The 2nd, 3rd, 4th, 5th and 6th ribs slope obliquely from behind downwards and forwards. Each rib is longer, its direction more oblique and it makes a fuller sweep outwards than its neighbor immediately above. During inspiration these ribs (with the exception of the 2nd) assume a more horizontal position, their anterior portions moving upward and forward. That is, each rib rotates around an oblique horizontal axis parallel to its neck (fig. 30.8CD). The sternum is thrust forward and upward, executing a movement at the manubrio-sternal joint. These movements increase the anteroposterior diameter of the thorax. The elevation of the ribs is effected by the external intercostal muscles. The muscle fibers pass obliquely downwards and forwards from the lower border of one rib to the upper border of the rib below. When the muscle contracts it exerts a pull upon these attachments which tends to depress the upper rib of the pair and to raise the lower. The first rib, however, acts through the contraction of the scalene muscles, as a fixed point above, so that contraction of the external intercostals can only result in an elevation of the ribs. Owing also to the obliquity of the fibers which are attached below to the anterior end of the long arm of a lever and above to the posterior end of the long arm, a distinct mechanical advantage is

FIG. 30.8 A diagram showing the axis of movement (AB and CD) of the ribs from the 2nd to the 6th. The ribs from the 7th to the 10th also make a movement around an anteroposterior axis but not around the axis CD. The interrupted lines indicate the position of the rib in inspiration. (After Gray.)

given to the upward movement (fig. 30.7). In general the internal intercostal muscles are expiratory in function. The internal and external intercostals receive impulses alternately along the intercostal nerves (Bronk and Ferguson).

The strongly bowed midportion of the body of each rib from the 2nd to the 6th also becomes elevated, in relation to its two ends, rotating around an oblique anteroposterior axis. This movement, which is compared to the raising of a bucket handle to a more horizontal position, increases the transverse thoracic diameter (fig. 30.8AB).

THE LOWER COSTAL SERIES AND THE DIAPHRAGM

The ribs from the 7th to the 10th also swing outwards and upwards (bucket handle movement) during inspiration, rotating around an oblique anteroposterior axis which passes through the midline in front and the necks of the ribs behind. The subcostal angle is widened by this movement and the transverse diameter of the lower part of the thorax increased, the anteroposterior diameter is slightly reduced.

The diaphragm is the chief muscle of respiration, its movements being responsible during deep breathing for about 60 per cent of the total amount of air breathed. It consists of a musculo-

tendinous sheet arched toward the thoracic cavity. The tendinous portion is centrally placed (central tendon) and is adherent to the pericardium. The muscular tissue is placed circumferentially. The diaphragm consists of two parts which differ from one another in their actions.

(a) The *costosternal* part arises from the back of the xiphoid and the cartilages and adjacent portions of the six lower pairs of ribs. It is attached to the anterior edge of the central tendon.

(b) The *lumbar or crural* part arises from the fibrous arches over the quadratus lumborum and psoas muscles and by two fleshy bundles (the crura of the diaphragm) from the bodies of the upper lumbar vertebrae. These fibers are inserted into the posterior margin of the central tendon.

ACTION OF THE DIAPHRAGM The diaphragm descends during inspiration and ascends during expiration. In full expiration its upper limit lies at a level situated between the costal cartilages of the 4th and 5th ribs. In quiet breathing the range of its movement is about 1.2 cm and in forced breathing about 3.0 cm. The total diaphragmatic surface is about 270 sq cm. A descent of 1.0 cm therefore (assuming that all regions descend practically to the same extent) will increase the thoracic capacity by 270 cu cm and cause a corresponding volume of air to enter the lungs.

As the diaphragm descends its domed shape alters very little; it may be seen by means of the fluoroscope to move up and down like a piston (fig. 30.9). At the end of expiration a considerable proportion of the diaphragmatic surface is in contact with the chest wall as high as the 6th or 7th rib, but during inspiration it is "peeled off" the thoracic boundary, while the base of the lung expands to fill the space (pleural sinus). As a result of the slight indrawing of the intercostal spaces caused by this movement, a faint shadow may be seen to move down the side of the chest wall in most normal persons. This is known as *Litten's sign*. The *costosternal* part of the diaphragm, (using the lower ribs, which through the action of the external intercostals, serve as fixed points) moves downward and forward, depressing the abdominal viscera. Thus, the capacity of the lower part of the thorax is increased. The abdominal wall distends but when, as a result of the resistance offered by the abdominal muscles, the downward movement of the viscera becomes arrested, the latter act as a fixed point for the continuing contraction of this part of the diaphragm, its force is now spent in raising the lower ribs to which it is attached. Through this action the ster-

FIG. 30.9 Upper, radiogram showing the position of the diaphragm during expiration and inspiration. Note the effect upon the position and shape of the heart. (After Norms and Landis.) Lower, diagram showing the expiratory and inspiratory positions of the diaphragm.

num is thrust forward and upward. The *spinal or crural* part in its descent acts solely in increasing the vertical diameter of the thorax.

The excursions of the diaphragm and consequently its midposition as well are influenced by (a) the upward pull of the subatmospheric intrathoracic pressure, and (b) the abdominal viscera. In the standing position the weight of the latter aids the descent of the diaphragm but hinders its ascent, the mean or midposition of the diaphragm is therefore taken up at a lower level than in recumbency. (c) The abdominal muscles, these, when lax and the body in the standing position, allow the viscera to subside to a lower level and so to increase the downward pull upon the diaphragm.

THE FLOATING RIBS AND THE ABDOMINAL MUSCLES

Functionally the floating ribs (11th and 12th) must be considered with the abdominal muscles which are the antagonists of the diaphragm. The recti and oblique muscles undergo a decrease in

tonus as the diaphragm descends, they regain tonus with its ascent.

Expiration

Expiration is to a large extent a passive movement, in quiet breathing, or *eupnea*, it is probably entirely so. That is, as the contraction of the inspiratory muscles ceases, the thoracic framework tends through its own weight and inherent elasticity to resume its former position, the elastic lungs recoil and the relaxed diaphragm is drawn upwards toward the thoracic cavity by the "negative" intrathoracic pressure. There is, however, also a definitely active element. As mentioned above, the abdominal muscles regain tonus and by pressing upon the viscera aid the ascent of the diaphragm.

Under conditions which require a considerable increase in lung ventilation (*hyperpnea*) or an increased muscular effort to maintain ventilation (*dyspnea*), the expiratory muscles contract to accelerate the expulsion of air from the lungs.

Movements of the bronchial tree during respiration In addition to the inspiratory elongation of the bronchial tree mentioned above, the bronchioles and small bronchi dilate during inspiration and constrict during expiration. Whether these rhythmic bronchial movements are purely passive in nature has been debated. The bronchioles also exhibit a peristaltic movement which can be detected by X ray photographs of the bronchioles after the injection of Lipiodol* or other material that is opaque to the X ray. It is not thought that the peristaltic movement plays any part in the movement of air, but it appears to assist in the movement of foreign material towards the larger air tubes. This bronchiolar peristalsis is said to be increased in lung abscess and diminished in bronchiectasis. It is decreased by morphine.

Pulmonic alveolar vents The existence of certain pores in the alveoli (pores of Kohn) have long been recognized, but the difficulty of being certain that they are not artefacts produced by the method of preparing the sections has prevented their wide acceptance as normal structures. Macklin, however, has been able to demonstrate the presence of such vents in thick sections prepared from the lungs of many species including man. Exsanguination of the sections justifies the belief that they are normal communications between the alveoli. While the function of the vents is not as yet completely understood, it appears probable that they play a significant part in the equalization of pressures in groups of the alveoli, particularly perhaps during forced inspiration. The vents are opened wide during inspiration and may be entirely closed in expiration.

The Work of Breathing

In recent years methods have been devised to obtain quantitative information about the forces and resistances involved in breathing. The action of muscles during inspiration opposes forces which can be analyzed into three components, the force required (a) to overcome elastic resistance, (b) to move nonelastic tissue, and (c) to overcome resistance to air flow through the tracheobronchial tree.

Elastic Resistance

The tissues of the lungs and thorax behave somewhat like springs in that they are stretched during inspiration and recoil to assume their previous state when the stretching force is removed. The slope of a line that is obtained when a distending force, namely pressure, is plotted against increase in volume of the system indicates

the stiffness or the distensibility. The less the increase in volume with a given increase in the pressure applied, the more rigid or the less distensible is the system. The mechanical compliance of the lungs is defined as the volume change per unit pressure change, where the former is expressed in liters and the latter in centimeters of water. The compliance of the lungs is decreased in disorders such as pulmonary congestion secondary to chronic cardiac failure and in diseases which lead to pulmonary fibrosis.

The respiratory system actually consists of two sets of elastic elements, those in the lungs and those in the thoracic wall. Methods have been devised whereby these may be evaluated separately (see Comroe *et al.* 1955).

Force to Move Nonelastic Tissues

This is for the most part the force required to overcome friction within those tissues which move during inspiration. The amount of force required is greater with more rapid inspiration. It is to be noted that the work involved in moving nonelastic tissues becomes zero at the termination of inspiration while at this point the elastic force is maximal since the maximal enlargement of the thorax has been reached.

Resistance to Air Flow

The total airway resistance depends on the number, length and cross-sectional area of the tubes through which the air passes. The amount of work required to move air through the air passages is determined by the resistance related to the structure of the airway itself and by the amount of air moved per unit of time. If air flow is at a velocity great enough to cause turbulence more work is required than when flow is laminar. If gases of lower density than air are breathed (e.g. helium) work involved in moving the gas is lowered correspondingly. The resistance to the flow of air is relatively greater at the bronchiolar level than elsewhere in the respiratory tree, and, since the bronchioles can undergo considerable changes in caliber, large changes in resistance can develop in this region of the bronchial tree. The major problem in bronchial asthma is the increase in resistance to passage of air through the bronchioles. When resistance in the airway is increased by bronchiolar constriction, it is compensated for by a more forceful inspiratory effort so that the normal volume of air is moved. On expiration, if only elastic recoil were operating, air would pass out more slowly than

* A preparation of iodized oil.

under normal conditions, but active expiration develops to produce a sufficiently rapid egress of air

The Cough Reflex

There are three mechanisms for the expulsion of foreign material from the larynx, trachea and lower air passages as far as the terminal bronchioles. First, the action of the cilia, second, the peristaltic motion of the bronchioles, and third, the cough reflex. The peristaltic movement has been referred to above. The cough reflex is most commonly initiated by the stimulation of afferent nerve endings in the region of the tracheal bifurcation, the most sensitive area, or in the laryngeal mucosa. It may also be initiated from the excitation of vagal afferents from the lungs, or from nerve endings in the pleura. Ear disease, through the stimulation of terminals of the auricular branch of the vagus (Arnold's nerve), may also cause coughing. The act itself consists of a short inspiration followed immediately by closure of the glottis and a forcible expiratory effort. A considerable degree of pressure is thereby developed within the lung. The glottis then opens suddenly and offending material is moved a variable distance along the air passage. During the subsequent inspiration the irritating particle, if not large enough to seriously obstruct the air passage, remains in its new position, from which it is carried forward again during succeeding expulsive efforts until it is swept away from sensitive areas.

Inert, nonirritating foreign matter of a particulate nature which has entered the alveoli, is removed by large ameboid cells—the alveolar macrophages, or “dust cells.” Normally, a few of these cells are to be seen in the alveoli, but they are attracted in large number by the presence of foreign particles. The origin of these cells is a controversial question. Some are thought to originate from the monocytes of the reticuloendothelial system, others from cells in the alveolar septa (septal cells). The foreign material is conveyed by the macrophages into the lymph channels draining the alveoli. In city dwellers or those who work in dust laden atmospheres e.g., coal miners, the lymph nodes are dark with the scavenged material. Irritating matter, especially pathogenic bacteria, are attacked as in other situations by the neutrophilic phagocytes of the blood.

Hiccup or singultus is a spasmodic and purposeless contraction of the diaphragm which results from many causes or may occur without known

cause, it occurs rarely in epidemic form. It is usually reflex in nature being initiated by some abnormal stimulation of the afferent nerve terminals in the diaphragm or viscera in the upper part of the abdominal cavity. The fibers of the phrenic nerve constitute the efferent limb of the reflex. Hiccup following abdominal operations may be most intractable and endanger the life of the patient. The inhalation of an air mixture containing 6 or 7 per cent of carbon dioxide (or simply breathing and rebreathing from a bag for a number of respirations) has been reported to be a valuable means of terminating an attack.

Pneumothorax

Air may enter the pleural cavity through a penetrating wound of the chest (*open pneumothorax*), as a result of the rupture of an emphysematous vesicle on the surface of the lung or from the extension through the pleura of a lesion of the pulmonary tissue (e.g., tuberculous) or of some other air-containing organ such as the esophagus or stomach. When the intrapleural space contains air but communication with the atmosphere has become occluded the pneumothorax is said to be *closed*.

If the opening through the thoracic wall were large and the mediastinum acted as a more or less rigid partition, the pleural cavity of the affected side could be considered quite separate from that of the sound side. The lung on the open side would exhibit its elastic properties and recede, the air would be expelled and the lung in the collapsed state. The opposite lung would be unaffected. Actually, the mediastinum, as a rule, is mobile, so the two pleural cavities though anatomically separate, act so far as the distribution of pressure is concerned, almost as if they were a single cavity. Consequently when an opening exists in the thoracic wall the yielding mediastinum with its contents—heart and great vessels—moves toward the sound side. The negative pressure on the sound side of the chest is therefore reduced, and the lung on that side also tends toward collapse. The response to the pneumothorax is deepening of the respirations. That is, the thorax enlarges and the lungs expand to a greater degree to create a negative pressure despite the communication between the chest cavity and the atmosphere. It therefore becomes a matter of competition between the amount of air entering the lungs through the trachea and that entering through the opening in the chest during inspiration. The chest may be compared

FIG 30 10 Bronchiectasis X ray photograph after injection of bronchial tree with Lipiodol (After Moll retouched)

to a bellows with a hole in its wall when the bellows is opened (inspiration) the volume of air entering through the leak and that through the nozzle (which is analogous to the trachea) will depend upon the sizes of the respective openings. From this it will be realized that with a small opening pulmonary ventilation of practically normal value could be maintained. Even with a large opening a normal tidal volume of air might be drawn in during inspiration. The reason for this is of course that the tidal volume is only a small fraction of the vital capacity. When however the opening is quite large the thorax even when the inspiration is maximal might fail to expand the lung sufficiently to maintain the tidal volume at its normal value. As a result of the work of Graham and his associates the following summary may be made

(a) Both lungs are affected in a pneumothorax. If the opening is small or if in a closed pneumothorax the pressure is low, the effect upon the two lungs is nearly equal.

(b) A bilateral open pneumothorax may not be fatal if the openings are small.

(c) The size of the opening compatible with life bears a relation to the vital capacity of the subject. Any pneumothorax, unless the opening is very small, would be fatal to a person who before the pneumothorax occurred had possessed a vital capacity little greater than his tidal air.

(d) The reduction in the intrathoracic negative pressure caused by a pneumothorax tends to impede the filling of the right heart and to produce stasis in the venous system.

When the mediastinum has been rendered stiff and resistant by previous disease some of the foregoing statements obviously will not apply. If the pleural surfaces on the side of the lung are adherent and so hold the lung out

against the thoracic wall a pneumothorax will not result. Or if as a result of such adhesions the pneumothorax is limited in extent only a part of the lung is affected.

Pleural shock Marked slowing of the pulse and a profound fall in blood pressure which may lead to fatal syncope sometimes follow puncture of the chest wall for the withdrawal of fluid or during the production of pneumothorax. The cardiovascular reaction is apparently due to a pleural reflex since a similar effect upon heart rate and blood pressure can be induced in animals by stimulating the pleura. It is more commonly seen when the chest is punctured for the withdrawal of fluid than during the injection of air in the production of pneumothorax, a fact among others which argues against its being due to air embolism. Injury to the visceral pleura or to the underlying layer of pulmonary tissue appears to be a factor essential for the production of this type of circulatory collapse.

Bronchiectasis

This is the term applied to an abnormal dilation of the bronchi or bronchioles. The dilation may be localized or widespread fusiform, sacular, beaded or uniform in distribution. The contour of the bronchial tubes is readily demonstrated by X ray after the injection of Lipiodol (fig 30 10). Secretion may collect within the dilated lumina and be expectorated at intervals as large quantities of a foul smelling sputum. This classical sign of the condition is only seen in its advanced stages. More commonly the sputum is small in amount and in the form of yellow chunky pieces (Warner).

Bronchiectasis is practically always secondary to some other affection of the lungs. The primary change leading to the condition is weakening of the bronchial wall as a result of infective processes. The elastic and muscular tissues are atrophic. As we have seen the bronchial tree dilates during inspiration and constricts during expiration. The latter movement is in part at least an elastic recoil. With the gradual deterioration of the elastic tissue of the bronchial wall the latter's resiliency becomes progressively less. The lumen of the tube does not regain its normal caliber after inspiration but remains more or less dilated. According to the most widely held view further dilation is induced because the pressure within the bronchial lumen during inspiration is higher than the pressure in the surrounding pulmonary tissue and in the pleural space. During expiration however, the intrabronchial pressure cannot rise

above the pressure in the surrounding tissue, the bronchial walls are supported. Coughing or other conditions causing a general rise in intrapleural pressure cannot, therefore, induce bronchiectasis. On the other hand, conditions which increase the negative pressure within the thorax, such as the collapse of an area of lung (atelectasis), of a lobe or of entire lung (massive atelectasis), will increase the tendency to bronchiectasis. Incomplete obstruction of a bronchus especially if it exerts a valve-like action, by permitting inspiration but hindering expiration, favors the development of bronchiectasis. The latter is, therefore, not an uncommon result of the lodgment of a foreign body in a bronchus. On the other hand, it is thought by some (Roberts and Blair) that retention of secretions, as originally suggested by Laennec combined with inflammatory weakening of the bronchial wall are the important causative factors and deny the significance of atelectasis and an increase in pleural negative pressure. Whitwell, in an examination of 200 lungs removed at operation, found atelectasis in only 10 per cent.

Fibrosis of a lung or portion of lung is considered by some as a potent cause of bronchial dilation. It is thought that the fibrosing lung as it shrinks makes equal circumferential traction upon the bronchi or bronchioles and thus leads to their dilation. It is probable that even in these instances previous weakening of the bronchial wall is the primary fault since bronchiectasis commonly occurs in the absence of fibrosis.

Pressure Breathing

Pressure breathing refers to breathing against a pressure greater than the ambient pressure. This has been utilized, for example, in pilots flying at altitudes such that the pO_2 in inspired air is insufficient even when breathing 100 per cent O_2 by mask, and also it has been used as a therapeutic measure in patients with pulmonary edema. In the latter case the rationale is to provide pressure such as to counteract the transudation of fluid into the alveoli. A subject can breathe against a pressure of around 20 mm. Hg for relatively prolonged periods and against somewhat higher pressures for a few minutes. An immediate effect of pressure breathing is the increased resistance to flow of blood through the pulmonary capillaries which results in a decreased flow of blood to the left side of the heart and consequently in a reduction of left ventricular output and of systemic arterial blood pressure. Since the return of blood to the right atrium is unimpeded, the pressure here increases, and as the right ventricular volume

increases, the strength of the ventricular contraction becomes stronger with the result that the flow through the pulmonary circuit is soon restored despite the greater resistance. When pulmonary blood flow is restored, the left ventricular filling also is restored, and arterial pressure is brought back up to approximately normal levels. At the new steady state circulation is essentially normal but is being maintained at the expense of increased right ventricular work. Some degree of vasoconstriction (both arteriolar and venous), set off reflexly from the aortic pressoreceptors also appears to be involved in maintaining the arterial blood pressure and contributing to elevated venous pressure (on the basis of decreased holding capacity of the systemic circuit) during pressure breathing.

The Valsalva Maneuver

By voluntarily closing the glottis and performing a strong expiratory effort one can produce an intrathoracic pressure of well over 80 mm. Hg, and this pressure is reflected in a similar rise in the alveoli and also in the blood vessels and other structures within the chest. Actually, this maneuver (which has an effect similar to that of the method described by Valsalva for blowing air into the middle ear and hence is known as the Valsalva maneuver) also involves contraction of the abdominal muscles and, consequently, there is a considerable rise in intra-abdominal pressure. A similar type of muscular activity is utilized in defecation, during which there may be a considerable rise in intrathoracic and intra-abdominal pressure. The Valsalva maneuver has the effect of preventing the return of blood from the four extremities and head just as if blood pressure cuffs were applied and inflated to a pressure level corresponding to that produced in the body cavities. Thus when the act is commenced, venous pressure in the extremities and head rises, venous return decreases sharply, cardiac output decreases, and arterial blood pressure falls. The heart rate is increased reflexly as a result of the fall in pressure in the sinoaortic zones. As soon as the expiratory effort is released the blood, which has accumulated in the veins, rushes into the right ventricle which now suddenly becomes quite enlarged and contracts forcibly to pump its contents through the pulmonary circuit and into the left side of the heart. The surge of blood into the left ventricle causes a sudden increase in the amount of blood pumped into the systemic arterial tree, and the concomitant rise of arterial pressure elicits reflexly from the pressoreceptors a

brief period of bradycardia, following which the conditions that existed prior to the maneuver are re-established. The normal heart can withstand the strain put upon it by the sudden rise in venous return which is seen on terminating the Valsalva maneuver, but in patients with chronic congestive heart failure, the heart is weakened and may be distended even under basal conditions, in such cases the influx of blood may produce overdistention of a degree which results in acute cardiac decompensation. This is considered to be the mechanism of some of the sudden deaths occurring in patients with chronic congestive heart failure during straining efforts.

