slow reaction $\text{H}_2\text{CO}_3 \rightleftharpoons \text{CO}_2 + \text{H}_2\text{O}$ and (2) because the formation and dissociation of carbohemoglobin is inherently rapid (fig 29 11)

THE MECHANICS OF BREATHING

PHYSIOLOGICAL ANATOMY

Air entering through the nasal openings is warmed, and some of the grosser impurities are retained by the fine hairs around the nostrils and by the mucous secretion. The nasal cavity just within the external nares (vestibule) is lined with skin. The remaining parts of the nasal cavities are lined with mucous membrane which is covered by a layer of ciliated columnar epithelial cells and scattered "goblet" cells, it is continuous with the membrane lining the accessory nasal sinuses. The nasal lining is very vascular, it contains a venous plexus whose channels anastomose freely and give the mucosa an appearance suggestive of erectile tissue. The vascular channels are dilated by several conditions, e.g., infections, local irritants, certain anaphylactoid states and a rise in temperature of the inspired air or of the environment, or by local heating of the skin, the mucosa swells and the airway is narrowed in consequence. Cooling the inspired air or skin causes vasoconstriction, as will also the application of adrenaline or epbedrine to the mucosa. The vascularity of the mucosa is also influenced reflexly by the application of heat or cold to the skin of remote regions of the body. The pharynx is, of course, a common pathway for food and air. As the food passes the laryngeal opening this is closed by reflex action and respiration is inhibited. The surface epithelium of the nasal part of the pharynx is provided with cilia and goblet cells. In the oral part of the pharynx the epithelium is of the stratified squamous type. The epithelium of the bronchial tree presents very definite changes as one proceeds from the larynx to the terminal bronchioles. The stratified squamous covering of the upper part of the larynx changes to ciliated in the lower part of the vestibule of this organ. The vocal cords are covered with squamous epithelium, but ciliated cells again line the trachea. The epithelium of the trachea contains also goblet cells and mucous and serous glands. The large bronchioles are similar to the trachea in this respect, but in the bronchioles the goblet cells and deep glands are lost.

CILIA. The nasal secretions are moved toward the nostrils largely by the action of cilia. The sinuses are kept clear, under normal conditions, by the beating action of the cilia with which the epithelium is very plentifully supplied. As stated

above, ciliated cells are found in the nasal part of the pharynx, in the lower part of the vestibule of the larynx and in the trachea. The cilia beat with a motion which propels material toward the mouth. They become even more abundant when the large bronchioles are reached, but are largely replaced by cuboidal or flattened cells in the respiratory bronchioles.

The efficiency of the ciliated cells of the trachea and large bronchioles in propelling mucus and waste material orally is, under normal conditions, of a high order. The cilia are not influenced by nerve impulses, but are very susceptible to chemical changes in the blood and to substances applied locally. Certain general anesthetics depress their activity and many sedatives exert the same effect. Ciliary action is depressed by cold and increased when the temperature of the cells is raised slightly above normal. The efficiency of the cilia depends in part on the viscosity and stickiness of the material which is in contact with them. Their effectiveness may be varied by changing the properties of this material as well as by an increase or decrease in the rate or force of their beating. The motion of the cilia is wavelike and has been well compared to the undulation of a field of windswept grain. The individual cilium moves, in the direction in which its force is exerted with a whiplike motion and then relatively slowly returns to its former position.

ELASTIC TISSUE. The bronchial tree is rich in elastic tissue, most of the fibers being disposed longitudinally in the tunica propria. This elastic membrane, which extends throughout the trachea, bronchi and bronchioles to the alveoli, is responsible for the recoil of the bronchial tree during expiration and probably in large part for the recoil mechanism of the whole lung. In the larynx, cartilage supports the special structures necessary for the attachment of the vocal cords and the functioning of the glottis. The cartilaginous rings in the trachea are incomplete on their posterior aspect. This arrangement provides for some contraction of the trachea, but the lumen cannot be obliterated as is the case with the small bronchioles. The tracheal lumen is narrowed somewhat when it is elongated during inspiration.