LUNG VOLUMES AND PULMONARY VENTILATION

The Lung Volumes

The amount of gas moved into the lungs and out during a single respiratory cycle is known as the *tidal volume*. The position of the chest at the cessation of expiration in eupnea (which is reached as a result of inactivity of the respiratory muscles) is known as the *resting end expiratory position*. The amount of gas that can be exhaled beyond this position is the *expiratory reserve volume* while the *inspiratory capacity* is the amount of gas that can be inhaled starting from this position. *Inspiratory reserve volume* is the amount of gas that can be inhaled beyond the tidal volume that is recorded in quiet breathing. Since tidal volume and inspiratory capacity are measured easily, inspiratory reserve volume can be obtained by subtracting the former from the latter (see fig. 31.1). *Vital capacity* is the maximal amount of gas that can be expelled from the lungs following a maximal inspiration. Not all of the air of the lungs can be forced out by a maximal expiratory effort and that which remains is the *residual volume*. *Total lung capacity* is the vital capacity plus the residual volume. Another volume which is of interest since it represents the amount of gas in the lungs to which the tidal volume is added on inspiration is the *functional residual capacity*. It may be seen in the table that this is the residual air plus the expiratory reserve volume. All of the names of the different volumes and capacities are abbreviated by the use of the first letters of the words employed. Mean figures for the various volumes in 50 young men were found to be

$$\begin{array}{r} \text{TV} - 0.5 \text{ L} \\ \text{IRV} - 3.3 \text{ L} \\ \text{ERV} - 1.0 \text{ L} \\ \text{RV} - 1.2 \text{ L} \\ \hline \text{TLC} - 6.0 \text{ L} \end{array} \quad \left. \vphantom{\begin{array}{r} \text{TV} - 0.5 \text{ L} \\ \text{IRV} - 3.3 \text{ L} \\ \text{ERV} - 1.0 \text{ L} \\ \text{RV} - 1.2 \text{ L} \\ \hline \text{TLC} - 6.0 \text{ L} \end{array}} \right\} = \text{VC} - 4.8 \text{ L}$$

In 50 young women the mean VC was found to be 3.14 or about two-thirds of the figure for men

VITAL CAPACITY AND ITS VARIATIONS

A relationship between certain body measurements and vital capacity has been shown by several investigators. Hutchinson, a pioneer in the field, invented the spirometer and studied the vital capacity in a large number of individuals, normal and diseased. He demonstrated a relation of vital capacity to height and weight. The most consistent relationship, as shown by Dreyer and by West, exists between vital capacity and surface area (see table below).

A fairly close relationship between total height and vital capacity was also found, the latter expressed as cubic centimeters being 2½ times the height in centimeters for men, 20 times for women and 29 times for athletes. For example, an average adult male 170 cm. tall would have a vital capacity of $(170 \times 2\frac{1}{2} =) 4250$ cc. The surface area of the same individual assuming an average weight for his height, namely 70 kg, would be 1.80 square meters. Therefore his vital capacity should be $(1.80 \times 2500 =) 4500$ cc. The difference in the results of the two methods of calculation of the normal standard is therefore around 5 per cent.

The ratios of vital capacity to height and surface area respectively, as found by West, are shown in the following table:

	Men	Women	Athletes
Vital capacity cc per cm height	25.0	20.0	29.0
Vital capacity cc per square meter of body surface	2500	2000	2800

Occupation, as shown by Dreyer and others, exerts a potent influence upon the vital capacity, the normal standard of persons employed in sedentary work being considerably lower than of those pursuing more arduous occupations. Dreyer divided his subjects into three classes, A, B, and C. Class A are those with the maximum vital capacity.

FIG. 31.1 Lung volumes indicated as they would appear on a spirographic tracing. See text for meaning of letters. (Reproduced by permission from Comroe *et al.* *The Lung*. Year Book Publishers, Inc. Chicago 1955.)

ities. Classes B and C have values 90 per cent and 85 per cent respectively of those of Class A. He considered a reduction of 15 per cent below the standard of the class to which the subject belongs as an almost certain indication of some abnormality. It should be mentioned that measurements of chest expansion, as by means of a tape measure, may bear little relation to the vital capacity. A subject with powerful muscles can enlarge his thoracic cage to a capacity greater than his lungs are able to fill. His diaphragm instead of taking a full downward stroke is drawn upwards while the viscera are forced into the extrathoracic space by a strong contraction of the abdominal muscles.

The vital capacity is reduced in many diseased conditions especially those involving the respiratory and cardiovascular systems. Among these are

(a) Conditions which directly involve the lungs, e.g., pneumonia, pulmonary tuberculosis, emphysema, etc.

(b) Mechanical interference with the enlargement of the thoracic cavity, e.g., as by abdominal conditions impeding the movements of the diaphragm or abnormalities of the thoracic walls. The movements of the thoracic walls may be seriously restricted by abdominal or pleuritic pain.

(c) Intrathoracic conditions which encroach

upon the space normally occupied by the lungs, e.g., pericardial or pleuritic effusions, pneumothorax, tumors, etc.

(d) Heart disease. Engorgement of the pulmonary vessels and pulmonary edema involving especially the lung bases lead to a reduction of the vital capacity in cardiac cases. Peabody found that when in heart disease the vital capacity reached 40 per cent of the normal, the subjects were almost constantly dyspneic or showed dyspnea upon the slightest exertion.

The vital capacity, the functional residual capacity and the residual volume, and consequently the total lung capacity are reduced in the recumbent posture.

MEASUREMENT OF FUNCTIONAL RESIDUAL CAPACITY (FRC) AND RESIDUAL VOLUME (RV)

The residual volume is the only one of the primary lung volumes that can not be measured directly. It can be estimated by indirect methods which involve diluting a known volume of gas with the residual volume and determining the amount of dilution which occurs. Both open and closed circuit methods have been used.

Using a closed circuit, helium can be used as the test gas. A known volume of a gas mixture containing 10 per cent helium is introduced into a spirometer. The initial concentration of helium

in the lungs is zero, and in the spirometer it is 10 per cent. Beginning from either the resting end-expiratory position (in which case FRC is measured) or from the position of maximal expiration (in which case RV is measured), the subject breathes from the spirometer until mixing is complete so that the concentration of helium in the lungs and spirometer becomes equal. Then the concentration of helium in the spirometer is determined.

The volume of gas in the lung with which the helium was mixed is calculated on the assumption that the same number of molecules of helium is present at the end of the test as at the beginning. This assumption is permissible since only a short time is involved in rebreathing and helium is only slightly soluble in water. The lung volume is calculated as follows:

$$V_L F_{IN L} + V_S F_{IN S} = (V_L + V_S) F_{END S}$$

where V_L = initial volume in lung — unknown
FRC or RV depending on position

$F_{IN L}$ = initial concentration of test gas in lung

V_S = initial volume in spirometer

$F_{IN S}$ = initial concentration of test gas in spirometer

$F_{END S}$ = final concentration of test gas in spirometer (and in lungs)

Suppose the initial volume of the gas mixture in the spirometer was 1000 ml and the initial and final concentrations of helium in the spirometer were 10 per cent and 5 per cent respectively. The calculation is as follows:

$$\begin{aligned} 0 + (1000 \times 0.10) &= (V_L + 1000) 0.05 \\ 100 - 50 &= 0.05 V_L \\ V_L &= 1000 \text{ ml} \end{aligned}$$

In practice it is preferable to measure FRC, because the resting end-expiratory position is a more constant point to work from than the position of maximal expiration. Then the ERV is determined experimentally, and this is subtracted from the FRC to obtain RV.

Tests of Mechanical Factors in Breathing

In the measurements of lung volumes neither the effort involved nor the time factor in movement of air is evaluated. Records of normal breathing, forced inspiration, forced expiration from the position of forced inspiration (*tidal vital capacity*) and *maximal breathing capacity* obtained on a moving drum provide information concerning the rate of movement of gas. In figure 31.2 a

spirogram obtained from a normal subject is shown for comparison with those characteristic of patients with pulmonary fibrosis, asthma, and emphysema. In fibrosis the major change is seen to be the decrease in vital capacity. In asthma, which is characterized by increased resistance in the airway, the rate of expulsion of air and rate of inhalation are greatly decreased, and, since air can not be moved as fast as in the normal, maximal breathing capacity also is greatly decreased. In emphysema the defects though similar to those seen in asthma, are of greater degree.

For these tests the instructions to the subject are very important if comparisons of records are to be made. First the subject breathes normally, then he is told to inspire maximally, and then to blow out as hard and fast as he can. Next he should inhale as quickly as possible to the position of maximal inspiration. Following this to obtain maximal breathing capacity (MBC), he is instructed to breathe as deeply and rapidly as he is able for 15 seconds. For this he is allowed to set his own frequency and amplitude.

The normal person can exhale about 83 per cent of the vital capacity in one second, 94 per cent in two seconds, and 97 per cent in three seconds. In patients with pulmonary fibrosis the vital capacity is below normal but the per cent exhaled per second may be normal.

The MBC is low in many types of cardiopulmonary diseases. It is not diagnostic of any single disease and is not as specific in evaluating the type of defect as simpler tests utilizing a single respiratory maneuver. However, it may be of considerable value in individual cases having impairment of breathing if repeated records are obtained for comparison in order to determine whether the patient is showing improvement under treatment.

RESPIRATORY MINUTE VOLUME (RMV) AND PULMONARY VENTILATION

The volume of gas moved in and out of the respiratory passages per minute, the *respiratory minute volume*, is the product of the mean tidal volume and the respiratory rate. It can be measured directly by having the subject exhale through a gas meter for a given period or the individual tidal volumes recorded during a minute can be added. The upper portions of the respiratory tree serve as conduits, since no exchange of gas occurs at these levels; it is evident that a correction needs to be made to determine how much of the RMV is available for alveolar ventilation. The latter also is known as pulmonary ventilation. As emphasized by Gray it is thus

FIG 31-2 Spirograms of normal subject and patients with pulmonary fibrosis, asthma and emphysema (Reproduced by permission from Comroe *et al* *The Lung* Year Book Publishers Inc Chicago 1955)

figure which may be expected to be of physiological significance rather than the RMV

The volume of the air passages from the nose and nasopharynx down to that level of the respiratory tree where interchanges of oxygen and carbon dioxide with the blood occur is known as the anatomic dead space. The volume of this space can be determined on the basis of the fact that expired gas is a mixture of gas from the dead space and from the alveoli. This method involves analysis of expired air and alveolar air samples and representative samples of the latter are difficult to obtain. Another method for determining the dead space is to inhale pure oxygen from a spirometer and then to exhale through a continuous gas analyzer. At the beginning of the expiration the first gas to leave the airway is pure oxygen which has been in the dead space without any admixture with other gases, then as expiration proceeds, the gas shows a progressive increase in nitrogen until it reaches the concentration found in alveolar air. Beginning with the point at which the nitrogen concentration in expired air becomes constant, alveolar air is expired. Thus there are three phases in the nitrogen concentration curve (see fig. 31.3) (a) no nitrogen present, (b) progressively increasing nitrogen concentration, and (c) maximal and constant nitrogen concentration. From the data obtained by such an analysis of a single exhalation the dead space can be computed. (Examples of the calculation

are given by Comroe *et al.* 1955.) Mean values for the dead space in persons in the supine or in a semi-recumbent position range around 150 ml.

The alveolar ventilation is calculated by subtracting the volume of the dead space from the tidal volume and multiplying this by the respiratory rate. If volume of expired air has been measured directly by means of a gas meter the product of respiratory rate times 150 ml. can be subtracted to convert to the figure for alveolar ventilation. Since the dead space is about 0.3 of the tidal volume under resting conditions alveolar ventilation is about 0.7 of the RMV. Average values for normal young men under resting conditions are 3 to 4 liters per min. per square meter for RMV and 2 to 2½ liters per min. per square meter for alveolar ventilation. As tidal volume increases, since dead space remains constant the figure for alveolar ventilation becomes a larger fraction of the RMV. Conversely, shallow breathing is relatively inefficient in producing alveolar ventilation, since the dead space becomes a larger fraction of the tidal volume.

The ventilation ratio (VR) which will be considered further in the discussion of the regulation of pulmonary ventilation, is the ratio of the alveolar ventilation under a given set of conditions to the alveolar ventilation under resting conditions. Thus it is the times increase in ventilation produced by a given set of conditions over that observed at rest.

FIG. 31.3 Single breath analysis using rapid, continuous gas analyzer. See text for explanation. (Reproduced by permission from Comroe *et al.*, *The Lung Year Book Publishers, Inc., Chicago*, 1955.)

ALVEOLAR AIR

This is the air contained in the air sacs and alveoli. Its gases come into equilibrium with those in the blood of the pulmonary capillaries. The alveolar air continually is being renewed largely as a consequence of the respiratory movements, but since the lungs are not emptied during expiration, it is quite clear that complete renewal of the air cannot be effected by a single respiration. The ventilation of the lungs occurs by the mechanical mixing of the inspired air with the volume of air known as the FRC and by the slower process of diffusion. During expiration the air of the upper respiratory passages is first expelled, then follows a part of the air of the bronchial tree. At the end of expiration the air which has been in the distended alveoli, since these have been reduced in capacity, now overflows into the bronchioles and bronchi. At the next inspiration this air is swept back again into the air sacs, its place being taken by fresh atmospheric air. The latter as compared with the alveolar air has a high oxygen pressure and a low pressure of carbon dioxide. Oxygen, therefore, diffuses from the inspired to the alveolar air and carbon dioxide diffuses from the alveolar air to the inspired air.

Methods of obtaining alveolar air samples. One method of obtaining alveolar air is as follows. The subject, after a normal expiration, makes a forced expiration through a Haldane tube of the type shown in figure 31-4. Toward the end of this maneuver gas is drawn into the sampling bulb. It is assumed that the last portion of air exhaled has the same composition as alveolar air, however, continued exhalation beyond the normal end-expiratory position has an effect on alveolar air composition somewhat like that produced by breath holding for the period during which forced exhalation is performed. Consequently when this method is used the value for $p\text{CO}_2$ may be a little too high and that for $p\text{O}_2$ a little low. Rahn (1954) believes that the gas which is exhaled four fifths of the way along a normal expiration most nearly approaches the mean composition of alveolar air. Rahn and Otis (1949) devised a method for collecting small portions of expired air at the appropriate phase of each expiration. The device is

FIG 31-4 Haldane tube and sampling bulb

referred to as an end tidal sampler. Samples collected by this method have a mean $p\text{CO}_2$ which is about 25 mm Hg lower than those obtained from the same subjects by the Haldane Priestley method and a $p\text{O}_2$ which is 43 ± 0.6 mm Hg higher. The alveolar $p\text{CO}_2$ values obtained by the end tidal sampler are reported to approach more closely those for arterial $p\text{CO}_2$, and this is presented as further evidence for the accuracy of the method on the grounds that it seems reasonable to assume that equilibration between alveolar $p\text{CO}_2$ and capillary $p\text{CO}_2$ in lungs is complete.

The average volumes per cent of O_2 in alveolar air, reduced to standard temperature and pressure, is around 14.2 and the figure for CO_2 is around 5.5. The percentage in the lungs is reduced however as a result of dilution with water vapor of which about 6.2 volumes per cent is present. The $p\text{CO}_2$ of alveolar air usually is around 39 to 40 mm Hg in normal resting subjects at sea level and under the same conditions the alveolar $p\text{O}_2$ is around 100 mm Hg.

Atmospheric air at STP contains 20.94 volumes per cent of O_2 and 0.04 volumes per cent of CO_2 . This gives a $p\text{O}_2$ of about 160 mm Hg and a $p\text{CO}_2$ of about 0.3 mm Hg.

Alveolar Capillary Diffusion and Diffusing Capacity

With a normal alveolar $p\text{O}_2$ of 100 mm Hg the diffusion gradient for oxygen at the arterial end of the capillary is around 60 mm Hg and decreases exponentially toward the venous end of the capillary where it may be only 0 to 10 mm Hg. The mean $p\text{O}_2$ gradient between alveolar air and lung capillary blood was calculated by C. Bohr (1909) to be 15 mm Hg in resting subjects and 30 mm Hg during severe exercise. Bohr developed the concept of 'diffusion constant' of the lung which is now known as 'diffusing capacity.' This quantity is written D_{O_2} or $\text{D}_{\text{L}\text{O}_2}$ and is defined as the number of milliliters of oxygen which are taken up by the blood per minute at an average $p\text{O}_2$ gradient of 1 mm Hg between the alveolar air and the lung capillary blood. Since rate of diffusion is proportional to the pressure gradient, O_2 uptake (V_{O_2}) = diffusing capacity (D_{O_2}) $\times$ average $p\text{O}_2$ gradient.

Measurement of diffusing capacity. To measure the diffusing capacity for oxygen three measurements are necessary: (1) ml of O_2 passing from alveolar air to blood per minute, (2) mean alveolar O_2 pressure, and (3) mean pulmonary capillary O_2 pressure.

$$D_{O_2} = \frac{\text{ml of } O_2 \text{ passing from alveolar air to blood per minute}}{\text{mean alveolar } pO_2 - \text{mean capillary } pO_2}$$

Item number 1 is measured as in the BMR test. For item 2 the most accurate figure is obtained by use of the alveolar air equation (This equation applies the principle that the total pressure of the four gases in the alveoli equals the barometric pressure. Hence if the partial pressures of CO_2 , N_2 and H_2O vapor are known the oxygen tension can be obtained by subtraction. Water vapor is assumed to be 47 mm Hg. pCO_2 is determined for arterial blood which is assumed to be in equilibrium with the pCO_2 of alveolar air and pN_2 can be calculated accurately if the respiratory exchange ratio is determined.) Item 3 has been computed by Bohr's integration procedure from the following: (1) pO_2 of mixed venous blood (which is what enters the pulmonary capillaries) (2) pO_2 in alveolar air (3) pO_2 in the blood at the end of the pulmonary capillaries and the physiological oxygen hemoglobin dissociation curve. Forster emphasizes the point that the most difficult problem is the measurement of end capillary pO_2 since there is no way of obtaining a sample to analyze. It is apparent that indirect methods for obtaining this figure involve the introduction of the experimental errors of the several tests involved and also the setting up of several assumptions some of which probably are unwarranted. Furthermore it is probable that the value for pO_2 in mixed end-capillary blood even if it were determined accurately would be of no real use since in a large proportion of the pulmonary capillaries the alveolar-capillary pO_2 gradient most likely becomes zero before the blood reaches the end of the capillary. The relatively slight difference in alveolar pO_2 and that of blood returning to the left atrium may be attributed to mixing of blood from poorly aerated portions of the lung with that from well aerated alveoli where equilibrium may be presumed to be complete well before the blood reaches the venular end of the capillary. It seems quite possible that the values calculated for the mean alveolar capillary pO_2 difference in the resting subject may be as much as two to three times that which actually is present. It is probable also that the amount of the error which is introduced in postulating that equilib-

rium between alveolar air and pulmonary capillary blood is not reached until the blood arrives at the end of the capillary is much greater at rest than during exercise when rate of blood flow is increased and this could explain a large part of the increase in the figure for DL_{O_2} in exercise as compared with that of the subject at rest.

Forster (1957) states that certain facts which he tabulates make it apparent that each method of measuring DL actually measures something different. The methods referred to are the DL_{O_2} , steady state method, the DL_{CO} steady state method (three modifications) and the DL_{CO} breath holding method (two modifications). Obviously if each measures something different only one could measure the specific membrane properties which physiologists wish to measure and it is possible at present that none of the methods in use measures any single specific aspect of lung function.

To summarize the situation with references to measurements of DL it would seem that one of the factors needed in the calculations namely the mean alveolar capillary pO_2 difference has not been determined accurately and consequently the errors involved probably are quite large.

THE CONTROL OF BREATHING

Control of Inspiration and Expiration

As described in chapter 30, inspiration during eupnea is accomplished by contraction of certain muscles, such as the diaphragm and external intercostals, which may be called *primary* muscles of inspiration, while expiration is the result of the elastic recoil of the lungs and thoracic cage, and the action of gravity when the inspiratory muscles relax. With increased demands for ventilation, additional muscles, collectively called *accessory* muscles of inspiration, are activated to produce a more rapid and deeper inspiration, certain muscles also contract during expiration to accelerate the return of the chest to the resting end-expiratory position. In eupneic breathing, therefore, for inspiration and expiration to occur it is necessary simply for the motor neurons supplying the primary muscles of inspiration to show intermittent bursts of activity.

The initial observation which is important in considering regulation of breathing is that apnea occurs when the CO_2 tension of the blood is below certain levels if at the same time the O_2 tension is above certain levels. This situation can be produced simply by hyperventilating with atmospheric air, or an even longer period of apnea can be produced by hyperventilating with oxygen. After hyperventilation is terminated apnea will supervene until CO_2 tension becomes elevated to a certain level or until O_2 tension becomes lowered below certain levels. Thus it is seen that the initiation of breathing after hyperventilation depends upon stimuli which derive either from a rise in CO_2 tension or from a fall in O_2 tension or from an interaction of these changes.

The relative importance of CO_2 and O_2 in influencing breathing in an individual at sea level (ambient pressure of 760 mm Hg) is illustrated when the percentages of these gases in inspired air are altered. If the O_2 percentage is increased above the amount normally found, even up to 100%, negligible influences on rate and depth of breathing are observed. Also, if the amount of $\frac{1}{2}\text{O}_2$ in inspired air is moderately lowered, namely,

down to about 18%, typically, little or no change in breathing is observed. Some persons will show stimulation of breathing as the O_2 is lowered to around 16% and levels of 10 to 12% regularly cause hyperpnea. From these facts it is apparent that reduction in O_2 tension is not an important factor in regulation of breathing until the tension is reduced below some critical level which is somewhat lower than that found in normal resting subjects breathing air at a pressure of one atmosphere. Any slight increase in the CO_2 tension of arterial blood, on the other hand, causes an increase in breathing and a decrease in CO_2 tension is associated with apnea even when the O_2 tension is moderately below that which is found normally at sea level. Such facts provide a basis for the interpretation that the inspiratory process at sea level in normal subjects is related to the action of CO_2 on certain neurons in the respiratory center in the medulla oblongata, causing them to discharge, and the termination of inspiration resulting in expiration, occurs as a result of "feed back" of inhibitory influences to these neurons. This mechanism serves to keep the CO_2 tension of arterial blood at a constant level of about 38 to 40 mm Hg in the presence of wide fluctuations in O_2 tension of arterial blood as long as the latter are at levels from about 80 to 90 mm Hg and up.

The Respiratory Center

It is customary and convenient to speak of the collections of nerve cells in the brain stem which are concerned with the integration of the activity of the muscles of respiration as the *respiratory center*. But the use of the term should not be taken to imply that the controlling nervous elements are a compact circumscribed mass, or confined to a closely restricted area. Section through the brain at any level rostral to the upper border of the pons usually does not alter significantly the respiratory rhythm. But sections at various levels behind this cause pronounced disturbances in respiration. If a cut is made through the medulla

caudal to the tip of the calamus scriptorius, all breathing ceases.

Legallois (1824) located the respiratory center in the lower part of the medulla oblongata, and Flourens (1842, 1858) found a small spot about the size of a pin's head just beneath the forepart of the calamus scriptorius in the floor of the fourth ventricle, on either side of the midline. He showed that after bilateral destruction of this area, which he named *nœud vital* (vital knot), the respirations ceased. It appears, however, that the respiratory failure in these animals could have been secondary to circulatory failure related to loss of vaso-motor tone.

Markwald (1887) described powerful and prolonged tonic inspiratory movements or 'cramps' which supervened after bilateral section of the vagus nerves and division of the brain stem immediately behind the posterior colliculi. He concluded that a center inhibitory to inspiration was located in the latter situation, but that the vagi also had an inhibitory action, consequently the inspiratory "cramps" appeared only after vagal influence had been abolished as well. Markwald's observations were confirmed shortly afterwards by other experimenters. The subject was studied further by Lumsden (1932), who found that the prolonged inspiratory movements occurred only if the section passed through the pons a few millimeters behind its anterior border and occurred whether or not the vagi were divided. The inspiratory cramps or *apneuses*, as Lumsden preferred to call them, last for several seconds. He postulated their dependence upon an *apneustic* or *inspiratory* center at the level of the *strææ acusticæ*, which was dominated normally by an inhibitory or *pneumotaxic* center situated in the upper part of the pons. The duty of the latter center was, through its inhibitory influence, to help to transmute the apneustic movements into the rhythmical movements characteristic of normal respiration. After section of the brain stem behind the *strææ acusticæ*, the respirations consisted of a series of gasps occurring at relatively long intervals. Lumsden concluded that these represented the activity of a primitive *gasp* center situated in the lower part of the medulla from which the two higher centers had evolved. It was considered to be of little importance in higher animals.

Lumsden's results were confirmed in the main by Stella and by Pitts, Magoun and Ranson. Stella, however, found in contradiction to Lumsden, that section through the pons (i.e. separation of the pneumotaxic center) did not result in

FIG. 321 Showing apneusis. Section of the brain stem along a plane passing dorsally immediately behind the posterior colliculi, and ventrally 2.5 mm. below the upper border of the pons. Between *x* and *z* the vagi were blocked by cold. Time 2 sec. (After Stella.)

apneusis unless the vagal influence was abolished also (see fig. 321). The results of Pitts and his associates are in essential agreement with those of Stella. They found that animals decerebrated through the upper part of the pons maintained a normal type of respiration which responded in the usual way to chemical and peripheral nerve stimulation so long as the vagi were intact but immediately developed apneustic respiration and a complete cessation of rhythmical movements when both vagi were severed. Stimulation of the central end of one of the cut vagi temporarily restores the respiratory rhythm. The apneustic center is therefore under a double inhibitory influence, either one of which is capable of converting the apneustic type of respiration to the rhythm of normal or nearly normal respiration. The vagal impulses influencing the apneustic center are initiated by the stretch of the lung towards the latter part of the inspiratory phase of normal breathing. Studies by Cohen (1938) indicate that the pneumotaxic center shows rhythmic activity synchronous with breathing when its connections with the respiratory center are intact but fails to show rhythmicity when these pathways are cut.

The apneuses like normal respirations are affected powerfully by the CO_2 tension of the blood, being increased in depth by having the animal breathe an air mixture containing a high concentration of CO_2 and reduced in depth, or prevented from occurring, by carbon dioxide lack. According to Stella the pneumotaxic center is bilateral but its connections with the

apneustic center are mainly homolateral, i.e. uncrossed

Pitts, Magoun and Ranson describe the respiratory center in the cat, which they locate in the reticular formation of the medulla, as consisting of an inspiratory and an expiratory division, both centers are bilaterally represented. The *inspiratory center* occupies the rostral half or two thirds of the reticular formation overlying the olivary nuclei on both sides, i.e., beneath the caudal third of the floor of the fourth ventricle (fig 322). When stimulated a maximal co-ordinated inspiration results, involving both diaphragm and thorax. If stimulated during apneusis, the magnitude of the inspiratory movement is increased, if stimulated during an interval between apneuses, an apneustic movement is produced. The *expiratory center* lies in the reticular formation dorsal to the inspiratory center. Electrical stimulation within this area causes expiration. If stimulated during inspiration or during apneusis, these movements are inhibited. Regular respirations—inspiration alternating with expiration—are induced by rhythmical stimulation of the inspiratory center, expiration then occurs passively. Rhythmical stimulation of the expiratory center also produces regular respiration, spontaneous inspirations then alternating with the expiratory movements. Intimate synaptic connections exist between the diffusely distributed neurons within each center and between the two oppositely acting

FIG 322 Dorsal view of lower brain stem of cat showing location of pneumotaxic (PN), inspiratory (INSPI) and expiratory (EXP) centers. Extent of expiratory center shown in light stippling. Extent of inspiratory center in heavy stippling. Though the centers are bilateral each is outlined on one side only, for the sake of simplicity. IC, olivary nucleus; AT, acoustic tubercle; BP, brachium pontis; CN, cuneate nucleus; V, vagus nerve. (Redrawn from Pitts, Magoun and Ranson)

FIG 323 Diagram illustrating the chief nervous connections responsible for the control of the respiratory rhythm. Inspiratory and expiratory centers in the medulla on the right side surrounded by dotted circles. (After Pitts, slightly modified)

centers on the same side, as well as between similarly acting centers on opposite sides of the medulla. Thus, unilateral stimulation of a small area of the inspiratory center causes maximal contraction of all the inspiratory muscles. Excitation of one center causes simultaneous activation of its fellow of the contralateral side, accompanied by reciprocal inhibition of both oppositely acting centers. Thus, the alternating rhythm of inspiration is established and sustained, and the respiratory movements synchronized on the two sides of the body. The functional importance of the bilateral connections is demonstrated in a striking manner by making a deep longitudinal cut through the midline of the caudal part of the medulla, then the respiratory rhythms on the two sides of the body become asynchronous (see fig 323).

The similarity in the effects of stimulation of the expiratory center and of the central end of the vagus, namely, inhibition of inspiration and of apneusis, has led Pitts and his colleagues to the conclusion that the vagal respiratory effects are mediated through the expiratory center. The influence of the pneumotaxic center probably is exerted in the same way.

The respiratory center is connected with the motor neurons of the phrenic and intercostal nerves in the cervical (C 3, 4 and 5) and upper thoracic segments of the cord (T 2-6) by descending tracts which run in the anterior columns and in the ventral parts of the lateral columns of the spinal cord

THE SPONTANEOUS ACTIVITY OF THE MEDULLARY RESPIRATORY CENTERS

This has been a subject of interest to physiologists for many years. Some investigators, such as Coombs and Pike, and Schafer, have denied that the center is capable of spontaneous activity, maintaining that afferent impulses, especially those set up in the lung by the stimulus of stretch and conveyed by the vagus, and those initiated from proprioceptors in the respiratory muscles and travelling by the posterior nerve roots, were essential. However, the results secured within recent years by means of improved methods of investigation leave little reason to doubt that, in certain species at least, the brain stem continues to discharge impulses to the respiratory muscles after all or nearly all afferent paths have been severed. For example, rhythmical bursts of impulses can be recorded from the central stump of the phrenic nerve of a decerebrate animal after section of the vagi, glossopharyngeal and other cranial nerves entering the pons and medulla, and division of the spinal cord below the level of the 7th cervical segment. Such an extensive operation would certainly interrupt all important afferent paths including those from the carotid sinus and the aortic arch. It is not to be supposed, of course, that the respirations would be normal after such a radical procedure, for even if not essential for maintaining the activity of the center, afferent nerve influences are of the utmost importance in the regulation of that activity and the production of the normal respiratory rhythm. Evidence for automaticity of the respiratory center of a cold blooded species has been secured by Adrian and Buytenhek. They succeeded in re-

corded rhythmical action potentials from the excised brain stem of the gold fish, the potential changes had the same range of frequency as the respiratory movements (fig. 32.4)

The spontaneous respiratory activity is apparently dependent primarily upon the inspiratory center, the expiratory center playing an inhibitory role to interrupt intermittently the inspiratory discharge. As shown by Cohen (1958) impulses are not discharged spontaneously from the pneumotaxic center. Pitts and his colleagues suggest that the pneumotaxic center is excited from the inspiratory center, that a proportion of the impulses discharged from the latter region ascend to the pontine center whence impulses descend to the expiratory center, a discharge of inhibitory impulses is transmitted from the latter to the inspiratory center. As the discharge of impulses from the expiratory center ceases, the inspiratory center resumes its activity, and the cycle is repeated. A rise in the rate of discharge of the inhibitory impulses will increase the rate of breathing, while a reduction in the frequency of the discharge will be followed by slowing of the respirations.

It appears, then, that in the intact animal the automatic alternating rhythm of the medullary centers is maintained largely by inhibitory impulses from the pneumotaxic center and vagal afferents impinging upon the expiratory centers, which in turn inhibit, intermittently the activity of the inspiratory centers. The vagal influence is evoked by inflation of the lungs (i.e., by inspiration), expiration, a passive act follows (cb. 30). Under ordinary physiological conditions the vagal regulating influence appears to play the dominant role.

Of the two main methods which have been used for localizing inspiratory and expiratory centers, namely stimulation versus "sounding" for action potentials, the latter would seem to be somewhat more suitable. Stimulation serves to expose only a dominant or major influence. Neurons having opposite effects could be pre-ent and could be

FIG. 32.4 Comparison of electrical potential wave rhythm and rhythm of respiratory movements (After Adrian and Buytenhek)

stimulated simultaneously, but the effects of the dominant one of the two groups would be expected to appear. Hence, inspiration elicited from a given site would not rule out the possibility that expiratory neurons are present in this region, nor could an expiratory response elicited from a specific site prove that no inspiratory neurons were being stimulated simultaneously. According

to Brookhart (1940) lower strengths of stimuli applied to the regions in which the inspiratory center and expiratory center are supposed to be located will elicit various types of effects, and somewhat stronger stimuli are required to produce the effects reported by Pitts and coworkers. On the other hand the recording of a burst of impulses only during one phase of the respiratory

FIG. 32.5 Schematic representation of organization of central respiratory mechanisms in the brain stem of the cat. Key to transection levels is indicated above. In vagotomized cats transection rostral to level 1 allows eupnea to be present, transection between level 1 and 2 causes apneustic breathing to appear, transection between 2 and 3 results in eupneic breathing or gasping or occasionally Biot's breathing, and transection caudal to level 3 is followed by absence of respiration (reproduced by permission from Wang, Ngai, and Frumin)

cycle would constitute evidence that only the inspiratory or expiratory neurons, depending on the time relations, were activated at that site under the conditions of the experiment. When the "sounding" method is used, according to Gesell, Bricker and Magee (1930), for the most part, impulses are recorded from a given site during both inspiration and expiration. This would indicate that expiratory and inspiratory neurons are intermingled and would tend to make one doubt that there are anatomically discrete expiratory and inspiratory centers.

A difficulty with the "sounding" method for determining the location of inspiratory and expiratory neurons of the respiratory center is that impulses may be picked up directly from motor neurons. Achard and Bucher (1954) investigated the region of the respiratory center with needle electrodes and determined by subsequent histological examination the precise cells from which recordings were obtained. Any purely inspiratory activity obtained by them was from motor neurons involved in inspiration, while action currents recorded from numerous other electrodes located in the area of the respiratory center did not permit a distinction between respiratory rhythms and the continuous asynchronous "background" activity in the reticular substance. It must be concluded, therefore, that the question of the precise location of inspiratory and expiratory neurons within the medulla has not yet been answered.

The relative importance of the pneumotaxic center in maintaining rhythmic breathing after vagotomy seems to differ according to the species of animal studied and the conditions of the experiments. According to Hoff and Breckenridge (1954) in dogs, and under certain conditions in cats, midpontine section combined with bilateral vagotomy does not cause cessation of breathing. This has been confirmed by Wang and coworkers. In fact vagotomy has been reported to have no effect on breathing in some instances in animals having the brain stem sectioned in the midpontine region. Hoff and Breckenridge have returned to the view that the cause of the rhythmic discharge of respiration lies within the medulla itself. "Just how the rhythm of respiration develops within the medulla is still problematical, and it may well be possible that within the confines of the medulla itself anatomical pathways are to be found wherein reciprocating self-limiting circuits, akin to those postulated between medulla and pons in earlier hypotheses, determine the rhythm of breathing."

FIG 32-6 Schematic representation of functional concept of central regulation of respiration. Relative locations in the brain stem of a cat of the regions which subservise the various functions are indicated (reproduced by permission from Brodie and Borison).

The situation at present can be summarized by stating that the presence of a respiration-regulating group of neurons in the upper pontine region, the so-called pneumotaxic center, has been clearly demonstrated and has an important role in regulation of rhythmic breathing in the intact animal. However, it seems to be clearly demonstrated, also, that rhythmic breathing still can occur when both this mechanism and the vagal reflexes are eliminated. Finally, the precise manner in which the pontine elements influence respiration has not been determined. In figures 32-5 and 32-6 are shown two recent attempts to explain the organization of the respiratory center.

Hering-Breuer Reflexes

The Hering-Breuer reflexes are effects on the respiratory cycle which are elicited by inflation and deflation of the lungs. The receptors concerned are in the lungs, and the afferent pathways are in the vagus nerves. The function of these reflexes apparently is to regulate the respiratory

FIG 32.7 Diagram to illustrate the reflex and chemoreflex control of respiration

cycle rather than to alter significantly the pulmonary ventilation for any prolonged period. The observations made by Hering and Breuer in 1868 were that inflation of the lungs causes arrest of inspiration, expiration then ensuing, and deflation of the lungs has an inspiration-exciting effect. They found that these effects were abolished when the vagus nerves were sectioned. Another way to demonstrate the effects of lung

distention is to block the airway at the beginning of either inspiration or expiration. When inflow of air is prevented, a stronger inspiratory effort results than in the preceding cycle, and when egress of air is blocked at the end of inspiration a longer interval than the preceding one occurs before the onset of the next inspiratory effort. In eupnea apparently the inflation effect during inspiration alone is a factor. As inspiration proceeds, distention of the lungs occurs, and impulses are carried by vagal afferents to the respiratory center where they cause inhibition of the inspiratory neurons, thus terminating inspiration. Once the lungs begin to deflate, impulses are no longer set up in the vagal afferents and, consequently, the inspiratory neurons again are free to discharge in response to their local chemical environment.

The mechanical problem in studying the Hering-Breuer reflexes can be circumvented in the case of the rabbit since this animal has a slip of muscle on the posterior surface of the diaphragm which can be dissected free and recorded from separately from the remainder of the diaphragm (fig 32.7). This diaphragmatic slip can be used as an indicator of the degree of activation of inspiratory muscles. If the lungs are distended, the rate and amplitude of contraction of the slip decrease, and if the lungs are deflated, an increase in rate and amplitude of contraction of the slip is observed (fig 32.8).

The stimulating effect of lung deflation on

FIG 32.8 Record of contractions of isolated slip of a diaphragm of a rabbit to illustrate Hering-Breuer reflexes. Upstroke is produced by contraction of the slip, i.e. inspiration. Above at + the trachea was occluded at the end of expiration and at 0 the obstruction was removed. Below at + the trachea was occluded at the end of inspiration, and at 0 the obstruction was removed (after Head).

inspiration is related under ordinary conditions to failure in the production of the normal amount of inspiration-inhibiting influence at the end of inspiration. However, severe deflation, as from pneumothorax, results in activation of other receptors, and reflex stimulation of inspiration follows. Finally, if lung inflation is severe, not only is inspiration inhibited but active expiration is elicited reflexly. This may not require a third type of receptor, but may be simply the result of greater degree of activation of the same kind of receptors which are concerned in the reflex inhibition of inspiration. The role of vagal reflexes in regulating inspiration and expiration has been described in detail by Wyss (1954).

A physiological role of the Hering-Breuer reflexes is to regulate the extent of lung inflation so that the tidal volume tends to fall within a certain range. Also, these reflexes serve to insure filling and emptying of the lungs despite a considerable increase in resistance in the airway. As would be expected, the typical result following bilateral vagotomy is an increase in the depth of breathing. The inspiratory act under these conditions is seen to be unnecessarily long since the chest tends to remain in the inspiratory position for a short period after ingress of air has stopped. This is an inefficient process since muscular work is being done while no air is being moved. Also, a decrease in respiratory rate develops in most animals after vagotomy. This probably is a compensatory change, secondary to the increased depth, which results in an amount of pulmonary ventilation similar to that which was present before vagotomy. An increased depth of breathing without a decrease in rate would soon wash out CO_2 so that the stimulus to the respiratory center would be removed, hence the rate soon would decrease to cause restoration of normal CO_2 levels. It should be mentioned, however, that the effects of vagotomy on rate and depth of breathing vary greatly depending upon the anesthetic agent which is used, and furthermore, changes are progressive for a prolonged period following vagotomy.

The effects on respiration of direct stimulation of the central end of the vagus nerve sectioned at the cervical level are somewhat unpredictable since the nerve contains several types of afferent fibers which carry impulses to the respiratory center. These include (1) aortic arch afferents, (2) aortic body afferents, (3) inspiration-inhibiting fibers activated normally during lung inflation, (4) inspiration-exciting fibers activated

physiologically by excessive lung deflation, (5) fibers concerned with visceral pain, and possibly still other types of fibers. However, strong stimulation of the central end of the vagus nerve usually causes apnea, and this may persist for a few seconds after cessation of stimulation. This result could be elicited if the effects of stimulation of (1) and (3) above were sufficient to override the effects of stimulation of (2) and (4).

The Hering-Breuer reflexes are basically proprioceptive in nature. In this case contraction of skeletal muscle not only increases the tension in muscles and shortens them but elastic objects, the lungs, also are put under greater tension. The lungs also are supplied with receptors from which information is carried back to the same neurons that activated the muscles. The muscles of respiration, like skeletal muscle in general, are supplied with proprioceptive innervation through which their contraction is regulated in the same way as described for the limb musculature. After vagotomy, breathing is still possible, although it is altered considerably, and some degree of proprioceptive control still is retained.

Reflex Effects from Pressoreceptors

A sudden rise in pressure in the sino-aortic zones elicits reflexly a decrease in rate and depth of breathing. If the pressure rise is considerable apnea may be produced. Typically, adaptation is rather rapid so that breathing is restored even though the new pressure level is maintained. Part of the recovery of respiration is related to adaptation in the receptors themselves, but also it occurs as a consequence of the rise in pCO_2 during apnea. The opposite change, a sudden fall in pressure in the sino-aortic zones, elicits hyperpnea. Thus, any sudden change in blood pressure *per se* tends to elicit respiratory responses. During rapid bleeding or following injection of vasodilator drugs, such as nitroglycerin or bethanechol (a choline derivative), respiration is stimulated (fig. 32-9), and the effect is prevented in considerable part by sino-aortic denervation (Schopp, Gilfoil and Youmans, 1957). The respiration stimulating effect of nitroglycerin which still remains after denervation can be partly or completely prevented if a device is used to prevent the fall in arterial blood pressure.

Schmidt in 1941, and recently Aviado and Schmidt (1955) have suggested that the effects on respiration elicited from the pressoreceptors serve no physiological purpose, however, this mechanism probably is of importance in influence-

FIG 329 Effects on blood pressure (*below*) and respiration (*above*) following injection of 0.1 mg per kg of nitroglycerin into dog anesthetized with alpha chloralose. The respiratory stimulation can be prevented if the fall in arterial blood pressure is counteracted by means of rapid infusion of blood from a pressure regulating device (from studies by Schopp, Gilfoil and Youmans)

ing the venous return (Youmans, 1958). Vasodilation promotes pooling of blood, especially in the abdominal viscera, and increased respiratory activity promotes the movement of blood from the abdominal portion of the inferior vena cava on into the thoracic portion. The concept of the respiratory pump, as a factor in aiding venous return, introduced by Donders in 1859, seems accurate according to the studies reviewed by Brecher (1956). Conversely, the respiratory inhibition during a rise in blood pressure, especially in a person in the orthostatic position, would favor pooling of blood in the splanchnic region so that venous return would be decreased, thus cardiac output would be lowered, and the rise in blood pressure would be counteracted. In short, one may interpret the respiratory responses from pressoreceptors, along with effects on heart rate and arteriolar tonus elicited at the same time, as being concerned with the stabilization of arterial blood pressure. The characteristics of these reflexes are such that they are useful in counteracting sudden changes of brief duration; they are not concerned with counteracting prolonged changes.