MUSCLE. The ends of the cartilaginous rings of the trachea may be approximated by the action of

the transverse smooth muscle fibers. In the bronchi the bands of fibers tend to become circular and this is seen even more definitely in the bronchioles. The amount of muscle is reduced in the respiratory bronchiole and does not extend beyond this subdivision of the bronchial tree.

BLOOD SUPPLY The bronchial tree as far as and including the respiratory bronchioles, is supplied by a rich plexus of vessels derived from the bronchial arteries—branches of the thoracic aorta. The blood is collected by the bronchial veins which in the case of the right lung empty into the azygos vein. Those from the left lung are tributary to the left superior intercostal vein (or sometimes to the accessory hemiazygos vein), but a part of the blood brought to the lungs by the bronchial arteries is returned directly to the pulmonary veins and some, as mentioned below, enters the pulmonary vascular bed. The respiratory part of the lung receives its blood from the pulmonary artery, the blood being returned via the pulmonary veins to the left side of the heart. Anastomoses between the pulmonary and systemic systems of vessels occur, however, in the walls of the respiratory bronchioles so that the blood from this region of the bronchial tree is returned in part to the right side of the heart and in part to the left. Such anastomoses are more numerous in certain inflammatory pulmonary conditions and it has been thought possible that an abnormal increase in the amount of blood entering the pulmonary vascular bed through such channels might raise the pressure in the capillaries sufficiently to overbalance the colloid osmotic pressure of the plasma and lead to

pulmonary edema. It has been suggested that certain types of paroxysmal pulmonary edema may be produced in this way, as a result of reflex vasodilation of the anastomosing channels of the bronchial arteries. However, the greatest quantity of bronchial artery blood which enters the pulmonary system has been calculated to be not more than 1 per cent of the total pulmonary circulation even with maximal vasodilation. It appears unlikely that this would be sufficient to seriously alter the hydrostatic-osmotic balance in the pulmonary capillaries. Not quite all the blood of the pulmonary artery traverses the capillary bed of human lungs, a portion is shunted through arteriovenous anastomoses a fact which accounts for the passage of relatively large parasites through the lungs.

NERVE SUPPLY OF THE BRONCHIOLES Excitatory (bronchoconstrictor) fibers to the bronchiolar muscle are derived from the vagus and inhibitor (bronchodilator) fibers from the sympathetic. Afferent fibers from the lungs run in the vagus. The nerve supply to the pulmonary vessels is considered in ch. 23. The bronchioles are constricted by acetylcholine, pilocarpine, histamine and by certain foreign proteins (anaphylactic reactions). They are dilated by adrenaline, ephedrine and atropine (figs. 301 and 345 p. 518).

THE BRONCHIOLES AND AIR SACS Macklin divides the bronchial tree into two parts. The first part which extends from the trachea to the terminal bronchiole inclusive serves simply as an air conduit and like the branches and twigs of a tree possesses no respiratory function. The terminal bronchiole is simply the last of a series of subdivi-

FIG. 301. Guinea pig. Showing the bronchoconstrictor effect of stimulating the vagus of the same side. The effect lasts after stimulation has ceased. Atropine in moderate dose had a very slight dilator action. Adrenaline in small quantity caused marked bronchodilation. During this action further stimulation of the vagus had an almost negligible effect. (After Thornton.)

FIG. 30.2 Description in text

sions of these nonrespiratory bronchioles. The muscle in its wall is more highly developed than in any other part of the bronchial tree and when fully contracted exerts a sphincterlike action which can completely shut off the air supply to the air chambers beyond. The structures lying distal to the terminal bronchiole are the "leaves" of the bronchial tree. They are respiratory in function, i.e., an interchange of gases between lung air and blood occurs across their walls. This part consists of (a) the *respiratory bronchioles*, (b) *alveolar ducts*, (c) *alveolar sacs* and (d) *pulmonary alveoli*. The cluster formed of these structures together constitutes a *lung unit* or *primary lobule* (i.e., the group of structures which like the nephron or renal unit carries out the specific function of the organ). It is the distensible or bellows part of the lung.