Regulation of Pulmonary Ventilation

Respiratory Adjustments to CO_2

The CO_2 content of inspired air is negligible, as far as human physiology is concerned, and can be increased somewhat without causing an increase in RMV. Its concentration at sea level can be increased by about 1% (7.6 mm Hg) before a measurable increase in pulmonary ventilation occurs. If 4% CO_2 is breathed, the RMV is approximately doubled on the average, but the effect may be scarcely noticed by the subject. Any further increase in CO_2 from 4% up to 10% produces a correspondingly greater RMV, and at the latter level it may be 8 to 10 times the resting level. Also the subject may have symptoms of dizziness, faintness and headache. Increasing the CO_2 percentage beyond 10 does not result in significantly greater increases in RMV, and at levels above 20% the RMV may begin to show a decrease. Also, these levels cause convulsive seizures. From the practical standpoint it would appear that if CO_2 is to be administered to stimulate breathing, there would be little use for any mixture containing less than 5% or more than 10% CO_2 .

It is generally agreed that the primary site of action of CO_2 in producing effects on breathing is in the inspiratory division of the respiratory

center. Cells in a respiratory center that has been isolated from extrinsic neural influences show alterations in rates of discharge in response to corresponding changes in pCO_2 of the blood reaching them, and injection of bicarbonate directly into the respiratory center causes an increased activity of these neurons. Considerable attention has been given to the question of the precise mechanism by means of which CO_2 exerts its stimulant action on the respiratory center. It has been debated whether CO_2 per se has such an effect or whether the effect is exerted indirectly as a consequence of the concomitant increase in pH . There is evidence that both a rise in pCO_2 and in pH in the respiratory center contribute to and supplement each other in causing an increase in pulmonary ventilation.

Another mechanism, reflex in nature, is available for the stimulation of breathing as a consequence of a rise in the pCO_2 of arterial blood. The chemoreceptors, already described as concerned with producing circulatory adjustments in response to changes in pO_2 and pCO_2 , when subjected to a sufficient rise in pCO_2 will elicit an increase in RMV. The extensive literature dealing with chemoreceptors has been summarized by Heymans and Neil (1958). The fact

of reflex stimulation of breathing in response to rises in $p\text{CO}_2$ of the blood flowing to the aortic and carotid bodies has been demonstrated by a number of methods and is generally accepted. A question which has been vigorously disputed, however, is whether the respiratory center in the intact subject is more sensitive than the chemoreceptors. In other words does the chemoreceptive reflex mechanism constitute the first line of defense against a rising $p\text{CO}_2$ in arterial blood or does the respiratory center have the greater sensitivity. Heymans has supported the view that the chemoreceptors are concerned with reflex drive of breathing even under resting conditions at sea level, while Schmidt and Comroe favor the interpretation that these receptors are activated in significant degree only after considerable increases in arterial $p\text{CO}_2$. The details of the argument are reviewed by Heymans and Neil, who conclude that the question remains open as to how much the chemoreceptors participate in the response to moderate hypercapnia in the intact animal. However, the majority viewpoint seems to be that the normally sensitive respiratory center responds to rising CO_2 and through increased ventilation prevents a rise in $p\text{CO}_2$ of arterial blood sufficient to elicit a response from chemoreceptors. If, on the other hand, the respiratory center is rendered relatively insensitive to CO_2 , for example, by anesthetic agents and narcotic drugs, respiration is depressed, and $p\text{CO}_2$ rises to a level sufficient to set up chemoreceptive drive of breathing. According to the latter interpretation the CO_2 -induced chemoreflex constitutes a secondary line of defense to help insure pulmonary ventilation when the sensitivity of the respiratory center is reduced.

The lowering of $p\text{CO}_2$ in arterial blood can be achieved by voluntary hyperventilation or by excessive artificial ventilation of anesthetized subjects. Following hyperventilation, apnea is observed, and breathing is resumed when either $p\text{CO}_2$ rises to approximately the level found in the subject under resting conditions or when the $p\text{O}_2$ of arterial blood drops to a level sufficient to set up reflex drive of breathing on an O_2 lack basis, whichever occurs first. After one has hyperventilated moderately with atmospheric air, oxygen lack develops quickly as the store of oxygen in the lungs is absorbed and utilized, breathing is resumed in sequence to the oxygen lack stimulus before the $p\text{CO}_2$ has been restored to the normal resting level. Then the oxygen lack is relieved by a few breaths, and apnea appears again. Gradually, the $p\text{CO}_2$ level becomes restored and takes

over as the sole drive. This is the basis for the appearance of a few cycles of periodic breathing after hyperventilation. As would be expected if one hyperventilates with 100% O_2 , rather than air, just as much CO_2 is blown off as before, with a given degree of respiratory activity, but the $p\text{O}_2$ in alveolar air is quite high at the end of the period of hyperventilation. Consequently a longer time will be required for the O_2 -lack stimulus to appear than for the $p\text{CO}_2$ level to be restored. Therefore, following hyperventilation with 100% O_2 the elevation of $p\text{CO}_2$ may be the initial factor in the restoration of breathing.

Respiratory Adjustments to O_2

The $p\text{O}_2$ in inspired air can be reduced by lowering the atmospheric pressure in a decompression chamber in which the subject has been placed, or he may breathe prepared gas mixtures having various ratios of O_2 to N_2 . Since O_2 tension is lowered in proportion to the decrease in barometric pressure with altitude, one may indicate the altitude at which the experimentally induced $p\text{O}_2$ would be encountered. Thus a certain altitude, as far as $p\text{O}_2$ is concerned, is simulated by the experimental conditions. For example, if one breathes a mixture of 10.5 per cent O_2 and 89.5 per cent N_2 at 760 mm Hg pressure, the $p\text{O}_2$ is about $\frac{3}{4}$ that in atmospheric air at the same pressure. This approximates the $p\text{O}_2$ found in atmospheric air at an altitude of 18,000 feet where the barometric pressure is about 380 mm Hg. The details concerning respiratory responses to $p\text{O}_2$ lower than that of room air at sea level have been described by Dripps and Comroe (1947) and by Rahn and Otis (1949). The major observations may be summarized as follows. Some subjects show a slight stimulation of breathing when the O_2 is lowered to 16 per cent to 18 per cent, while others do not respond until a level in the range from 16 per cent down to 12 per cent, or even lower in occasional subjects, is reached. At levels of 10 per cent or below, breathing is stimulated but irregularities may develop. As the O_2 tension in inspired air is lowered and respiratory minute volume increases the CO_2 tension in alveolar air and arterial blood falls. Thus at the same time that the oxygen lack stimulus is operating to cause an increased RMV, the CO_2 and CH drives of breathing are being withdrawn. It is apparent, therefore, that the stimulating effects of oxygen lack *per se* on breathing could be recorded if the fall in CO_2 tension were prevented, as by adding the appropriate amount of CO_2 to the inspired air. In the discussion of hyperventila-

tion it was noted that a relatively slight reduction in CO_2 tension (3 to 4 mm Hg) results in apnea when there is no accompanying O_2 lack. At altitude, therefore, where the CO_2 tension is lowered more than this (secondary to increased RMV), it must be assumed that respiratory drive is entirely on an oxygen-lack basis or that a readjustment in sensitivity to CO_2 tension has occurred. Acutely, the former seems to be true, while after prolonged exposure to low oxygen tension the latter change apparently occurs.

Papers on respiration written before the discovery of the chemoreceptors of the carotid bodies refer to a stimulant action of oxygen-lack on the respiratory center. It is now believed that a lowered O_2 tension in the medulla does not result in stimulation of breathing, and decreases in O_2 tension of arterial blood, within ranges that the animal can tolerate for significant periods, do not cause stimulation of breathing if the carotid and aortic bodies have been denervated. Thus, the only sensitive mechanism which responds to oxygen-lack and elicits an increase in RMV is the chemoreceptor reflex. Here, too, as in the case of the CO_2 effect, the precise level at which a lowered arterial O_2 tension elicits stimulation of breathing is disputed. Comroe and Schmidt (1938) first reported that the O_2 tension in blood perfusing the carotid bodies was lowered to about 50 mm Hg before the receptors were activated, but others have reported the threshold to be above 100 mm Hg pO_2 . Experiments showing the effects on RMV of blocking the chemoreceptors do not serve to establish the level of activity under normal resting conditions if anesthetic agents are used, since, as already explained, these substances usually cause depression of the respiratory center so that some part of the drive of breathing is transferred to the chemoreceptors. If oxygen lack stimulates breathing only through activation of chemoreceptors, then depression of breathing should be produced as a result of breathing mixtures containing more O_2 than that found in atmospheric air. To be relevant to the question the experiment must be performed on normal, resting subjects at a barometric pressure of approximately one atmosphere, and the gas to be tested should differ from the control only in that an inert gas, such as nitrogen, is substituted for oxygen. Loeschke (1953) reported an 8 per cent reduction of RMV for about a minute when 32 per cent O_2 in N_2 was substituted for room air in unanesthetized man, and this was followed by a rise until equilibrium was reached after about 4 minutes.

On returning to room air, RMV increased a little for a few minutes and then returned to the control level. Dripps and Comroe (1947), however, reported only 3.1 per cent reduction in RMV caused by inhalation of 100 per cent O_2 , whereas Baker and Hitchcock (1957) found an increase in ventilation in response to 100 per cent O_2 . The results cited indicate that if there is any drive of breathing related to O_2 -tension effects in normal subjects at sea level it is so small that it can be detected only by very careful measurements. Furthermore, it is possible that even the slight increases in ventilation which have been reported are not related to the removal of chemoreceptor drive, but rather to a rise in pCO_2 tension in the respiratory center secondary to the vasoconstriction produced by high O_2 tension in the arterioles of the brain (See Kety, S. S. and Schmidt, C. F., 1948).

Effects of Hydrogen Ion Concentration and the Interactions between Respiratory Drives

Since changes in pCO_2 are accompanied by changes in pH, a question may be raised whether changes in hydrogen ion concentration as such have an influence upon breathing. Gray (1950) has emphasized the point that in metabolic acidosis pulmonary ventilation is greatly increased while arterial pCO_2 is below normal. Obviously then if it is true to begin with that only three drives (pO_2 , pCO_2 , cH) operate to control breathing, increased acidity per se is capable of stimulating breathing since neither of the other two factors has changed in a direction which would cause such stimulation. Gray further states that an increase in RMV is not regularly associated with an increase (and in fact may occur in the presence of a decrease) in drive related to any one of the three factors considered to be concerned with the control of pulmonary ventilation, however, at least one of three changes must be present: (1) rise in arterial pCO_2 , (2) decrease in arterial pO_2 , or (3) increase in arterial cH . It is envisaged that any one of these may assume the major role in driving respiration under certain circumstances. In the case of administering CO_2 the arterial cH increases almost linearly with the increase in arterial pCO_2 so that, according to Gray's multiple factor theory, the stimulation of breathing is greater than would be produced by either the rise in pCO_2 alone or the rise in arterial cH alone.

The evidence seems to be sufficient to establish

that the level of pulmonary ventilation in subjects at rest is determined by either the arterial $p\text{CO}_2$ tension, the arterial $p\text{O}_2$ tension, the arterial cH or by interaction of these three drives. The relationship between each of these drives and the other two has been discussed at length in physiological literature. Gray advanced the hypothesis that effects of the three factors are simply additive, and, in line with this view he presents an equation for calculation of the ventilation ratio (ratio of alveolar ventilation under new conditions to alveolar ventilation under control conditions) from the changes in $p\text{CO}_2$, $p\text{O}_2$ and cH of arterial blood.

According to Gray's theory if $p\text{CO}_2$ is lowered further below the level which leads to apnea because of lack of a CO_2 stimulus to the respiratory center, the $p\text{CO}_2$ effect is further subtracted. Stated in another way, if breathing is put on an oxygen-lack drive, the lower the $p\text{CO}_2$, the lower will be the amount of respiratory stimulation because of the lesser $p\text{CO}_2$ effect to be added to the oxygen lack drive. In experiments by Nielsen and Smith (1952) the alveolar $p\text{O}_2$ tension was maintained at constant low levels, eliciting O_2 -lack drive, while the effects of adding CO_2 were tested. It was found that CO_2 had no effect, or only a slight effect, on the ventilation under these conditions until a threshold value of arterial $p\text{CO}_2$ of about the same magnitude as that which causes initiation of breathing under normal conditions was reached. Hence, it appears that the CO_2 level does not at all influence the level of ventilation when breathing is being maintained by the hypoxic stimulus. Christensen (1954) comments that it is difficult to see how Gray's multiple factor theory can explain an unchanged ventilation when the alveolar and arterial $p\text{CO}_2$ are changed between 21 and 33 mm Hg at a constant alveolar $p\text{O}_2$. It seems possible that just as $p\text{O}_2$ is not a factor in respiratory regulation when it is above a certain level, $p\text{CO}_2$ may not be a factor at all when it is below a certain level.

Immediate respiratory responses to exposure to a given reduction in $p\text{O}_2$ in inspired air are of lesser degree than those which are seen after chronic exposure. Acclimatization occurs so that during prolonged exposure pulmonary ventilation is increased, as indicated by a further lowering of the alveolar $p\text{CO}_2$ beyond that observed initially. Rahn and Otis (1949) suggest that a rise in alkalinity of the blood due to decreased oxyhemoglobin saturation inhibits the respiratory stimulation that would be expected to result from

the decrease in $p\text{O}_2$ *per se*. Regardless of the mechanism of acclimatization which occurs during chronic exposure to lowered $p\text{O}_2$ in inspired air, when it has occurred, there is increased pulmonary ventilation, lowered alveolar $p\text{CO}_2$, increased alveolar $p\text{O}_2$ beyond that observed initially, and a lowered alkali reserve. During the process of acclimatization, alkali is removed by urinary excretion. The pH of the blood is within the normal range. It appears that other more complex changes in respiratory control are involved in the gradual adjustments to hypoxia. For example, the alveolar $p\text{CO}_2$ which is lowered initially may return to or even exceed the level in normal subjects at sea level, hence sensitivity of the regulatory mechanism to CO_2 must have become readjusted. In short, in acute hypoxia the CO_2 drive may be largely or completely eliminated, but it must be assumed that the CO_2 drive is in some degree restored during acclimatization.

Mechanisms of Hyperpnea during Exercise

During exercise pulmonary ventilation increases, and the rise is quite proportionate to the amount of increase in muscular activity. Since an increased rate of production of CO_2 and of acid metabolites and an increased rate of utilization of oxygen occur as a consequence of increased muscular activity, *a priori* it is logical to think that the respiratory stimulation is induced by the same three factors which are considered to operate in the resting subject. However, a number of studies show that muscular exercise is not regularly associated with either a decrease in arterial $p\text{O}_2$, or a rise in arterial $p\text{CO}_2$ or cH . In individual experiments none of these factors shows a change during exercise in the direction needed to elicit increased respiratory activity (Grodins 1950).

The $p\text{CO}_2$ of mixed venous blood is increased and the $p\text{O}_2$ decreased during exercise, but no respiration influencing receptor located on the venous side of the systemic circuit has been demonstrated. (The presence of bodies similar to the aortic bodies around the pulmonary artery and receiving a blood supply from it have been described, and if such receptors exist they might be expected to elicit stimulation of breathing during exercise.) There is evidence that respiration is stimulated reflexly by impulses arising in the working muscles or the joints which are acted upon by these muscles. Still another possibility is that during voluntary activity impulses are

directed in descending nerve tracts into the respiratory center to exert a stimulant effect. In any case it appears that accessory respiratory drives are brought into play during exercise so that increased ventilation may occur even before a change in $p\text{CO}_2$, $p\text{O}_2$ or cH have had time to occur at the sites upon which these stimuli act. The factors which are concerned in the stimulation of breathing, which most respiratory physiologists believe must be present in exercise over and above that related to the three chemical stimuli which operate under resting conditions are referred to by Grodins (1950) as the *exercise stimulus*. It is probable that afferent influences from various sources are concerned and also that chemical events not yet identified play a role.

Periodic Breathing

Under certain conditions irregular or "periodic" breathing may develop. There are two major types: Biot's breathing and Cheyne-Stokes breathing. In Biot's breathing there are periods of variable length during which breathing is present, and these alternate with apneic periods of different lengths. The transitions from the periods of activity to apnea and back are abrupt. In contrast to this in Cheyne-Stokes breathing, although periods of respiratory activity alternate with apneic periods, the amplitude of breathing increases gradually to a maximum and then decreases gradually until the next period of inactivity. Biot's breathing has been observed in meningitis and other pathological conditions affecting the medulla. Cheyne-Stokes respiration has been observed in a number of different circumstances, some of which are pathological and some physiological (fig. 32-10).

Cheyne-Stokes breathing occurs in some normal subjects at moderately high altitudes, (for example, 12,000 to 15,000 feet) and it may be seen in normal sleeping infants. Experimentally, it may be produced in normal subjects following a prolonged period of voluntary hyperventilation, and it can be produced by having the subject breathe deeply through a tube of a certain

length. In the latter case, the dead space is increased by a specific amount, and if there is too little or too much increase in dead space, Cheyne-Stokes breathing will not develop. Several drugs, notably morphine, will cause the appearance of Cheyne-Stokes breathing if given in adequate doses. The condition is commonly seen in persons suffering from chronic congestive heart failure, and in such cases the periodicity tends to be aggravated by sedation or during sleep.

The basis for Cheyne-Stokes breathing after hyperventilation, as explained on page 497, appears to be that oxygen lack drive makes its appearance and is relieved several times before the $p\text{CO}_2$ finally is built back up to levels sufficient to drive normal respiration. The oxygen lack drive presumably is via the chemoreceptors. However, there is evidence that two or more types of initial defect may cause Cheyne-Stokes breathing. For example, during periodic breathing there also are cyclic changes in the blood pressure level, and in some instances, the rise in mean arterial blood pressure occurs during the phase of respiratory activity while in other cases the rise in blood pressure is during the apneic phase. These two types most likely are related to quite different basic mechanisms. The former has been demonstrated to occur in dogs having the sino-aortic pressoreceptors and the carotid and aortic bodies denervated or isolated (Youmans and Schopp, 1957) hence chemoreceptive drive could not have been a factor. It is still probable, however, that the other type of periodicity is dependent upon a seesawing between reflex and central drives. Guyton (1956) has described experiments in which he found that Cheyne-Stokes breathing was produced if the time required for blood to flow from the heart to the brain was prolonged by increasing the length of the channels. Since circulation time is increased in chronic heart failure, this may be the change that initiates periodic breathing in patients suffering from this condition.

Eyster (1906) produced periodic breathing in dogs by elevating the intracranial pressure. His records show that breathing occurred when blood

FIG 32-10 Two examples of Cheyne Stokes breathing (After Lewis)

pressure rose above the level of the intracranial pressure, and apnea was present when the pressure was below this level. In clinical cases with increased intracranial pressure, Lyster observed the same pattern of cyclic changes in respiration and blood pressure as that produced experimentally in dogs.

Reflexes Initiated in Other Parts of the Body

The experiments of Churehull and Cope show that a reflex increase in the respiratory rate results from distention of the pulmonary vascular bed. When the vessels of the lung, which was isolated from the body except for its nerves, were injected with fluid to cause overfilling of the vascular bed, rapid shallow breathing immediately ensued. Section of the vagal fibers abolished the response.

Stimulation of almost any afferent nerve may bring about a reflex change in respiration. Stimulation of pain fibers is especially potent in this regard, and the respiratory effects of the excitation of the cutaneous nerves by extremes of heat or cold are well known. The thermal effect upon respiration is apparent in the panting of the dog. The increased pulmonary ventilation in fever is also partly due to the stimulation of receptors (*thermoreceptors*) responsive to a rise in temperature. The thermoreceptors are situated peripherally, especially in the skin, and centrally in the hypothalamus, the latter, being stimulated

through the rise in temperature of the blood, set up impulses which are transmitted to the respiratory centers, the pneumotaxic center in particular. The great increase in pulmonary ventilation occurring in muscular exercise is dependent in part upon reflexes originating in the active muscles and moving joints. Proprioceptive impulses from the diaphragm and other respiratory muscles during one respiratory movement exert an important influence upon the succeeding movement. Stimulation of sensory nerves in the respiratory tract, as by ether anesthesia, or of the abdominal viscera, either during surgical operations or as the result of disease may cause profound changes in breathing. Also, as pointed out by Harrison and his associates, stimulation of afferent nerve endings in the great veins and right auricle by the rise in venous pressure is a possible factor in the hyperpnea of exercise or in the dyspnea of cardiac failure. The glossopharyngeal nerve contains afferent fibers which inhibit respiration during the second stage of the act of swallowing. Abrupt inhibition of respiration is also caused by the inhalation of an irritant gas through stimulation of nasal branches of the 5th nerve. In other instances irritation of these endings may cause sneezing—a modified respiratory act (see fig. 327). Coughing though it can be brought about by a voluntary effort is most commonly reflex in character, and initiated by the stimulation of afferent nerve endings in the trachea and larynx (p. 477).