The *respiratory bronchiole* has the same diameter as the terminal bronchiole, of which it appears as a branch or a continuation. The *alveolar ducts*, five or six in number, arise from each respiratory bronchiole (fig. 30.2). Each alveolar duct after a variable number of rebranchings gives rise to from 3 to 6 dilations, the *alveolar sacs*. The bays in the walls of the latter constitute the *pulmonary alveoli* which are lined by a single layer of flattened epithelial cells cemented together. The alveolar walls contain elastic fibers and a rich network of capillaries. Frequently a single capillary channel alone intervenes between the walls of adjacent alveoli. The blood in the capillaries is therefore separated from the air in the alveoli by two membranes of the utmost delicacy—the alveolar and capillary walls—so the greatest freedom is afforded for the diffusion of gases from the blood to the alveolar

air and from the alveolar air to the blood (Willson, Macklin).¹

The bronchioles, as they are traced toward the periphery of the lung, branch and rebranch repeatedly, diminishing in length with each subdivision. The first branchings are about 1.5 mm in length and from 0.3 to 0.4 mm in diameter. The terminal and respiratory bronchioles are from 0.2 to 0.5 mm in length, but of about the same diameter as the earlier subdivisions. That is, the bronchioles, though becoming shorter, show practically no decrease in diameter as they pass toward the periphery. The alveolar sacs, however, are considerably wider than the respiratory bronchiole or than the alveolar duct from which they arise. The diameter of each pulmonary alveolus which has a semiglobular form is from 0.075 to 0.125 mm, and the total number in the lungs has been estimated by Zuntz at 750 millions. Willson estimates the total epithelial surface of the lungs at 70 square meters. Of this, probably 55 square meters is respiratory, this is over 25 times the surface area of the skin.

The Expansion of the Lungs at Birth

Before birth the alveoli contain a small quantity of fluid, the thorax is unexpanded and completely filled by the quite airless lungs. At this time the smaller proportion of the blood of the right heart passes through the lungs. The remainder passes by the ductus arteriosus into the aorta and via the foramen ovale in the interauricular septum to the left heart. Respiratory movements are made by the fetus *in utero*, a fact clearly demonstrated by the work of Barcroft and of Snyder and Rosenfeld. In man, they can be induced by suitable stimulation after the 17th week. India ink injected into the amniotic sacs of rabbits was found in the alveoli. The significance of the latter observation is debatable. Windle states that he has observed the aspiration of amniotic fluid into the alveoli of experimental animals only under asphyxial conditions. Davis and Potter, on the contrary, injected thorotrast (a radio-opaque material) into the amniotic sacs of ten women about to be delivered by Caesarian section and were able to demonstrate the presence of the material in the lungs of half of the newborn infants.

The fetal respiratory movements are readily

¹ The results of Joselyn's studies on the anatomy of the alveoli strongly suggest that the alveolar lining may be a discontinuous membrane and that the capillaries are uncovered in certain areas, therefore the air in the alveoli would be separated from the blood only by the capillary endothelium and a small amount of fluid.

induced by tactile stimulation. Either anoxia or carbon dioxide excess alone causes strong movements. Asphyxia, caused by clamping the umbilical cord, brings about gasping respirations. The local respirations are depressed by anesthetics, narcotics, or by carbon dioxide deficit. In experimental animals the sensitivity to anoxia and CO_2 (inhaled by mother) has been observed to vary with the age of the fetus.² Barcroft and Karvonen found that anoxia, induced in sheep fetuses by cyanide, had no effect upon the respirations, except between the 58th and 91st days, before and after this time, no effect was observed. They believe that the effects are brought about through the carotid body (ch. 32). The commencement of breathing at birth they attribute to cutaneous nerve stimulation, rather than to mild asphyxia.