Dyspnea

Dyspnea literally means difficult breathing. When the respirations from whatever cause can not be carried out with ease and practically unconsciously, the individual is said to be dyspneic. The term therefore implies a subjective element. Dyspnea thus differs from hyperpnea. The latter term means simply increased pulmonary ventilation, and this may occur quite unconsciously or if the subject is aware of the augmentation of the breathing, there is not necessarily any sensation of difficulty or distress. When the hyperpnea becomes extreme and yet leaves the need for which it has been instituted unsatisfied, discomfort or distress is experienced, and the term dyspnea is applicable. Meakins offers the following concise definition: "Dyspnea is the consciousness of the necessity for increased respiratory effort."

Causes of Dyspnea

Since the respiratory and circulatory functions are directed toward the acquisition of oxygen

and the elimination of carbon dioxide, dyspnea may result if either of these functions be disturbed to such an extent that the normal gaseous exchanges cannot be accomplished. On the other hand, the oxygen requirement and the carbon dioxide production may be so great that the normal respiratory and circulatory mechanisms find difficulty in meeting the demands of the moment. Or again the supply of oxygen itself may be inadequate as a result of a low oxygen tension in the atmosphere (e.g., high altitudes). In considering the causes of dyspnea we must, therefore, in many instances look beyond the lungs themselves. The lungs are the bellows, but it is the tissues which consume oxygen and produce carbon dioxide, and it is the heart and the blood which are concerned with the carriage of these gases between lungs and tissues. The height of the hyperpnea at which dyspnea appears is called the *dyspneic point*. There is a relationship between the latter and the *vital capacity*. A person with a large vital

capacity obviously can breathe a larger volume of air without discomfort than can one with a smaller vital capacity. There is a close relationship however between the onset of dyspnea and the ratio of the *functional residual capacity* to the *total lung capacity*. The more nearly equal are the functional residual capacity and the total lung capacity, the greater will be the tendency toward dyspnea.

The fundamental or immediate causes of dyspnea can in most instances be reduced to the following categories: (1) Stimulation of the respiratory center either (a) reflexly from the carotid and aortic bodies (anoxia or increase in H ion concentration due to fixed acids), (b) directly, by CO_2 excess, (c) a combination of (a) and (b) as in asphyxial states, or (d) by impulses from cerebral centers or by afferent impulses, especially of a painful character, from abdominal or peripheral regions (2) Hypersensitivity of the Hering-Breuer reflex, thus bringing about earlier inhibition of the inspiratory phase and causing, as a consequence, a more rapid shallow type of breathing.

The abnormal conditions chiefly associated with dyspnea are

- (1) Prevention of adequate oxygenation of the blood in the lungs (arterial hypoxia, ch 33)
- (2) Interference with the transport of the respiratory gases. Anoxia of the hypokinetic or anemic type (a) slowing of the circulation as in cardiac failure, (b) severe anemia, breathlessness chiefly on exertion
- (3) Restriction of the action of the diaphragm or intercostals
- (4) Acidosis, reduced alkali reserve or retention of CO_2
- (5) Increased metabolism
- (6) Nervous conditions, e.g., emotional disturbance, neurasthenia, hysteria, encephalitis, or the direct stimulation of the respiratory center by cerebral tumor, hemorrhage or edema

DYSPNEA DUE TO PULMONARY DISEASES

Dyspnea is a feature of various respiratory diseases

- (a) In some instances, e.g., laryngeal or bronchial obstruction and asthma, the dyspnea is due to a combination of anoxia and CO_2 retention
- (b) In other instances owing to the reduced distensibility of the lungs resulting from edema, congestion, inflammation, fibrosis, etc., the Hering-Breuer reflex is thought to be abnormally sensitive
- (c) Limitation of the movements of the dia-

phragm and chest wall. In emphysema, for example, owing to the loss of lung elasticity the resting position of the chest is one of nearly full inspiration. The diaphragm is fixed and the thorax elevated. Any further enlargement of the chest entails unusual effort on the part of the intercostal muscles (see also ch 30) and the enlistment of the accessory muscles of respiration. Expiration involves active contraction of the expiratory muscles.

CARDIAC DYSPNEA

Dyspnea upon exertion is a feature of certain chronic pulmonary and heart lesions e.g., mitral stenosis. Stimulation of the carotid and aortic bodies by oxygen want or of the respiratory center by carbon dioxide excess is not, in the absence of cardiac failure, responsible for the dyspnea, since the oxygen saturation of the arterial blood may not be reduced to any important degree, and the carbon dioxide tension is within or even below the normal range. Pulmonary engorgement leading to diminished distensibility of the lung is considered by Meakins, Christie and associates to be the prime cause of cardiac dyspnea. Though the reduction in the vital capacity may be roughly proportional to the dyspnea, the two do not bear the relationship of cause and effect, since the subject's vital capacity is always greater than the volume of air required for the exertion which causes the dyspnea. Due however, to the diminished distensibility—the stiffness of the lung—a greater inspiratory effort is expended in breathing the extra volume of air which the muscular exertion demands. The lung might be compared to stiffened bellows leather; more force is required to distend it. The elasticity of the lung is also moderately reduced so that expiration instead of being a passive act brought about largely by the recoil of the lung now requires the aid of the contraction of expiratory muscles in order to “squeeze” the air from the chest. The intrapleural pressure, therefore, instead of remaining “negative” throughout the respiratory cycle becomes positive toward the end of expiration (Christie and Meakins). The decreased distensibility of the lung for the same reason that it increases the difficulty of enlarging the volume of tidal air, reduces the vital capacity. In other words the dyspnea and reduced vital capacity are due to a common cause. The reduced distensibility will also have the effect, as already mentioned, of increasing the sensitivity of the Hering-Breuer reflex with the production of shallow breathing.

In congestive heart failure with marked slowing of the circulation there is commonly hyperpnea and dyspnea even during rest, and then there may be added to the pulmonary factor itself the stimulating effect of carbon dioxide excess upon the respiratory center. But, according to Christie and Meakins, this is of minor importance. When pulmonary edema supervenes, interference with the absorption of oxygen and the production of arterial hypoxia (stimulation of carotid body) may possibly be a factor. Hindrance to the absorption of oxygen, caused by the presence of exudate in the alveoli and the edematous swelling of the alveolar walls, is accompanied by little or no interference with the elimination of carbon dioxide, this is probably due in part to the much greater solubility of carbon dioxide than of oxygen and, in consequence, to the freer diffusion of the former gas through the edema fluid. In congestive heart failure arterial hypoxia with a normal or even a subnormal carbon dioxide content of the arterial blood may exist even in the absence of pulmonary edema.

Experimental support can be cited for the view that reduced distensibility of the lungs as a result of congestion is an important factor in cardiac dyspnea. It has been mentioned elsewhere (p. 502) that distension of the pulmonary bed causes rapid shallow breathing. The production of multiple emboli in the pulmonary capillaries by the intravenous injection of starch granules causes congestion of the lungs and rapid shallow breathing, and Partridge found that after rapid breathing has been induced in this way, the impulses recorded from the vagus nerve are of higher frequency than those resulting from inflation of normal lung to an equal degree. It has also been shown that in man pulmonary congestion does actually reduce the distensibility of the lung tissue.

Harrison and his colleagues found in subjects of cardiac failure the CO_2 content of the jugular blood to be within normal limits and observed no significant reduction in the cerebral blood flow (i.e., through the respiratory center).

Though there is much to be said for the reflex origin of cardiac dyspnea, not all are agreed as to its paramount importance. McMichael, for example, in a clinical study found a reduction in cardiac output in those subjects showing hyperpnea (which is always associated with the dyspnea) during rest. The hyperpnea showed a closer correlation with the cardiac output than with the vital capacity which, he points out, is contrary to what

might be expected were congestion of the lungs the dominant causative factor. He is inclined to believe that the hyperpnea and dyspnea of the cardiac patient during rest is due to reduced blood flow through the center, resulting in a high CO_2 tension, and possibly to the accumulation of acid products of its own metabolism.

Orthopnea In congestive heart failure with dyspnea at rest the breathlessness is usually more pronounced in the recumbent than in the sitting position. When propped up with pillows, the patient may be quite comfortable but becomes dyspneic when he lies down. Many theories have been advanced in attempts to explain the less difficult breathing in the upright position. Among these are:

(a) Removal of the weight of the abdominal viscera which interferes with the descent of the diaphragm in the recumbent position.

(b) Reduction in the intracranial venous pressure and the improved draining of blood from the medulla and in consequence, augmentation of the flow through the respiratory center. Mere bending of the head forward (when recumbent) which reduces the cerebral venous pressure, but not the pulmonary engorgement, reduces the volume of expired air in the orthopneic patient (Battro and Labourt).

(c) Draining of blood from the chest and the relief of pulmonary congestion. This is probably the most important factor. The vital capacity is less in the recumbent than in the sitting posture. This is true even for the normal person but in cardiac cases the effect is accentuated by the vascular engorgement and decreased distensibility of the lung induced by recumbency.

Cardiac asthma (paroxysmal nocturnal dyspnea)

In some patients with severe chronic congestive heart failure acute dyspnea which may terminate in pulmonary edema comes on during the night. The patient has a feeling of suffocation. He assumes the upright position and may go to the window for air. These attacks are related to excessive engorgement of the lungs with blood so that pulmonary capillary pressure rises to the point of producing transudation into the alveoli. As indicated above the volume of blood in the lungs increases when one changes from the upright to the recumbent position. Patients with chronic heart failure already have an elevated venous pressure which increases further when they recline. The key question is with regard to the fact that paroxysmal nocturnal dyspnea comes on

after a delay usually of several hours since the effects of changing from the upright to the recumbent position insofar as they are related to gravity might be expected to occur within seconds or minutes. The clue to this problem probably is provided in the observation that edema fluid in patients with congestive heart failure is transferred from the interstitial spaces into the blood, and a rise in blood volume occurs slowly during the night. This could lead to a further elevation of venous and pulmonary capillary pressure. The paroxysm could be set off in two ways. The pressure in the pulmonary capillaries could rise to the point of producing transudation and hence impairment of exchange of O_2 and CO_2 . On the other hand, the venous pressure might reach the critical level at which overdistention of the heart would result in a decrease in the output of the heart. Once this occurs a vicious cycle is produced: decreased output leads to further elevation of venous pressure, and elevation of venous pressure leads to further overdistention of the heart and decreased output. In either case the change to the orthostatic position would be beneficial in that the blood would tend to remain in the dependent part of the body and thus decrease the volume and pressure of blood in the heart and lungs. Also, it should be noted that acute cardiac decompensation, produced by exceeding the critical pressure on the curve which relates cardiac output to venous pressure, leads to a rise in pulmonary capillary pressure and hence to acute pulmonary edema.

DYSPNEA IN ANEMIA

When at rest, the anemic subject as a rule is not dyspneic. The hemoglobin, though reduced in amount, becomes fully saturated with oxygen in the lungs. The oxygen tension and consequently the quantity of the gas in simple solution in the arterial blood are normal. The arterial blood of a patient whose hemoglobin is 30 per cent of the normal value will, however, contain only a little over 6 volumes per cent of oxygen. In the healthy resting body the blood in its passage through the capillaries gives up about 5 volumes per cent. If the velocity of blood flow through the tissues in anemia were the same as during health, a unit volume of blood would give up an equivalent amount of oxygen. This would leave a reserve of only 1 volume per cent, i.e., the venous blood would be almost completely reduced. The tissues, including the carotid and aortic bodies, would suffer at all times from anoxia. The circulation rate (cardiac output) is, however, increased in

anemia so that each unit of blood gives up a smaller proportion than this of its oxygen load. The chemoreceptors apparently are not stimulated, and the patient is not dyspneic while resting even though his hemoglobin is greatly reduced. Fahr and Ronzone reported a case in which the hemoglobin was 12 per cent of the normal and the arterial blood contained only 2.2 volumes per cent of oxygen. There was no dyspnea during rest. Not only is the output of the heart increased, but a redistribution of the blood occurs. The vessels of the skin are constricted, and a greater proportion of the total blood volume is driven through other regions. The extent to which the circulatory readjustments can compensate for the blood defect is limited, therefore during exertion the extra demand for oxygen cannot be met. Oxygen want follows, the respiratory mechanism is stimulated, hyperpnea and dyspnea result.

It is to be remembered that in anemia the carriage of carbon dioxide may also be interfered with since hemoglobin constitutes an important part of the mechanism provided for the transport of this gas (see ch. 29).

DYSPNEA DUE TO INCREASED METABOLISM

Muscular exercise is an outstanding cause of a great increase of metabolism. Reflexes initiated in the active muscles, and from the walls of the great veins as a result of the high pressure of blood entering the right side of the heart, and possibly as well the irradiation of impulses from the motor cortex, are thought to play an important part in the hyperpnea of exercise (p. 499). As the severity of the exercise is increased, hyperpnea merges into dyspnea. The athlete and the untrained person differ widely in respect to the degree of muscular exertion which will produce this physiological type of dyspnea. The difference depends upon the following factors:

(a) *Vital capacity* In the average normal man the pulmonary ventilation increases from 4- to 5-fold before the dyspneic point is reached. The athlete on the other hand, since his vital capacity is greater, shows a correspondingly greater increase in his pulmonary ventilation before dyspnea supervenes. The existence of any pulmonary condition which reduces the vital capacity will depress the level of the dyspneic point.

(b) *Circulation rate* The trained man's circulation rate increases to a greater degree than the untrained, and so more oxygen is delivered to his tissues.

(c) *Neuromuscular integration* Co-ordination

of the several muscles in a given muscular act is more precise in the trained than in the untrained man. There is thus less waste of effort. In the performance of a given amount of work, therefore, the untrained man consumes a greater volume of oxygen, i.e., he is a less efficient machine. Yet his respiratory center appears to be more sensitive to nervous influences—impulses from the contracting muscles and from the cerebral cortex.

A pathological increase in metabolism, e.g., hyperthyroidism, fever, etc., cannot apparently in the absence of some respiratory or circulatory abnormality cause dyspnea during rest. The increase in metabolism would need to be around 300 per cent before dyspnea might be expected to occur and such a metabolic level is never reached in these or any other pathological condition. Nevertheless, in hyperthyroidism dyspnea will follow upon a degree of exertion which would cause no distress in a healthy person, for the greater metabolic rate, due to the disease, added to that of the exercise will increase the metabolism sufficiently to raise the pulmonary ventilation above the dyspneic point. The dyspnea of hyperthyroidism, when pulmonary and cardiovascular complications are absent, therefore, is like that of anemia in that it is evident only upon exertion.

DYSPNEA DUE TO ACIDOSIS

The importance of the part played by pulmonary ventilation in resisting a rise in the hydrogen ion concentration of the body fluids has been dealt with elsewhere (ch. 13). Little more need be said here. Nonvolatile acids, e.g., lactic in muscular exercise, β -Hydroxybutyric and acetoacetic acids in diabetes, and retained acids in nephritis, react with bicarbonate. The alkali reserve becomes reduced, but the ratio,

$$\frac{H_2CO_2}{NaHCO_3} = \frac{1}{20}$$

is maintained through the stimulating effect of CO_2 upon the respiratory center. It is thus that the CO_2 of the alveolar air (and so of the arterial blood) is kept at a level proportional to the reduction in the denominator of the equation. When this can no longer be effected, i.e., when the hydrogen ion concentration of the blood rises, the acidosis being then uncompensated, the center is stimulated both directly and through reflexes initiated from chemoreceptors of the carotid and aortic bodies.

J. B. S. Haldane produced a severe acidosis and dyspnea in himself by the ingestion of acid-forming salts ($CaCl_2$ and NH_4Cl). But as a matter of fact, the production of fixed acids in diseased conditions rarely causes such a high degree of hyperpnea that dyspnea results unless the circulatory and respiratory mechanisms are very inefficient or the metabolic rate is increased. According to Means the "alkali reserve" must drop to around 12 volumes per cent before dyspnea supervenes as a result of the acidosis itself. In milder grades of acidosis, however, dyspnea occurs upon exertion. The hyperpnea due to the increased metabolism of the exercise is then added to that due to the acidosis, with the result that the dyspneic point is soon reached.

In severe diabetic acidosis *air hunger*, or Kussmaul breathing, may be seen in the comatose patient.

Carbon dioxide retention may, as in emphysema, be accompanied by a compensatory rise in bicarbonate and a normal blood reaction (compensated CO_2 excess). Dyspnea is not a notable feature in this condition. In other instances of CO_2 retention, compensation is incomplete (uncompensated CO_2 excess or gaseous acidosis) and dyspnea results. In others, again, the CO_2 retention is due to the depression of the respiratory center itself, as in morphine narcosis in such instances, although compensation is incomplete, dyspnea of course does not occur.

HYPOXIA, ASPHYXIA, DYSBARISM, OXYGEN THERAPY, AND RESUSCITATION

Types of Hypoxia

The terms *hypoxia* and *anoxia* are synonymous, although the former etymologically is more suitable. Both terms are in common use and will be used interchangeably in the following discussion. The most useful definition of hypoxia is that it refers to any condition in which there is an inadequate supply of oxygen to the tissues. According to this definition it is synonymous with *oxygen lack* or *oxygen want*. Upon the basis of three quite different categories of causes Barcroft classified anoxia into *anoxic*, *anemic* and *stagnant* types. The categories described by him still need to be differentiated, but changes in the names of two of them seem to be preferable. A fourth type, caused by cyanide and known as *histotoxic anoxia*, was added by Peters and Van Slyke, however, there is no oxygen lack in this case, but rather inability of the cells to utilize the oxygen brought to them, with the result that oxygen tension of the tissues is actually elevated. Hence it would seem to be preferable not to classify cyanide poisoning as a form of hypoxia. For reasons which will become apparent in the subsequent discussion *arterial hypoxia* is preferable to *anoxic anoxia* in Barcroft's classification, and *hypokinetic hypoxia* is a better term for stagnant anoxia. The three major types of oxygen lack, together with the principal causes of each, are listed below. Also, it should be realized that two or more of these types or causes can be present simultaneously, and each type may be acute or chronic.

OXYGEN LACK MAJOR TYPES AND CAUSES

ARTERIAL HYPOXIA is characterized by a lower than normal pO_2 in arterial blood. (Oxygen capacity of blood and rate of blood flow are normal or elevated.)

A Low pO_2 in inspired air

- 1 Altitude
- 2 Breathing in closed space¹

¹ Arterial pCO_2 is increased

3 Breathing artificial gas mixture containing lower pO_2 than that found in atmospheric air

B Decreased pulmonary ventilation

- 1 Airway obstruction¹
- 2 Weakness or paralysis of respiratory muscles¹
- 3 Depression of respiratory center by drugs¹
- 4 Pneumothorax

C Inadequate oxygenation in (abnormal) lungs

- 1 Poor mixing¹
- 2 Impaired diffusion (alveolar-capillary block)
- 3 Bronchiolar constriction (asthma)¹
- 4 Filling of alveoli with fluid. Pulmonary edema, pneumonia, pulmonary hemorrhage, drowning¹

D Venous-arterial shunts. Various types of cardiac or vascular abnormalities in which unoxygenated blood is mixed with oxygenated blood.

ANEMIC HYPOXIA is characterized by a lowered oxygen capacity of the blood. (The pO_2 of arterial blood and rate of blood flow are normal or elevated.)

A Less than normal hemoglobin content. Anemias of all types.

B Hemoglobin combined with something other than oxygen, e.g. carbon monoxide.

C Hemoglobin altered so that it can not combine with O_2 . Methemoglobin found after poisoning with chlorates, nitrates, ferri-cyanides, acetanilid, etc.

HYPOKINETIC HYPOXIA is characterized by a decreased rate of blood flow.

A Generalized. Congestive heart failure, hemorrhage, shock, etc.

B Localized. Vasospasm, thrombosis, embolus.

Some confusion has arisen in the use of the term *anoxemia*. In some of the medical dictionaries and textbooks it is defined as synonymous with arterial hypoxia while some authors (Comroe and Driggs, 1950) use it as referring to a diminution of oxygen in the blood whether it be

related to decreased pO_2 or decreased hemoglobin. In any case it would seem to be preferable to use the more specific terms, arterial hypoxia and anemic hypoxia, since these are not ambiguous.

ASPHYXIA *Asphyxia* refers to conditions in which hypoxia is combined with *hypercapnia*—an increased CO_2 tension in the arterial blood and hence in the tissues also. It will be noted that a number of the causes of arterial hypoxia also lead to hypercapnia, while in some cases, notably at altitude, hypercapnia is not a factor. The opposite change, a lowered CO_2 in the body, is referred to as *hypocapnia* or *acapnia*. The reactions in asphyxia are related to effects of decreased arterial and tissue pO_2 and increased arterial and tissue pCO_2 . Asphyxia of some degree is present in a number of those conditions listed in the classification of causes of oxygen lack, since elimination of CO_2 , as well as uptake of oxygen, is impaired. Respiratory stimulation and dyspnea are prominent, and although the stimulation is derived from both the lowered pO_2 and increased pCO_2 , the latter is more important. Cyanosis, being related to the presence of an increased amount of reduced hemoglobin in the blood in the cutaneous capillaries (p. 524), also is characteristic of asphyxial states as well as those in which arterial anoxia is present without hypercapnia. Blood pressure tends to be elevated due to the stimulant action of CO_2 on the vasoconstrictor center, except in the terminal stages. Chronic adjustments to asphyxia include the increase in erythrocyte count, hematocrit, hemoglobin and oxygen capacity of the blood, which are induced by the lowered pO_2 tension, and renal excretion of acid to compensate for the rise in pH produced by retention of CO_2 .

Tensions and Volumes Per Cent of Oxygen in the Blood in Hypoxia

In the arterial type of hypoxia both the pO_2 and the volumes per cent of O_2 are lowered. The blood has a normal or elevated O_2 capacity (20 volumes per cent or more), but it is not exposed to pO_2 which is high enough to produce the usual degree of saturation (95 + per cent). However, even though the blood is carrying less than a full load of O_2 , when it reaches the capillaries in tissues which are functioning at a lower than normal oxygen tension it can unload as much oxygen per 100 ml of blood as occurs normally. That is, normally about 20 volumes per cent would be present in the arterial blood and 15 volumes per cent in mixed venous blood, while in arterial hypoxia arterial blood capable of holding 20 volumes

per cent would actually contain 15 and give off 5 so that the mixed venous blood would contain only 10 volumes per cent. In the latter case 50 per cent desaturation of hemoglobin would be produced at the tissue level as compared with 25 per cent in the normal.

In *hypokinetic* hypoxia both the pO_2 and volumes per cent of O_2 in the arterial blood are normal, however, as the blood flow through the tissues is slower than in the normal state and the cells continue to use oxygen at an essentially normal rate, the pO_2 in the tissues becomes lowered, and this causes the unloading of more O_2 per unit volume of blood flowing through the tissues. In very active tissues which are subjected to a severely deficient blood flow, virtually all of the oxygen in the blood delivered to the tissue may be extracted. This indicates that the pO_2 in such tissues approaches zero. Such a situation can not exist for more than a very short time before damage to the tissue results.

In *anemic* hypoxia the arterial pO_2 is normal so that saturation of hemoglobin approaches 100 per cent, but the volumes per cent of O_2 carried is reduced in proportion to the reduction in the amount of hemoglobin. Hence if blood carrying, for example, 10 volumes per cent of O_2 at full saturation of the hemoglobin gives up 5 volumes per cent per 100 ml of blood flowing through the tissues, it is apparent that the O_2 in the tissues is so low as to cause 50 per cent desaturation. Again this is to be contrasted with the normal state in which, on the average, only about 25 per cent desaturation occurs as blood flows through the tissues.

Arterial Hypoxia at Altitude

Arterial hypoxia, uncomplicated by hypercapnia, is observed in individuals breathing air at high altitudes or in decompression chambers. Knowledge of both the acute and chronic adjustments to altitude is of great interest since man ascends rapidly in airplanes or resides for years at levels of 15,000 to 18,000 feet.

The per cent composition of atmospheric air is the same at altitude as at sea level. But the barometric pressure decreases with altitude. It is noteworthy that at an altitude of 18,000 feet the barometric pressure is about 38 mm Hg or one half of that at sea level. The oxygen tension, therefore, is diminished to one half of that at sea level, since the pO_2 at any altitude is calculated by multiplying the barometric pressure by 20.94. Thus, a second vertical scale showing oxygen tension could be derived.

tiplying each of the figures in the barometric pressure scale by 2094

At altitude as one breathes air containing a lower pO_2 than that of air at sea level the alveolar pO_2 becomes lowered. The decrease in alveolar pO_2 at altitude if severe enough is counteracted in part by an increase in pulmonary ventilation, although this response is not as prominent immediately as it is after some delay.

Conditions at altitude can be simulated in an air tight chamber from which the air has been partially evacuated. At a given barometric pressure a certain altitude is simulated as far as gas tensions are concerned. Chambers have been constructed in such a way that they may be very rapidly, i.e., explosively, decompressed and the reactions of the subject followed from moment to moment. During acute exposure to simulated altitude, produced by rapid decompression of a chamber containing the subject, alveolar ventilation is increased so that alveolar pCO_2 is lowered, and the amount of decrease is proportional to the reduction in ambient pressure (increase in altitude). For example, shortly after decompression to a simulated altitude of 18,000 feet the alveolar pCO_2 is in the range of 27 ± 2 mm Hg, and the alveolar pO_2 is in the range of 42 ± 3 mm Hg. The alveolar pO_2 is less than half that found at sea level. At this point it should be noted that the water vapor tension in alveolar air, being determined by body temperature which is constant, remains at 47 mm Hg at all altitudes, and when expressed in terms of per cent it increases in direct proportion to the decrease in total pressure in the alveoli. For example, at sea level the per cent of water vapor is $47/760 \times 100$ whereas at 18,000 feet it is $47/380 \times 100$. At an altitude where the barometric pressure is only 74 mm Hg, water boils at body temperature and the alveoli are filled with water vapor.

Immediately after sudden exposure to altitude, respiratory adjustments occur, however, conditions continue to change from one 5-minute period to the next for a period of 30 to 60 minutes (Riley, Otis and Houston, 1954). Some of the bases for these changes already have been discussed.

The immediate circulatory adjustments to acute arterial hypoxia are an increase in heart rate and blood pressure, and the onset of cyanosis as a result of an increase in the amount of reduced hemoglobin in arterial blood. The amount of desaturation can be estimated from the alveolar pO_2 and the oxygen-hemoglobin dissociation curve.

In the normal subject breathing air (about 21 per cent O_2), about 95 per cent saturation of the hemoglobin of arterial blood with oxygen is attained. In a person breathing air at any given altitude somewhat less than 95 per cent saturation would occur but could be achieved if the O_2 per cent in inspired air were increased sufficiently. It is found that at 18,000 feet it would be necessary to breathe about 45 per cent O_2 in order to attain 95 per cent saturation, and at about 34,000 feet, 100 per cent O_2 is needed. It follows that at altitudes higher than 34,000 feet some degree of arterial hypoxia will occur even when the subject breathes pure O_2 , and at very high altitudes intolerable degrees of oxygen lack would be experienced even when breathing 100% O_2 . The limit at which aviators can fly in non-pressurized cabins breathing 100 per cent O_2 is in the range of 40,000 to 45,000 feet. Above this level cabins containing gases under pressures higher than that of the ambient air are required.

Several mountain climbing expeditions have been made in the past by different groups of physiologists for the purpose of studying the effects of low oxygen tensions upon the respiratory functions and of determining the factors underlying the phenomenon of acclimatization. An expedition was made to Monte Rosa (15,000 feet) in 1894 by Mosso and by others; subsequently, to the peak of Tenerife (12,000 feet) in 1910 by Zuntz, Barcroft and associates, and in 1911 to Pike's Peak (14,100 feet) by the Anglo-American expeditions of which Haldane, Douglas, Headerson and Schneider were members. In 1921 to 1922 Barcroft headed a party to Cerro de Pasco (14,200 feet) in the Peruvian Andes. A Himalayan expedition was led by Hartman in 1931 and in 1933 Dill led a party to the Chilean Andes. Recently, Pugh (1957) has reported observations made on Mt. Everest during the successful British expedition of 1952.

GENERAL SIGNS AND SYMPTOMS

Airplane ascents, if made rapidly without the use of oxygen, may result in sudden loss of consciousness due to the reduction in oxygen supply to the brain. When the ascent is made more slowly, or the altitude is not so great as to cause immediate loss of consciousness, the aviator may at first experience sensations of excitement, exhilaration and well being. As higher altitudes are reached effects of a more serious nature develop, often insidiously. Mental and sensory dullness, muscular weakness, headache, vomiting, cyanosis, dyspnea and perhaps a tendency toward periodic breathing may be induced. A common

and dangerous effect is the development of fixed ideas which may result in the performance of foolhardy and ill judged actions

When a person climbs to a mountain height, the time taken in the journey allows a certain degree of physiological readjustment to take place, and the symptoms are usually less intense. But, as in the case of the aviator, mental features, e.g., a feeling of elation, exuberance, talkativeness and sometimes emotional outbursts, laughing or crying, quarrelsomeness or the development of fixed ideas are prominent. Mental tasks, e.g., calculations, memory tests, and telling the time from the mirror image of a clock face are performed less efficiently. Similar effects upon the mind are produced upon persons exposed to low oxygen pressures within a steel cabinet. The mental effects as pointed out by Barcroft are not unlike those caused by drunkenness. To quote his words,

"Alcohol affects different persons in different ways, so on my journeyings in high altitudes I have seen most of the symptoms of alcoholism reproduced. I have seen men vomit, I have seen them quarrel, I have seen them become reckless, I have seen them become morose. I have seen one of the most disciplined of men fling his arms about on the ledge of a crevasse to the great embarrassment of the guide. I have seen the most loyal companion become ill tempered and abusive to the point at which I feared international complications would arise."—Lessons from High Altitudes

Complete prostration may follow the earlier symptoms. If the individual remains at the high altitude the symptoms pass off after a time as he becomes acclimatized to the low oxygen tension.

At a simulated altitude of about 20,000 feet (i.e., in a decompression chamber) most subjects experience failing vision, incoordinations, and inability to write or to execute simple mental tasks within 15 minutes or so after the extra oxygen supply has been cut off, at 26,000 feet none are able to retain "effective consciousness" for this length of time without oxygen.

CHANGES ASSOCIATED WITH ACCLIMATIZATION

At an altitude of 14,200 feet as at Cerro de Pasco where Barcroft and his party carried out their investigations, the barometric pressure is around 440 mm Hg. The partial pressure of oxygen is therefore about 92 mm Hg. The oxygen tension of the alveolar air is not as far below that of the atmosphere as at sea level, and varied among the greater number of the party from 55 to 60 mm Hg. The closer approximation of the

atmospheric and alveolar oxygen tensions at high altitudes is due to the increased breathing which results in a more effective ventilation of the air sacs. The increased respiration is brought about through the action of the lowered oxygen tension in the blood. The oxygen tension is slightly lower in the arterial blood than in the alveolar air which indicates that the passage of the gas is due purely to diffusion and not to an active secretion by the pulmonary epithelium. If this occurred, as has been suggested (Haldane), one would expect the arterial oxygen tension to be higher than that of the alveolar air. Alveolar carbon dioxide tension also, as a result of the increased pulmonary ventilation, is lower than that at sea level, it varied in different individuals of Barcroft's party from 23 to 29 mm Hg. At 14,200 feet the arterial blood is from 85 to 88 per cent saturated with oxygen (see fig. 29-4, p. 456).

A marked increase in the number of red cells (see ch. 6) and a corresponding increase in hemoglobin content of the blood occur at high altitudes. The blood volume is also augmented. The natives of mountainous regions have a red cell count of from 6 to 8 million per cubic millimeter. The greater quantity of hemoglobin of course raises the oxygen capacity of the blood and so tends to compensate for its lowered oxygen saturation. That is, the total oxygen content of the arterial blood tends in spite of the low saturation to rise. Nevertheless, it may not be evident at first sight how a rise in the oxygen capacity is of advantage, for blood of normal hemoglobin content even when only 80 per cent saturated possesses a quantity of oxygen which is quite adequate for the needs of the tissues. It has already been pointed out, however, that the important factor in supplying the tissues is the oxygen pressure gradient between the plasma in the capillaries and the tissue cells. So then, if there are a greater number of red cells, each will be required to give up less of its oxygen store in passing through the capillaries to furnish a given quantity of oxygen (see anoxia due to anemia p. 509). Consequently the saturation and the oxygen tension of the venous blood will be maintained at a higher level than otherwise would be possible. This means that the mean intracapillary oxygen pressure will also be higher, and as a result the tissues are more effectively supplied with oxygen.

The reduction in the alveolar carbon dioxide results in a corresponding decrease in the carbon dioxide tension of the arterial blood. The ratio $H_2CO_3/NaHCO_3$, which tends to be altered by the loss of carbon dioxide, is adjusted by a de-

crease in the excretion of acid and ammonia in the urine, a consequent lowering of the "alkali reserve" and depression of the CO_2 dissociation curve (p 461) The actual pH of the plasma changes little if at all Up to about 12,000 feet if any change occurs it is toward the alkaline side, above this level the blood reaction shows little further change or tends to return to normal Lactic acid, which was thought at one time to be produced in excess as a result of the anoxia is actually formed in smaller amounts at high altitudes than at sea level Even during severe exercise at 15,000 feet and higher altitudes the lactic acid concentration in the blood is lower than during exercise of comparable severity at sea level

Barcroft and his party observed a shift to the left in the oxygen dissociation curve of hemoglobin, i.e. the affinity of hemoglobin for oxygen was increased The shift in the dissociation curve is ascribed by Barcroft to an increased alkalinity of the interior of the red cell This increased alkalinity is in turn a direct result of the rise in the number of red cells The buffering power of the blood is increased through the greater facility offered for the action of the "chloride shift" mechanism (ch 13 and 29) In other words, when a given amount of carbon dioxide is liberated by the tissues, it is distributed among a greater number of red cells than under normal circumstances, therefore, the alkalinity of each cell is reduced to a proportionately less extent There have been conflicting reports concerning this question of the shift in the oxygen dissociation curve Some observers have been unable to confirm Barcroft's finding, while others claim that a shift to the right occurs The truth appears to be that up to about 14,000 feet the affinity of hemoglobin for oxygen increases, but at higher levels the dissociation curve tends to assume the form found at sea level, and at altitudes of 19,000 feet there is a definite shift to the right

One might suppose that an increased circulation rate would be an important adjustment to the rarefied atmosphere whereby an adequate oxygen supply to the tissues would be maintained, but except for a temporary increase during the first few days no change in cardiac output occurs at altitudes of less than 14,000 or 15,000 feet Above 15,000 feet the greater degree of anoxia results in an increase in the minute output of the heart Before acclimatization, the pulse rate during rest increases by from 15 to 20 beats per minute at altitudes between 15,000 and 18,000 feet At greater altitudes, especially in persons

In poor physical condition, the increase in rate may be greater than in the normal The acceleration of the pulse, according to Barcroft, is a signal of distress flown by the heart laboring under the effects of the anoxia, rather than an indication of an increased minute volume The blood pressure shows little or no change up to 15,000 feet, a small rise may occur at higher altitudes For an account of the effect of anoxia on the coronary circulation

Those who have lived all their lives at very high altitudes (around 14,000 feet) have a larger vital capacity than dwellers at sea level Barcroft reports that a native of Cerro de Pasco of 5 feet, 3 inches in height had a chest of a man of 6 feet Moderate altitudes up to about 7500 feet, appear to have little or no effect upon the chest development

Although anoxia is the most serious effect of high altitudes with which the mountain climber or aviator has to contend, rapid ascents, as by airplane, cause other important physiological disturbances which should be mentioned, namely (1) expansion of gases in the gastrointestinal tract, (2) aerocembolism (see below) and (3) pressure disturbances in the ears (ch 78)

Expansion of gases in the gastrointestinal tract Like the gases of the atmosphere those in the stomach and intestine increase in volume in proportion to the reduction in pressure Gas having a volume of 1 liter at sea level expands to 2 liters at the pressure (375 mm Hg) existing at 18,000 feet to 4 liters at 34,000 feet to 6 liters at 42,000 feet (pressure 123 mm Hg) Distention of stomach and intestine will result unless the abdomen is supported by a belt or other means, or the gases are freely evacuated In rapid ascents distress or even severe pain results if there is any hindrance, as by an obstruction in the colon, to the ready passage of flatus

Dysbarism

The term *dysbarism*, or decompression sickness, refers to the signs and symptoms which result when the total pressure of ambient gases suddenly is reduced It refers to the effects of reduction in pressure as such rather than to those caused by a lack of oxygen Dysbarism is seen in deep sea divers or caisson workers when they pass too quickly from the high pressure in which they have been working to the ordinary pressure of the atmosphere, hence the name *caisson disease* has been used The "bends" is a popular name for the condition In dysbarism the percentage reduction in pressure is a more important factor than the absolute amount of decrease A sudden reduction in pressure to approximately 45 per cent of the pressure with which the subject was equili-

brated ordinarily is necessary in order to cause dysbarism. Therefore, an aviator who flies rapidly from sea level to an altitude where the pressure is one-third of an atmosphere would have about the same chance of developing decompression illness as a diver who is decompressed quickly from three atmospheres to one. A diver who has been exposed to a pressure of, for example, 8 atmospheres usually can be subjected to a quick reduction in pressure to 4 atmospheres without developing symptoms, then after he has been at this pressure long enough to approach equilibrium with the surrounding pressure he can be quickly lowered to 2 atmospheres where he remains for a time and next the pressure can be lowered to 1 atmosphere.

The cause of symptoms during rapid decompression is the formation of bubbles of gas in fatty tissues and blood. The gas is mainly nitrogen. The total amount of nitrogen dissolved in the body when one is exposed to a gas mixture having the same percentage composition as atmospheric air is several times that of O_2 and double that of CO_2 . Also nitrogen diffuses less readily and, unlike O_2 , it is not used in metabolic processes. When body fluids are saturated with N_2 at a given pressure and the ambient pressure suddenly is lowered, N_2 is evolved in gaseous form just as CO_2 is evolved from carbonated water when the cap is removed from the bottle containing it. Bubbles in the blood tend to lodge in the smaller vessels and obstruct the flow of blood. Symptoms vary depending upon the sites where the bubbles lodge. Fatty tissue usually is the site of bubble formation since N_2 is 5 times more soluble in oil than in water. The involved tissues include subcutaneous tissue, bone marrow, adrenal cortex, myelin sheaths, etc. Bubbles in the myelin sheaths of sensory nerves cause pain (bends), paresthesias, itching, etc., and those in myelin sheaths of motor nerves may cause temporary paralysis. It has been recognized for many years that obese persons are more susceptible to "the bends" than lean persons.

In rapid ascents in airplanes dysbarism is not a problem up to 20,000 feet since the reduction in pressure is less than 55 per cent, and in fact, symptoms ordinarily do not appear below 30,000 feet. Above this level, however, dysbarism is common. The tendency to develop decompression illness is greater the more rapid the ascent. The most effective way to prevent or diminish the effects of rapid decompression is to have the aviator breathe 100 per cent oxygen or an oxygen-

helium mixture for a time before the flight and thus wash much of the nitrogen out of the body. When this is done the aviator should be able to ascend quite rapidly to 40,000 feet (continuing to breathe 100 per cent O_2) without discomfort.

The effects of aeroembolism in flyers during rapid ascent take the form most commonly of severe pain in one or more of the large joints and itching of the skin or cutaneous sensations of heat or cold. Other more serious symptoms such as paralysis, intense burning pain in the chest or pulmonary edema may, though rarely, occur. The symptoms are rarely as severe as in compressed air illness, since the amount of gas which can be released is not as great in the decompression which occurs in ascent to altitude.

The explosive decompression technique which is used to study adjustments to lowered pO_2 in the inspired air also is useful in the study of dysbarism. A rate of ascent can be simulated in this way which is much faster than any which has been attained even in rockets. Many thousands of flying personnel have been subjected to explosive decompression as a routine procedure during the past fifteen years. The subject is instructed to breathe with mouth open. As the gas in the lungs expands during decompression it rushes out through the open airway. Gas in the sinuses also expands suddenly and exhausts through the natural channels, but if these openings are not patent severe pain is produced.

Experimental animals have been found to have an astonishingly high tolerance to explosive decompression at simulated high altitudes (from sea level to 50,000 feet—750 to 87 mm Hg). The rate of decompression in the experiments of Whitehorn and his associates ranged from about 1100 mm Hg per second to as high as 33,000 mm Hg or more per second. That is to say, decompression from 750 mm Hg to 87 mm Hg was brought about in the latter instance in 0.02 second. Then the animal was quickly recompressed and the effects of anoxia thus prevented. The chief effects observed in these experiments were distension of the hollow viscera and lungs, fixation of the expanded thorax in the inspiratory position and of the diaphragm in the expiratory position, due to upward pressure of the distended stomach and intestines, sharp but temporary fall in blood pressure with cardiac slowing, hemorrhages into lungs and hollow organs, or rupture of the latter. The fall in blood pressure, which does not occur for a heart beat or two, seems to be due to decreased cardiac filling caused by the

increased intrathoracic pressure, due in turn to the rise of the diaphragm. The cardiac slowing does not occur after bilateral section of the vagus nerves. In no instance out of some 700 decompressions on several different species of laboratory animal did a fatality occur from a single decompression. The injuries which are most likely to occur from explosive decompression are damage to ears and lungs, though rupture of the stomach or intestine may result.

Respiration in a Sealed Cabin

In flight beyond the earth's atmosphere the passengers must be in a sealed compartment. The total pressure of gases in the compartment could be reduced quickly to one half that at sea level without causing any difficulty in normal subjects providing the pO_2 were kept up to a level sufficient to prevent arterial hypoxia. This could be done if the per cent of O_2 were about 35 to 40 at a cabin pressure of 380 mm. of Hg. It would be necessary to release the oxygen from a container, and there would be no point in permitting a lower oxygen tension than that which produces full saturation of hemoglobin in arterial blood, since oxygen can not be saved simply by reducing the supply. Also, there would be no advantage in providing a higher oxygen tension than that breathed at sea level.

The sealed cabin must contain apparatus for absorbing the CO_2 . A rise in CO_2 content up to 2 per cent at 380 mm. Hg pressure would appear to be permissible even for indefinitely long periods. Circulation of the gas in the cabin through canisters, such as are used in the closed CO_2 -

absorption methods of administering anesthetic gases, could accomplish CO_2 removal quite readily. (Chemicals could be used which could be regenerated by exposing them to the exterior of the cabin by some sort of double-window arrangement or in a hollow sphere in the wall of the cabin which would be equipped with a window, providing exposure for part of the time to the inside of the cabin and part time to the exterior.) The cabin would need to be equipped with instruments for continuous monitoring of pO_2 and pCO_2 . For long term space flight the idea of using the photosynthetic process to take up CO_2 and produce O_2 has been advanced.