At the moment of birth the respiratory movements become more forceful, the diaphragm descends and the external intercostal muscles contract with the result that the diameters of the thoracic cavity are very considerably increased. A large proportion of the venous blood is now conveyed through the lungs. The general enlargement of the capacity of the thorax—a closed cavity—tends to reduce the pressure on the outer (pleural) surfaces of the lungs. The greater the degree of enlargement of the chest, the greater will be the reduction in the pressure upon the outer pleural surfaces. The interior of the lungs, however, is in direct communication, through the air passages, with the atmosphere. The visceral and parietal pleurae being inseparable the lungs follow the thoracic wall as it enlarges, and therefore must expand. The reduced pressure of the pulmonary air as a result of the expansion results in a flow of atmospheric air into the lungs. Full expansion of the lung is not attained until some few days after birth. The lung throughout the individual's life remains in the expanded position—pressed as it were against the thoracic framework as a result of the greater pressure exerted upon the alveolar than upon the pleural aspects of the pulmonary tissue.

Rhythmically alternating increases and reductions of the expanded state of the lungs initiated at birth continue throughout life and constitute

respectively the *inspiratory* and *expiratory* phases of respiration. The alternate inflations and partial deflations of the lung are the direct result of corresponding changes in the capacity of the thoracic cavity occasioned by the movements of the diaphragm and other respiratory muscles. Changes in pressure within the lung—the *intrapulmonary pressure*—and upon its pleural surfaces—the *intrapleural pressure*—occur coincidentally with the alterations in lung volume.

INTRAPULMONARY PRESSURE The mean intrapulmonary pressure is atmospheric but there are rhythmic variations with the phases of respiration. These variations may be demonstrated by connecting one nostril with a manometer and breathing with the mouth closed. The pressure will be found to be about -2 mm. Hg during the inspiratory phase and to rise to $+3$ or $+4$ mm. Hg during the expiratory phase of ordinary quiet respiration.³ The variations are accentuated considerably during forced respiration. The maximal negative pressure capable of being developed within the lungs by a forced inspiration as when a strong sucking effort is made is from -40 to -50 mm. Hg. When expiratory efforts are made against a closed glottis as in coughing during muscular effort with straining or during defecation or micturition the intrapulmonary pressure becomes raised by from 10 to 40 mm. Hg above the pressure of the atmosphere. If the free flow of air into and out of the lungs is hindered as a result of some diseased condition the intrapulmonary pressures will be increased beyond the normal range.

THE PLEURAL CAVITIES The lungs are invested by the visceral layer of the pleural membrane. The membrane is reflected from the root of each lung on to the inner aspect of the walls of the chest and upper surface of the diaphragm—this is the parietal layer of the pleura. The two layers thus form a closed membranous sac on each side of the chest. The potential space enclosed by the pleural membranes is spoken of as the pleural cavity. In health no actual space exists, the two membranes are in apposition except for a thin film of fluid which serves as a lubricant to allow the surfaces to glide over one another during the respiratory movements. This potential cavity may, however, as the result of disease become an actual one. Serous fluid (hydrothorax), pus (pyothorax or empyema), blood (hemothorax) or air (pneumothorax) may collect and separate the

² Windle has drawn attention to the serious effects upon the central nervous system of fetal anoxia, even of short duration, and suggests that asphyxia of the newborn even though of short duration, may be responsible in some instances for nervous and mental conditions e.g. subnormal mentality, or even feeble mindedness in the adult.

³ As a result of the obstruction to breathing offered by the apparatus these values are somewhat greater than actually exist during normal breathing.

two layers. Between the two pleural compartments lies the *mediastinum*, a space which is subdivided by the heart with its pericardial investment into an anterior and a posterior part—the *anterior* and *posterior mediastina*.