Average values for the daily metabolic turnover of a "standard" man are presented below (compiled by H. G. Clamann, United States Air Force School of Aviation Medicine, Randolph Field, Texas). Calculations of what supplies must be taken in a sealed cabin for trips of any duration can be made on the basis of such data (table 33 1).

Perhaps it is worth mentioning that if a passenger in a sealed cabin were provided with a pressure suit which could withstand an internal pressure about one-fourth of an atmosphere greater than that on the outside and which was equipped with an oxygen source he could put this on, establish a pressure in the suit with oxygen at 160 mm. Hg, and then open the cabin to allow evacuation of all gases from it. Such a suit would be of the same type as that needed if one were to leave a space ship when beyond the earth's atmosphere.

TABLE 33 1

Daily metabolic turnover

(Man 70 kg. RQ = 0.82 Food Protein 80 grams, Carbohydrate 270 grams, Fat 150 grams)

	Input			Output

Pneumonia

In *lobar pneumonia* the oxygen saturation of the arterial blood varies in different cases from normal to less than 70 per cent. The signs and symptoms of anoxia usually appear when the saturation is around 85 per cent. Cerebral symptoms, e.g., sleeplessness and delirium, cyanosis and dyspnea increase with the oxygen desaturation, and a saturation of less than 80 per cent is associated with a very high mortality. In 33 cases reported by Stadie with a saturation as low or lower than this only 1 recovered. In *lobar pneumonia* the carbon dioxide content of the arterial blood is reduced on the average by about 15 per cent (Meakins and Davies). The "alkali reserve", however, is normal or only slightly reduced. The blood pH may in some cases be shifted slightly toward alkalinity. From these findings it appears that there exists a partially compensated alkalosis, induced by the hyperventilation (blowing off of carbon dioxide).

The increased ventilation of the alveoli also increases the percentage of oxygen in the alveolar air, but this fact cannot, as we shall see presently, increase appreciably the oxygen in the arterial blood.

In *bronchopneumonia* a higher degree of oxygen desaturation of the arterial blood is usually present than in the *lobar type*. The cyanosis may be extreme. There is often retention of carbon dioxide when a rise in plasma bicarbonate results, to compensate, in part at least, the gaseous acidosis. The carbon dioxide content of the arterial blood may be 80 volumes per cent or more and the carbon dioxide dissociation curve well above the normal level.

The causes of hypoxia in pneumonia. The main factors concerned in the production of the hypoxia are (a) the passage of blood through unaerated (consolidated) portions of the lung and (b) shallow breathing. The oxygen unsaturation is not due to any change in the hemoglobin itself (e.g., the formation of methemoglobin) since the blood of pneumonia patients has a normal oxygen capacity. The oxygen dissociation curve at a given carbon dioxide tension is not appreciably different from that of normal persons.

In *lobar pneumonia* during the stages of engorgement and red hepatization the alveoli of the affected portion of the lung are poorly aerated. Mucus blocks the bronchioles and the air spaces are filled or their walls coated with exudate. But a large proportion of the vessels of these unaerated regions are still pervious. Consequently blood

traversing such areas must remain poorly oxygenated or entirely venous. This blood with a low oxygen saturation and a high carbon dioxide content mixes with blood which has passed through aerated regions. The general arterial blood therefore has its oxygen saturation reduced in proportion to the amount of unsaturated blood with which it is mixed (see also Shunt, p. 521). When the pneumonic area passes into the stage of gray hepatization the vessels of the affected lobe become obliterated to a large extent and the pulmonary blood then passes through aerated regions (fig. 331). That is, the arterial blood is no longer vitiated by blood from non-aerated areas. Therefore in a typical case of *lobar pneumonia* when the disease is confined to a single large area and the breathing is not shallow, there is little anoxemia at this stage. If however, bronchopneumonic areas co-exist, the respiratory functions will be affected as described below. (See Oxygen Therapy, p. 526).

In *bronchopneumonia*, patches of lung tissue are cut off from their air supply. The fine bron-

FIG. 331 X-ray photograph of lung (injected with barium) from a case of *lobar pneumonia* (after Gross). Upper right hand area Consolidated area—red hepatization. The main vessels are constricted and the finer vascular structure is less dense than in the normal lung. Lower right hand area Consolidated area—gray hepatization. The main vessels are patent but the finer vessels have been occluded. Lower left hand area Healthy portion of lung except for compensatory congestion, the vessels are dilated.

choles become plugged with mucus, groups of alveoli become filled with exudate and the alveolar walls are edematous and thickened. Yet, obliteration of the vessels to any great extent does not occur. Blood continues to flow through un-aerated areas. This blood which has a low pO_2 on mixing with that from aerated alveoli lowers the saturation of the general arterial blood.

SHALLOW BREATHING In pneumonia breathing is frequently very rapid and shallow. Instead of the tidal air being around 500 ml. as in health it may be reduced to 250 ml. or less. It will be recalled that 150 ml. are required to fill the anatomical dead space, therefore only 100 ml. will enter the air sacs of the healthy parts of the lung. We have seen that the expansion of the lungs is not equal in all its parts (p. 471). The alveoli towards the hub of the radiating rays expand less than those near the periphery. Those parts, such as the apex, which are indirectly expanded have even in health a tendency to be ventilated less than those which are directly expanded. In shallow breathing, these differences are greatly exaggerated. Although the tidal volume is only half the normal, the total quantity of air breathed per minute (minute volume) is, as a result of the increased respiratory rate, much greater than normal. Since a proportion of the alveoli are very

poorly ventilated or not at all, owing to the unequal expansion of the lung, those in other areas tend to be overventilated. The O_2 tension in the latter is therefore raised. But so far as the oxygenation of the blood is concerned the overventilation of some alveoli cannot make up for the underventilation of others. We know that the hemoglobin is nearly saturated already at the ordinary alveolar oxygen tension of 100 mm. Hg. As already mentioned the dissociation curve of hemoglobin in pneumonia does not differ appreciably from that in health, and the most, therefore, that could be expected from a rise in the alveolar O_2 tension would be an increase of 2 per cent or less in oxygen saturation of the blood traversing overventilated regions and a slight increase in the amount of O_2 held in simple solution. In other words, the blood flowing through the poorly ventilated parts of the lung will have a low saturation since the O_2 tension is low, while that flowing through the overventilated parts will be little above the normal. The net result will be a low oxygen saturation of the mixed arterial blood.

Matters are different in the case of CO_2 elimination. The shape of the CO_2 dissociation curve which shows a progressive slope throughout the entire range of CO_2 tensions is quite unlike that for oxyhemoglobin (fig. 33.2). The greater total ventilation results in a lowering of CO_2 tension in the overventilated parts of the lung and consequently, in a 'blowing off' of CO_2 from the blood circulating through these regions. CO_2 is retained in the blood circulating through poorly ventilated regions. In the patient with lobar pneumonia the amount of CO_2 blown off may exceed that retained, the net result will be a lowering of the CO_2 content of the arterial blood. In bronchopneumonia a larger proportion of the pulmonary blood circulates through non-aerated areas. As a consequence, CO_2 retention is greater, and a normal or a higher than normal CO_2 content of the blood is more usual.

The cause of shallow breathing in pneumonia. Pleuritic pain, by restricting the respiratory excursions, may result in this type of breathing. In other instances it appears to be of a reflex nature resulting from the inflammatory process which, through a reduction in the distensibility of the pulmonary tissue, exalts the sensitivity of the afferent vagal endings in the alveolar walls. Thus the inspiratory movement is terminated before a full excursion has been completed (see Hering-Breuer reflex, p. 493). In support of a reflex origin may be mentioned the experiments of

FIG. 33.2 Carbon dioxide and oxygen dissociation curves. The small rectangles indicate the extent of the variation of the O_2 and CO_2 of the subject's blood when at rest. (From L. J. HENDERSON.)

Dunn and of Binger, Brow and Bronch who produced this type of breathing in animals by the intravenous injection of potato starch granules. These, acting as small emboli, plugged the pulmonary capillaries. The rapid shallow breathing was immediately abolished by section of the vagi or prevented if the nerves had been cut before the injection. Breathing a mixture rich in carbon dioxide with intact nerves also restored the respiratory rate and depth to normal—the action of carbon dioxide upon the respiratory center itself overcoming the afferent nervous influence. Also, in pneumonia it has been found that oxygen inhalations, even though they may restore the oxygen saturation of the arterial blood to normal, do not necessarily abolish the shallow breathing—further evidence for the existence of a nervous element in the production of this type of breathing. Shallow breathing may also result from other diseases involving the alveoli, e.g., inflammation by irritant gases (phosgene and chlorine), pulmonary edema, mediary tuberculosis and pulmonary emboli, which would be expected to stimulate afferent nerve endings. It also occurs in certain nervous states, hysteria, certain forms of neurasthenia and sometimes in encephalitis lethargica, but is not seen in lesions involving the bronchi or bronchioles alone, e.g., bronchitis and asthma.

Severe arterial hypoxia, however produced, tends itself through its damaging effect upon the respiratory center to induce rapid shallow breathing, and in any event will exaggerate this type of breathing, since it also tends to increase the sensitivity of the Hering-Breuer reflex. Thus a vicious circle—shallow breathing inducing anoxemia and the latter reacting to enhance the former—is set up. Owing to the narrowed state of the cutaneous vessels the cyanosis is of the pale leaden gray type (p. 526), and if the anoxia is not relieved, failing circulation adds to the oxygen want (anoxia of the hypokinetic type).

Bronchial Asthma

This is a paroxysmal disease in which acute oxygen want is caused by a spasm of the smooth muscles of the finer bronchioles. Edema of the broncholar mucosa is probably also present. The alveoli are poorly ventilated, and some may be completely cut off from their air supply. The high percentage of carbon dioxide and low percentage of oxygen in the alveolar air result in a low oxygen saturation of the arterial blood and the retention of carbon dioxide. The acidosis related to CO_2 retention is met by the excretion of a highly acid

urine and a rise in the "alkali reserve." An intense plum-colored cyanosis may develop. The continued stimulating effect of oxygen want and carbon dioxide excess upon the respiratory mechanism causes severe dyspnea.

Difficulty is experienced both in inspiration and expiration, but since there is a natural tendency for the bronchioles to narrow during expiration and dilate during inspiration, the greatest respiratory effort is exerted during expiration. The respiratory muscles contract with great force, and the accessory muscles of respiration are brought into play. The expiratory muscles compress the chest, the abdominal muscles contract in the attempt to squeeze the air from the lungs. The intrapulmonary pressure is greatly elevated, and the air escapes through the constricted tubes with a distinct wheezing sound. Due to the difficulty and prolongation of the expiratory phase normal deflation of the lungs cannot occur before the next inspiration ensues. The lungs therefore remain somewhat expanded even at the end of expiration. That is, during the asthmatic paroxysm a very large volume of residual air is present in the lungs (fig. 33-3). The tidal volume and the vital capacity are greatly reduced. The changes in volume of the overdistended lung are small and not commensurate with the excursions of the thoracic walls. As a consequence, the high value of the intrathoracic negative pressure induced during inspiration causes the structures at the root of the neck to be drawn toward the thoracic cavity to take up the space which the lungs are unable to fill. During expiration the veins of the neck and face become engorged. The restricted movements of the lung also greatly reduce the effect of mechanical mixing upon the lung air, the process of diffusion being depended upon to a larger extent for the freshening of the alveolar air.

Causation

Asthma often shows a strong hereditary tendency. The bronchial spasm may be (a) of a reflex nature and due to the stimulation of hypersensitive afferent vagal endings in the larynx or of trigeminal fibers by some nasal abnormality; the bronchoconstrictor impulses travel via efferent vagal fibers, (b) an allergic phenomenon, i.e., the result of sensitization to some foreign protein. This is the most common cause of the condition. It is then frequently associated with other allergic conditions, e.g., hay fever, urticaria or eczema either in the patient himself or in members of his

family The foreign protein may be inhaled Pollens of various grasses and flowers, the dandruff of animals, e.g., horse, cat or dog, or feathers are among the most common excitants, the exciting cause may be some kind of food or the protein of bacteria within the respiratory tract itself may be responsible The sensitivity of certain individuals to foreign proteins presents many features resembling those of anaphylactic shock in animals Sudden death may result from the injection of horse serum (e.g., diphtheria antitoxin or antitetanic serum) into an asthmatic subject A guinea pig when injected with a protein to which it has previously been sensitized dies rapidly from anaphylactic shock The bronchiolar muscle is strongly contracted The air is trapped so that the lungs are maximally distended and do not collapse when the thorax is opened Even when the pulmonary tissue is deeply incised the air does not escape from the distended lung This manifestation of anaphylaxis is associated with perhaps due to, the liberation of histamine It is well known that anaphylaxis and histamine administration produce almost identical effects in the guinea pig (fig. 33.4) Histamine producing bacteria

FIG. 33.4 Guinea pig Reaction of bronchial muscle to 0.01 mg histamine (After Thornton)

have been reported in the bronchial secretions of asthmatics

The treatment of asthma resolves itself into the relief of the paroxysm and the removal of the underlying cause Adrenaline or ephedrine acts by inhibiting the broncholar muscle during the attack Atropine paralyzes the bronchoconstrictor (vagal) fibers Of the three drugs, adrenaline is the most effective In the allergic form of the disease every effort is made to identify the offending protein Antihistamine drugs have been employed with varying degrees of success

Chronic Emphysema

The lungs in emphysema (Greek *em* + *physis*, a blowing) are in a state of extreme distention as a result of the enlargement of the air sacs The latter, however, show fewer alveoli in their walls owing to the atrophy of the interalveolar septa Contiguous air sacs within a lobule coalesce or even adjacent lobules may fuse to form large air spaces For this reason the total respiratory surface is reduced The alveolar and capillary walls become thickened and the interstitial pulmonary tissue increased Many capillaries become occluded The pulmonary elastic tissue is reduced in amount so that the lungs, when removed from the thorax, do not collapse normally but remain in an overexpanded state The peripheral lobules, which in health expand to the greatest extent, are those mainly affected in emphysema, the

FIG. 33.3 Diagram showing subdivisions of the lung air in asthma (II) and emphysema (III) compared with the normal (I) A, inspiratory reserve volume, B, tidal volume, C, expiratory reserve volume and D, residual volume (After Coke)

enlarged lobules appearing as blebs upon the surface of the lung

The chest is what is known as barrel shaped. The ribs are more horizontal than normally, the thoracic spine is bowed backwards (kyphosis) so that the anteroposterior diameter of the chest is as great as or exceeds the transverse. The position of the chest is one of nearly full inspiration. The position of the diaphragm is at a much lower level than usual and its excursions above and below this level are restricted. The respiration is therefore mainly costal. In some instances the diaphragm is practically fixed or indeed may be drawn up during inspiration (paradoxical movement). As in the paroxysm of asthma the residual air is 2 or 3 times the normal, and the complementary air is reduced. The tidal volume is normal or only moderately reduced and the vital capacity (fig 33.3) is lowered by from 20 to 60 per cent. Owing to the loss of the elasticity of the lung, expiration is no longer simply a passive movement but is aided by a forcible contraction of the expiratory muscles. When the patient is asked to make a deep inspiration, he does not expel all the air during the next expiration. Several respirations occur before the chest returns to its original size. Expiratory reserve volume is greatly decreased, and residual volume is markedly increased (fig 33.3). These phenomena are due to the fact that the inelastic lungs have been overstretched and are brought back to their original volume with difficulty.

In emphysema there are anoxemia and retention of carbon dioxide. The oxygen saturation of the arterial blood runs from a little below normal to around 75 per cent or even less. The carbon dioxide tension in the alveolar air in well marked cases is from 50 to over 60 mm. Hg (7 to 8 per cent) and the carbon dioxide content of the arterial blood correspondingly high.

Owing to the obliteration of many capillaries in the lungs, the resistance in the pulmonary circuit is increased, a greater burden being thus put upon the right ventricle.

The cause of the impaired gaseous exchange is not altogether clear. Thickening of the alveolar and capillary walls and the obliteration of capillaries have been considered to be factors. Yet if this were so one would not expect the retention of carbon dioxide which, owing to its greater solubility (30 times that of oxygen) has a much higher rate of diffusion through the pulmonary membrane to be so much more pronounced than the anoxia. The sharp rebound at the end of inspira-

tion which occurs in the healthy lung causes mechanical mixing of the lung air and is an important factor in the efficient ventilation of the alveoli. The absence of this effect in the emphysematous lung and its greater dependence, in consequence, upon the slower process of diffusion is probably an important factor leading to the defective aeration of the blood. According to Christie, the impaired gaseous exchange is due mainly to the fact that, as a result of the loss of elasticity, the intrathoracic pressure is not distributed evenly throughout the lung. As a consequence, the outlying alveoli which are largely functionless with obliterated vessels are ventilated to a greater extent than the relatively healthy ones more centrally placed. Owing to the shapes of the respective dissociation curves such under-ventilation of the functioning alveoli will tend to have a greater effect in preventing the elimination of CO_2 than in interfering with the absorption of oxygen. Other factors which are probably of importance are the slower rate of diffusion of CO_2 owing to its larger molecule, in the alveolar air, and the increased residual volume.

The red cell count, hemoglobin percentage and consequently the oxygen capacity of the blood, are increased above the normal in emphysema. The cyanosis (p. 524) is often pronounced, yet the patient's dyspnea is less than might be expected from his color and from the carbon dioxide retention which exists. This is explained by the well established fact that in emphysema the respiratory center is relatively insensitive to carbon dioxide. A normal person when breathing a carbon dioxide rich mixture (8 per cent) increases his pulmonary ventilation by 300 per cent or more, the breathing of the emphysematous patient, on the other hand, shows relatively little change as a result of breathing a rough stronger mixture (see fig. 33.5).

Causation

Two factors are concerned in the production of emphysema: (a) reduction in the elastic tissue of the lung and (b) increased distention of the alveolar spaces.

It is very questionable whether, in the absence of some abnormality of the lung tissue itself, emphysema can result from increased intrapulmonary pressure, such as occurs in those following certain occupations, e.g., glass blowers and the players of wind instruments. The study of groups of men following such occupations does not indicate that emphysema is produced in this way.

FIG. 33.5 Chart showing the percentile increase in tidal air per minute as the percentage of inspired carbon dioxide is raised. Note that when the normal subject inspires air containing 8 per cent carbon dioxide, the tidal volume is increased about 300 per cent, whereas in the emphysematous subject it is increased only about 25 per cent. (After R. W. Scott.)

Emphysema has, however, been induced in animals by stenosis of the trachea or bronchus or by the insertion of a valved apparatus into the trachea which allowed the free ingress of air but offered an obstruction to expiration. It is probable that in these instances the persistently high intraalveolar pressure by stretching the lung structures during inspiration first caused atrophy of the elastic tissue. During inspiration the air spaces are dilated by the negative pressure upon their outer surfaces. The trapped inspired air causes an ever increasing distending pressure to be exerted upon the alveolar walls. Inasmuch as the intrathoracic pressure is "less negative" during expiration, a reduction rather than an enlargement of alveolar capacity would result at this time. Asthma and chronic bronchitis which frequently are forerunners of emphysema also, probably, exert their damaging effect upon the alveolar structure during the inspiratory phase. In the former condition the spasm of the bronchiolar muscle exerts a valve-like action. In chronic bronchitis mucous plugs would act similarly. Coughing, it has been supposed, places a strain upon the alveolar walls. But during the phase of coughing when the glottis is closed the alveolar walls are supported. When the

glottis opens, the air escapes from the alveoli if the obstructing material has been dislodged, and no strain upon the alveolar wall would result. If, however, the air remains entrapped its sudden re-expansion (rebound), as the pressure in the surrounding pulmonary tissue falls at the end of a cough, may injure the alveolar membrane and start the emphysematous process.

What may be termed a physiological or compensatory emphysema occurs when part of the pulmonary surface is reduced as by the collapse of a part or the whole of one lung. This is more in the nature of an hypertrophy. A similar enlargement of both lungs occurs at high altitudes.

A type of emphysema also occurs in the elderly—senile or postural emphysema—and is secondary to the change in the shape of the thorax which becomes more barrel shaped and increased in capacity. The lungs enlarge to fill the increased space. This condition is associated with few symptoms. There is little reduction in the vital capacity, and the oxygen saturation of the arterial blood is practically normal.

Atelectasis

Any condition which lowers the pressure within the alveoli or increases the pressure upon the lung surface, i.e., reduces the "negative" intrapleural pressure, may lead to collapse of the lung. Thus pleural effusions, pneumothorax, tumors, etc., pressing from without or the isolation of the alveoli from their air supply by the obstruction of a bronchus will therefore result in collapse of the lung or of the portion of the lung affected. Atelectasis (Greek *ateles*, incomplete, *clasis*, distention) is also the term applied to the condition in the newborn in which, as a result of the blockage of a bronchus or of a group of bronchioles by mucous secretion, or owing to weak inspiratory movements, a portion of the lung fails to become distended with air.