INTRAPLEURAL PRESSURES It has already been mentioned that the pressure on the pleural surfaces of the lungs is less than that upon their alveolar surfaces, i.e., the intrapleural pressure is subatmospheric. We must now consider the manner in which this 'negative' pressure is produced. As stated above (p. 469) when the chest cavity is first expanded, the lungs are carried outwards by the inflow of air to fill the enlarged space. If this were all that occurred, the pressure within the lung and in the pleural cavity would be equalized and in the expanded position of the thorax after birth, as in the unexpanded state in the unborn animal, the pressure in the pleural cavity would not be subatmospheric. The expansion of the thorax, however, and the consequent inflation of the lungs puts the pulmonary tissue upon the stretch. In other words, the closed thoracic box, as a result of the first breath, becomes too large for the lungs to fill by a simple unfolding and distention of the walls of the air spaces. The elastic tissue of the bronchial tree, blood vessels and of the air sacs themselves is put under stress. The pull or recoil of the elastic lung amounts, in the adult when the chest is about midway between inspiration and expiration, to a pressure of from -4 to -5 mm. of mercury. The existence of such a pressure can be demonstrated indirectly by connecting a manometer with the trachea of a dead subject and puncturing the chest wall. Thus the negative pressure in the pleural cavity is abolished, and the lungs are permitted to recoil, i.e., to collapse. Air is expelled from the alveoli, and the manometer registers a pressure of $+4$ mm. Hg. This represents the pull which had been exerted before the puncture was made and is just equal in amount to the negative (suction) pressure in the pleural cavity. In the newborn the lungs fill the thoracic cavity with comparatively little stretching. The distension of the lungs increases, however, in later years since the thoracic cage grows more rapidly than the lungs, the elastic pull in consequence also increases and with it the intrapleural negative pressure. The intrapleural pressure may be demonstrated directly by plunging a cannula connected with a manometer into the pleural cavity in such a way as to prevent leakage between it and the margins of the puncture. The manometer registers a negative pressure equivalent in amount to the positive

pressure recorded in the previous experiment. In other words, the mercury is "sucked" toward the pleural cavity until the pressure within the latter just equalizes that of the atmosphere.

Another and apparently a more important factor in preventing the separation of the pleural surfaces, and maintaining the lungs normally in the expanded state against their own elastic pull, is the "hydraulic traction" (West) exerted by the film of fluid between the layers of the pleura. This so-called hydraulic traction depends upon the tensile strength of water (as is exhibited when an attempt is made to pull apart two wet, smooth surfaces, e.g., two apposed moist glass slides). A film of water is capable of withstanding a pull of 3600 mm. Hg per square centimeter. The introduction of air into the pleural cavity permits shear to take place, just as the two glass slides can be easily separated if a small quantity of air is allowed to enter between them. That inequality of pressure on the two sides of the two aspects of the lung is not the sole, nor perhaps the most important, factor holding the pleural layers in close apposition is evident from the fact pointed out by Burns, that the intrapulmonary pressure can be reduced far below the intrapleural pressure without the lungs collapsing.

The intrapleural pressure (and the pressure throughout the thoracic cavity generally) is always subatmospheric under ordinary circumstances, even after death. This 'negative' pressure is increased during inspiration—since then the distention of the elastic lungs is greater—and reduced during expiration. During the former phase of quiet respiration (human) it amounts to about -6 mm. Hg during an ordinary expiration is about -2.5 mm. Hg. In the midposition as stated above it is about -4.5 mm. Hg. When the movements are forced it may be very greatly increased or diminished in the respective respiratory phase. During a strong inspiratory effort with the closed glottis it may amount to -40 mm. Hg and in forced expiration under the same circumstances it is abolished and a positive pressure of 50 mm. Hg or so substituted. These changes in intrathoracic pressure exert an influence upon other thoracic structures. An increase in the "negative" pressure causes the thin walled veins and auncles to expand and fill with blood drawn from extrathoracic regions (fig. 303). On the other

*The intrapleural pressure may be measured in the human subject by inserting a hollow needle into the pleural cavity, injecting a small quantity (40 cc. or so) of air and connecting the needle with a water manometer and a recording system.

FIG 303 Model to illustrate the manner by which changes in thoracic capacity cause corresponding changes in the volume of air in the lungs and affect the return of blood to the heart. The large glass chamber represents the thorax, it is hermetically sealed and has a flexible bottom or diaphragm. The Y tube which is in communication with the atmosphere, represents the trachea and bronchi, the lungs are represented by the attached balloons composed of thin rubber. The pressure within the chamber, i.e., surrounding the balloons, is subatmospheric to start with; the balloons are therefore partially expanded. When the diaphragm is drawn down (as indicated by the dotted lines) the pressure within the chamber is further reduced. The rubber balloons are distended to a corresponding extent by atmospheric air entering through the Y tube. As the diaphragm is allowed to rise again the negative pressure within the chamber returns to its previous value and the elastic balloons recoil to their original dimensions.

The bottle shown in the lower left-hand part of the drawing contains fluid upon which pressure can be exerted to cause a steady flow up the tubing into the small oval chamber within the larger one. The oval chamber may be taken to represent the heart, the tubing connecting it with the pressure bottle represents the large veins, and the tubing leading from its right side the arteries. If the tubing on the left, as well as the upper part of the oval chamber (which corresponds to the auricles) be composed of some thin resilient material, then during the inspiratory reduction in intrathoracic pressure they will undergo expansion (dotted lines). A greater body of fluid will in consequence

hand, in forced expiration against the closed air passages the thoracic walls press powerfully upon the air-filled lungs. The rise in pressure which results is transmitted to structures lying in the mediastinum. Blood is thus expelled from the large intrathoracic veins and auricles into the veins of the abdomen and neck.

The Respiratory Movements

What has been said in the foregoing paragraphs should have made it clear that the flow of air into and from the lungs depends entirely upon changes in the capacity of the thoracic cavity. The air is not drawn in and expelled by active dilation and contraction of the pulmonary passages, as was the belief at one time. Air is drawn in or forced out strictly in accordance with the pressure differences between the atmosphere and the lung air caused by the expansion or contraction of the thoracic boundaries. The principles are well illustrated by the model shown in figure 303. We will now consider how these changes are brought about.

The respiratory cycles of an adult person occur normally at the rate of from 16 to 18 per minute. In the newborn infant during quiet breathing the rate is between 30 and 40 per minute.

During inspiration the thoracic cavity is enlarged in all diameters: vertical, anteroposterior and transverse. The enlargement, however, is not equal in all directions. The upper part of the thorax increases much less in capacity than does the lower part, and since the position of the spinal column remains relatively fixed, the increase in the anteroposterior diameter of the thorax is due mainly to an expansion forwards. The increase in the vertical diameter is due to the downward elongation resulting from the descent of the diaphragm.

Unequal enlargement of the thoracic box entails unequal expansion of the lungs. The lung is not distended equally from a center as in the inflation of an elastic walled globe. Keith distinguished three zones in the expanding lung:

(a) A nonexpansile root zone containing the bronchus, pulmonary vessels and lymphatics and their main divisions.

(b) An intermediate zone in which the vascular and bronchial branches radiate outwards toward the lung surface. Between these rays lies expansile

be transferred from the bottle to the small chamber representing the heart.

The manometer inserted into the wall of the large chamber registers the pressure changes (indicated by dotted lines) occurring during the descent and ascent of the flexible diaphragm.

pulmonary tissue This zone, therefore, consists of tissue of varying degrees of expansibility, that lying near the periphery of the rays being more expansile than that situated more centrally

(c) An outer or subpleural zone, from 1 to 1½ inches deep, of maximal distensibility

Those regions of the lung lying in relation to the relatively immobile regions of the thoracic walls, namely (a) the dorsal surface of the lung apex, (b) the posterior surfaces of the lungs in contact with the spinal column and attached segments of the ribs, and (c) the mediastinal surface lying in relation to the pericardium and other structures of the mediastinum, are expanded *indirectly* The parts of the lung which are *directly* expanded during inspiration are those lying in contact with the freely movable boundaries of the thorax, namely (a) the sternum and ribs and (b) the diaphragm

It is evident that those portions of lung in contact with practically stationary regions of the thoracic walls can only be expanded indirectly, that is, when other parts of the lung move out of the way This could not occur did the root of the lung remain fixed As a matter of fact the lung root moves downwards, forwards and laterally during inspiration (fig 30 4) and, as shown by Macklin by X-ray studies upon human subjects,

FIG 30 4 Mediastinal aspect of the right lung to show the respiratory movement of the lung root The crus of the diaphragm is also indicated, and its attachment to the root of the lung through the pericardium The arrows indicate the direction of the inspiratory movement of the various parts of the lung (After Keith)

FIG 30 5 X ray photographs (retouched) of the bronchial tree of a young woman A in full expiration, B, in full inspiration (After Macklin)

the bronchial tree becomes elongated (stretched) during the inspiratory phase The trachea becomes stretched and the apex of the lung actually descends as it expands During expiration the highly elastic bronchial tree recoils to its previous length and the lung root ascends (fig 30 5) If the root of the lung were fixed, little expansion of a region such as the apex or of other regions classed as expanding indirectly could result Nor could anything but a very moderate expansion of other regions (e.g., costosternal and diaphragmatic, etc) occur if the bronchial tree were unable to lengthen It is the *elongation* of the rays as described above rather than the widening of the spaces between them at their original lengths, like the separation of the sticks of a fan, that is of importance in permitting the expansion of the intervening pulmonary tissue

The effect of the enlargement of the thorax is exerted first and to the greatest extent upon the lung tissue in relation to the movable parts of the chest walls The inspiratory decrease of intrapleural pressure in the diaphragmatic regions of

the thorax is considerably greater than that in the region of the apex or in other parts of the lung which are expanded indirectly. As a result of the greater negative pressure in the lower part of the thorax, a horizontal groove is sometimes developed here (Harrison's sulcus) when the framework, as in rickets, is soft and yielding. The restricted expansion of the air sacs of the apex and other regions of the lung which are expanded indirectly has been held responsible for their being so commonly the primary site of tuberculous infection.

The Enlargement of the Thoracic Cavity during Inspiration

This is effected, according to Keith, by four distinct mechanisms which consist of the movements of

- (a) The thoracic lid or operculum (1st rib and manubrium sterni)
- (b) The upper costal series (2nd to 5th ribs inclusive)
- (c) The lower costal series (6th to 10th ribs inclusive) and the diaphragm
- (d) The floating rib series and the muscles of the abdominal wall

THE THORACIC LID OR OPERCULUM

The thoracic lid or operculum is formed by the first pair of ribs and the manubrium sterni. It is jointed behind to the spinal column and in front to the sternum by the manubrio-sternal joint. During the elevation of the thorax in inspiration the thoracic lid moves as a single piece upon the body of the sternum, assuming a more horizontal position (by from 1° to 16°). That is, the manubrium is pushed upward and forward (fig. 30.6). Thus, the upper part of the thorax is increased in its anteroposterior diameter. The anterior por-

FIG. 30.6 Diagram to show the respiratory movements of the first pair of ribs and manubrium sterni, and the effect of these movements on the expansion of the apex of the lung (After Keith.)

FIG. 30.7 Diagram to illustrate the action of the external intercostal muscles during inspiration, ↓, expiration and ↑, inspiration

tion of the lung apex is directly expanded to some extent by this mechanism. The extent of the movement of the thoracic lid varies considerably in different individuals and with the depth of inspiration. It is very slight in quiet breathing. The manubrio-sternal joint becomes ankylosed in later life but rarely before the 60th year.

THE UPPER COSTAL SERIES