Absorption of air from isolated alveoli and other closed spaces. When a bronchus or bronchiole in a previously distended lung is obstructed the imprisoned air soon becomes absorbed from the affected alveoli. Collapse of the air sacs cannot take place until this has occurred. Absorption is brought about in the following way, as pointed out by Henderson. The air in the isolated alveoli has a total pressure of 760 mm Hg. The partial pressures are in round numbers, O₂, 100 mm, N₂, 570 mm, CO₂, 40 mm and aqueous vapor, 47 mm. In the venous blood the total pressure is 703 mm, the nitrogen and aqueous vapor being the same as that of the alveolar air, but the partial pressure of oxygen is only 40 mm.

and of carbon dioxide 46 mm. An interchange of the latter gases therefore occurs between the alveolar air and the venous blood. It might be thought that the imprisoned air would then be in equilibrium with the blood and no further absorption occur. But the alveolar air loses more oxygen than it gains carbon dioxide whereupon its volume is reduced. The atmosphere acting upon the body surface and through the yielding soft tissues compresses the air so as to maintain its total pressure practically constant at 760 mm. As a result of the absorption of oxygen the percentage and consequently the partial pressure of carbon dioxide and of nitrogen are increased. These gases now diffuse into the blood. The volume of the alveolar air is further reduced thereby but its total pressure still remains unaltered. The percentage and therefore the partial pressure of oxygen rises and more of this gas passes into the blood. The process continues in this manner until no air remains, and the walls of the original space are ultimately approximated by the pressure of the atmosphere. Air is absorbed from the pleural cavity or from any other closed cavity of the body in the same way (Henderson and Henderson). The absorption of the air confined within the pleural cavity permits the lung, if the air pressure had caused its collapse, to re-expand (see also p 477).

The collapse and shrinkage of the lung which results from blockage of a bronchus increases the intrathoracic negative pressure, since the closed thoracic box is less completely filled. The diaphragm is therefore drawn upwards and uncollapsed portions of the lungs are expanded to a greater extent (compensatory emphysema) in order to fill the unoccupied space.

Shunt

In the fetus the vessels of the airless lungs are bypassed by the greater part of the blood brought to the heart. That is to say, most of the blood is shunted to the arterial side through channels which normally close at, or shortly after, birth. It is clear that if one or more of these channels should persist after birth, or if the interventricular septum is defective so that a large part of the venous blood does not traverse the lungs, but is short circuited from the right to the left heart or directly into the aorta, the oxygen saturation of the arterial blood will be seriously reduced. Arterial hypoxia evidenced by cyanosis (p 524) and dyspnea (p 501) will result (fig 33 6). These will be especially pronounced upon exertion since the

unsaturation of the polluting venous blood will be thereby increased.

The fetal circulation. Before the congenital abnormalities are described the fetal circulation and the circulatory readjustments which occur at birth, or shortly thereafter, will be briefly reviewed.

In the fetus the oxygenated blood from the placenta is carried by the umbilical vein to the liver, where it separates into two streams: one of which is distributed to the left $\frac{1}{3}$ or so of the liver, the

Fig. 33 6. Diagram (upper) showing the proportion of oxyhemoglobin to reduced hemoglobin in different parts of the circulation in an instance where a portion of the blood passes through un aerated channels (shunt) from the venous to the arterial system. Lower diagram represents a case in which the oxygen unsaturation of the blood is abnormally high in a part of the peripheral capillaries but normal in the arterial blood (stagnant type of anoxia) (After Lundsgaard and Van Slyke.)

remainder passes directly via the *ductus venosus* into the inferior vena cava, thus mixing with blood returning from the lower part of the body. The portal vein supplies the rest of the liver. That portion of the blood from the umbilical vein which has traversed the vessels of the liver is also delivered by the hepatic veins into the inferior vena cava. The hepatic veins are a number of small vessels and two much larger ones, the latter form a junction with the ductus venosus just before the latter joins the inferior vena cava. The blood in the vena cava beyond this point is, therefore, partly oxygenated (from placenta via umbilical vein and ductus venosus) and partly reduced, having traversed the tissues of the lower limbs, intestines and liver. The caval blood, upon reaching the right auricle, separates into two unequal parts. The much larger stream passes directly through the foramen ovale (*via sinistra*) into the left auricle, the smaller stream enters the right ventricle. The blood which has reached the left auricle, after being joined by a small but by no means inconsiderable volume of blood returned from the pulmonary tissue, flows into the left ventricle, and is discharged into the aorta and distributed to the brain by the brachiocephalic artery, and to the myocardium by the coronary arteries. The remainder flows down the aorta.

The blood returned from the head and entering the right auricle by the superior vena cava, together with the small fraction of blood of the inferior vena cava which was not directed through the foramen ovale, enters the right ventricle and is ejected into the pulmonary artery. A smaller part, yet, as shown by Franklin and his associates, more than has been generally supposed is con-

veyed to the lungs by two branches of the latter vessels. The main stream, discharged from the right ventricle, passes by a wide vessel, the *ductus arteriosus*, into the aorta, and mixing with the blood coming from the left ventricle, is distributed throughout the body. That portion which is supplied to the lower limbs is returned by two vessels—the *umbilical arteries*—to the placenta.

During birth, or very shortly after, the three umbilical vessels close (even though the cord has not been tied or broken) by the contraction of smooth muscle in the vascular walls. The flow through the ductus venosus ceases as a result of contraction of a smooth muscle sphincter at the point where it leaves the umbilical vein. This occurs in the sheep fetus, according to Franklin and his associates, in from 5 to 25 minutes after the umbilical vessels have closed. Within 5 minutes or so after the commencement of breathing the foramen ovale closes, and a little later (apparently never before the obliteration of the foramen ovale) the ductus arteriosus becomes occluded. All the blood from the right side of the heart is normally from now on directed through the lungs. Franklin and his associates found, however, in the case of the new born lamb, that should the general condition of the latter seriously deteriorate, the ductus arteriosus may open again. The mechanism of closure of the ductus appears to be initiated in some way by the action of the oxygenated blood upon the vascular muscle and not through a nervous mechanism. In the lamb this channel has never been observed to close before occlusion of the umbilical vessels.

CONGENITAL CARDIAC DEFECTS

Patent ductus arteriosus, or foramen ovale in interventricular septal defects, stenosis of the pulmonary artery and coarctation of the aorta (narrowing of aorta in the neighborhood of the ductus arteriosus) are among the congenital defects most commonly met with.

The development of the direct Fick method (catheterization of the right side of the heart) for determining the cardiac output has provided means of the greatest value in diagnosing congenital defects of the circulation. It is now possible to obtain samples of blood for gas analysis from the right ventricle or from the pulmonary artery (See fig. 337.)

Patent foramen ovale or other defect in the interauricular septum. In patency of the foramen ovale, the opening is guarded by a valvelike membrane which prevents blood from passing from the left to the right auricle, and none passes in the opposite direction unless the pressure in the right auricle is high. With other defects of the interauricular septum, a shunt from right to left with cyanosis may occur, but if there is mitral stenosis and a large defect (*Lutembacher's syndrome*) the high

FIG. 337. Numbers from 1 to 11 indicate the positions from which blood samples may be taken by means of the intracardiac catheter (After Groom and associates.)

pressure in the left auricle causes a shunt from left to right

Patent ductus arteriosus Blood enters the pulmonary system from the arterial side, the oxygen content in the pulmonary artery is increased, but is normal in the right auricle and ventricle

If a defect of the *interventricular septum* exists alone, the oxygen content of the blood in the right ventricle and pulmonary artery is increased but not of that in the right auricle

Neither of these last two defects, if it exists alone, will cause cyanosis, since the shunt is from left to right (arteriovenous shunt) Rarely, however, in the case of a patent ductus arteriosus, the direction of flow is reversed temporarily at certain times (during crying or coughing), blood passing from the pulmonary artery into the aorta

Often the abnormalities are multiple For example, a patent foramen ovale, together with stenosis of the pulmonary artery, results in the passage of venous blood to the arterial side, i.e., through the auricular defect, slight or moderate cyanosis is seen The combination of congenital defects, originally described by John Hunter and later by Fallot, and now generally known as the *tetralogy of Fallot*, consists of, (a) an *interventricular septal defect*, (b) narrowing of the pulmonary artery, or stenosis of its orifice, and (c) *dextroposition of the aorta*, the orifice of this vessel being shifted to the right to straddle the septal defect (d) The fourth element making up the tetrad is *right ventricular hypertrophy* The blood flow through the lungs and the pulmonary pressure are reduced Owing to the high pressure developed in the right ventricle blood is driven through the defect into the overriding aorta If the pulmonary stenosis is very severe, the ductus arteriosus must be patent *in order to provide sufficient blood flow* through the lungs to support life Cyanosis and dyspnea are usually pronounced Blalock and Taussig have devised an operation for the correction of the chief effects of these conditions It consists of anastomosing a large branch of the aortic arch (usually carotid or subclavian) to the right or left pulmonary artery

Another combination of defects has three features of the tetralogy of Fallot, namely, defect of the *intraventricular septum*, *dextroposition of the aorta* and *right ventricular hypertrophy*, but pulmonary stenosis is absent It is known as *Eisenmenger's complex* The shunt is from left to right in early life, but later, when as a result of the large volume of blood entering the right ventricle from the left side as well as through the normal channels this chamber enlarges and hypertrophies, the high pressure developed may force venous blood into the overriding aorta, cyanosis then appears

In those congenital cardiac anomalies showing cyanosis, the arterial oxygen saturation is found

to be, during rest, from 45 per cent in severer degrees of cyanosis to 90 per cent in the milder cases The red cell count, however, is likely to be increased, and the hemoglobin concentration may be high as 26 grams per cent The arterial oxygen content, i.e., the volumes of oxygen per 100 cc of blood, in those with the higher hemoglobin concentration is, consequently, much higher than normal and may reach a value of 20 volumes per cent, as against the normal maximum of 22 volumes per cent (see Cyanosis p 524) Exercise, which in normal subjects causes little or no change in arterial oxygen saturation produces a profound fall in the congenital heart cases amounting in some to a reduction of over 30 per cent

Carbon Monoxide Poisoning

References to carbon monoxide poisoning are contained in the earliest medical writings This gas was used by the Greeks and Romans for the execution of criminals and as a means of committing suicide Carbon monoxide is today the most important gaseous poison against which physicians have to contend During times of peace it accounts for more deaths than all the other gases combined Carbon monoxide combines with the hemoglobin of the blood and thus renders it unavailable for oxygen carriage The affinity of hemoglobin for carbon monoxide is approximately 300 times its affinity for oxygen Therefore, when the atmosphere contains only a very small percentage of CO, the hemoglobin takes up the poisonous gas and in so doing prevents its combining with an equivalent volume of oxygen

Recovery from carbon monoxide poisoning is usually complete when the exposure has not been too long or the concentration too high It is important that the carbon monoxide hemoglobin should be broken up as soon as possible since injury to the tissues is produced by the anoxia It is possible to displace the carbon monoxide by oxygen if the tension of oxygen is sufficiently high and that of carbon monoxide low Mixtures with a high percentage of oxygen and from 6 to 7 per cent carbon dioxide combined with artificial respiration are used in the treatment of CO poisoning The carbon dioxide, as well as acting as a respiratory stimulant, reduces the affinity of hemoglobin for carbon monoxide Intravenous injections of methylene blue have been advocated but are valueless Carbon monoxide, as well as its action in displacing oxygen from hemoglobin, has histotoxic properties, inhibiting the tissue respiratory enzymes This fact has no practical bearing however, upon carbon monoxide poisoning in man, for the concentrations at which such action occurs is

many times greater than could ever occur in the body

Cyanide Poisoning

No interference with oxygen carriage is caused by cyanide but there is inhibition of tissue respiration. Cyanide inhibits the action of cytochrome oxidase, carbonic anhydrase and probably of other enzyme systems. It follows from this that any antidote for cyanide poisoning must have one of two actions. Either the cyanide must be removed or detoxified or the inactivated catalyst must be replaced. Methylene blue does act as a catalyst for certain biological oxidations and this led to its use as an antidote for cyanide poisoning. When methylene blue is given to the intact animal there is a marked rise in body temperature which is due to increased metabolism. Methylene blue permits inhibiting effects of cyanide on cellular oxidations. This fact has been established from investigation on a great number of tissues. Sahlin in 1926 provided the first experimental demonstration that methylene blue antagonizes the action of cyanide in the intact animal. He used rats and the observation has been confirmed on other animals—dogs, rabbits, mice. The evidence suggests that methylene blue acts by removing the cyanide from tissue. Methylene blue and cyanide do not combine directly but methylene blue forms methemoglobin which combines with the cyanide to form cyanmethemoglobin. The cyanmethemoglobin is relatively nontoxic and is broken down slowly to the detoxification probably being brought about by conversion of the cyanide to thiocyanate (Smith and Malcolm). Other substances which form methemoglobin (Hug Wendel) such as sodium nitrite, amyl nitrite, pyrogallol etc. are also effective in the treatment of cyanide poisoning. Such methods of course are limited by the quantity of hemoglobin that can safely be converted to methemoglobin.

A number of sulphur compounds have been found effective in cyanide poisoning. Chen, Rose and Clowes showed that sodium thiosulphate and sodium tetrathionate may protect dogs against as much as three lethal doses of cyanide.

Cyanosis

Cyanosis (Greek, *kyanos* blue) may be defined as the diffuse, dusky or bluish color of the skin and mucous membranes caused by the presence in the blood of the superficial capillaries (subpapillary venous plexus) of reduced hemoglobin above a certain definite amount.¹ Cyanosis

is seen in the arterial and hypokinetic types of anoxia but not in the anemic or histotoxic forms. It seems scarcely necessary to state that the retention of carbon dioxide in the blood has no direct effect upon the production of cyanosis. The blue color of the skin depends fundamentally upon the absolute amount of reduced hemoglobin in the capillary blood and not upon the relative proportions of reduced hemoglobin and oxyhemoglobin. For example in anemia the hemoglobin content of the blood may be only 20 per cent of the normal. In the capillary blood all of this could be in the reduced form, yet cyanosis would not result, since the absolute amount of reduced hemoglobin (i.e., 'blue pigment') would be insufficient to produce any blue discoloration. On the other hand in polycythemia the hemoglobin may be 100 per cent above normal. Cyanosis will occur when the hemoglobin of the capillary blood is only 20 per cent reduced for the absolute concentration of reduced hemoglobin will then be raised to threshold value. The greater quantity of the bright-colored oxyhemoglobin present exerts little or no influence, that is it does not as might be expected tend to neutralize the color effect of the reduced hemoglobin.

Normal blood contains about 15 grams of hemoglobin per 100 cc. Lundgaard found that the capillary blood must contain approximately 5 grams of reduced hemoglobin per 100 cc. before cyanosis will appear. When fully saturated (20 volumes per cent), $\frac{3}{4}$ gram of hemoglobin will take up 1 cc. of oxygen. Five grams of hemoglobin therefore hold about 6.7 cc. of oxygen and 5 grams of reduced hemoglobin are formed when the blood contains 13.3 volumes per cent of oxygen. Cyanosis may therefore be expected to appear when the blood in the capillaries is on the average around 7 volumes per cent unsaturated. As a result of certain modifying factors (p. 526) the precise level of capillary unsaturation at which cyanosis makes its appearance varies in different cases between 6 and 7 volumes of oxygen per cent.

The oxygen unsaturation of the capillary blood does not of course occur abruptly at the arterial end but is progressive from point to point along the course of the vessel. The loss of oxygen may

¹ The presence of abnormal compounds of hemoglobin, e.g. methemoglobin and sulfohemoglobin resulting from the action of various toxic substances causes a type of cyanosis (enterogenous cyanosis), but these will not be considered

here (see p. 57). Cyanosis may result from anoxia of either the arterial or hypokinetic type. It obviously cannot occur in the anemic type which is due essentially to a low hemoglobin concentration in the histotoxic type in which the hemoglobin gives up less of its oxygen store than in health nor in the arterial and hypokinetic types if a severe grade of anemia exists.

FIG. 33-8 Diagram showing hypothetical variations in the shape of the reduction curve of oxyhemoglobin during the passage of the blood through tissue capillaries (After Lundsgaard and Van Slyke)

be uniform from the arterial to the venous end of the capillary as shown in Curve I, figure 33-8, or the desaturation may occur mainly toward the venous end (Curve II) when the capillary blood would approximate arterial blood in its content of reduced hemoglobin. Under other circumstances the greatest oxygen loss may occur toward the arterial end (Curve III) when the unsaturation of the capillary blood throughout would approach that of venous blood. It is difficult to obtain data from which the true curve may be drawn. The simplest of these curves (Curve I) is assumed and the average unsaturation of the capillary blood is taken as midway between that of arterial and venous bloods respectively. Thus

$$\frac{1}{2}(A + V) = C$$

where A and V represent the unsaturation in volumes per cent of arterial and venous bloods respectively and C the average unsaturation of the capillary blood.

For example, in a normal person the arterial unsaturation is 0.5 volume per cent (19.5 volumes per cent saturation), another 5 volumes per cent are given up in the capillary, the venous unsaturation is therefore 5.5 volumes per cent. So

$$\frac{1}{2}(0.5 + 5.5) = 3.0 \text{ volumes per cent average unsaturation of capillary blood}$$

$$(3.0 \times 0.75) = 2.2 \text{ gram reduced Hb}$$

We have seen that the average unsaturation of the capillary blood must be between 6 and 7 volumes per cent (approximately 5 grams of reduced Hb) before cyanosis appears. This degree of unsaturation of the capillary blood may be brought about either by an increase in the arterial unsaturation (arterial type of anoxia) or as a result of a greater amount of oxygen being lost from the blood in its passage through the capillaries (hypokinetic type of anoxia). That is, by an increase in the venous unsaturation (V) alone. In order to produce an average unsaturation of from 6 to 7 volumes per cent in the capillary blood the arterial unsatura-

tion would need to be from 4 to 4.5 volumes per cent, or the unsaturation of the venous blood—that in the arteries being normal—11 to 13 volumes per cent. Meakins and Davies found that when the veins of the arm were obstructed in normal individuals cyanosis was just detectable when the venous blood reached an unsaturation of 11.4 volumes per cent.

These facts may be clarified by examples. If the blood as it leaves the lungs contains only 15.5 volumes per cent of oxygen, i.e., if it has an unsaturation of 4.5 volumes per cent and the tissues abstract the usual quantity of oxygen, namely 5 volumes per cent, the unsaturation of the venous blood will be 9.5 volumes per cent and that of the capillary blood

$$\frac{1}{2}(4.5 + 9.5) = 7 \text{ volumes per cent}$$

$$(7 \times 0.75 = 5.2 \text{ grams Hb})$$

If on the other hand the arterial unsaturation is around the normal value of 0.5 volume per cent but as a result of slowing of the circulation each unit volume of the blood gives up a greater quantity of oxygen, and the venous unsaturation is increased to say 13 volumes per cent, the average unsaturation of the capillary blood will be

$$\frac{1}{2}(0.5 + 13) = 6.7 \text{ volumes per cent}$$

In either of these instances slight cyanosis would be expected to appear.

Let us now consider what occurs when the hemoglobin percentage is above or below the normal value.

In anemias the amount of hemoglobin is below normal, and the oxygen capacity of the blood is correspondingly lowered. If the hemoglobin content be only 30 per cent of the normal, the volumes per cent of oxygen in the arterial blood, though the latter be fully saturated, will be only about 6 volumes per cent, i.e., the quantity of hemoglobin in 100 cc of blood is less than 5 grams. It is obvious that such a person could not become cyanotic even if, as a result of defective oxygenation of the blood or of slowing of the circulation, all his hemoglobin were in the reduced state. A patient whose hemoglobin was, say, 60 per cent (oxygen capacity 12 volumes per cent) would, like one with a normal hemoglobin content, become cyanotic when his arterial blood reached an unsaturation of about 4.5 volumes per cent, that is when his capillary blood had an average unsaturation of around 7 volumes per cent. But the oxygen want of the anemic subject would be greater than that of the subject with a normal

hemoglobin content since in the case of the former 4.5 volumes per cent constitute nearly 40 per cent of the oxygen capacity of his blood. In a less enlightened age when bleeding was resorted to for the relief of cyanosis, the brilliant success of that procedure is not to be wondered at—nor that the patient died. In the hypokinetic type of anoxia the unsaturation of the venous blood of a subject with 60 per cent hemoglobin content could not reach the value necessary to produce cyanosis until all the hemoglobin was in the reduced state. Thus $\frac{1}{2}(1 + 12) = 6.5$ volumes per cent unsaturation of the capillary blood.

In *polycythemia*, in which the hemoglobin content is say, double the normal (oxygen capacity 40 volumes per cent), cyanosis occurs in very mild degrees of anoxemia. At an arterial unsaturation of 4.5 volumes per cent the polycythemic subject would have the same degree of cyanosis as an ordinary person with this quantity (5 grams) of reduced hemoglobin in his blood. But in the polycythemic subject with a hemoglobin content of 200 per cent, 4.5 volumes per cent is only 11 per cent of the oxygen capacity of his blood, in the person with a normal hemoglobin content it constitutes 22.5 per cent. The oxygen want in the former would be relatively slight as compared with that of the latter. Or put in another way and including the anemic subject—if the anoxemia were of the same degree in each, the anemic person would show little or no cyanosis, the polycythemic, a cyanosis of high degree and the normal subject a color intermediate in intensity. In a person with an abnormally high blood count a degree of slowing of the peripheral blood flow which would be without effect upon one possessing a normal hemoglobin content will result in cyanosis. Thus in regions such as the face, ear lobes and hands, where the cutaneous vessels are well filled with blood, cyanosis is readily induced in the polycythemic subject by exposure to cold. In certain conditions associated with arterial anoxemia, e.g., emphysema (p. 518) and congenital heart disease the red cell count is increased and the cyanosis, in consequence, enhanced. It will be evident from these examples that the presence of cyanosis indicates anoxia but the absence of cyanosis does not rule out the possibility of anoxia.

THE FACTORS WHICH INFLUENCE THE DEPTH OF CYANOSIS CAUSED BY A GIVEN QUANTITY OF REDUCED HEMOGLOBIN

(a) *The state of cutaneous capillaries.* When these are dilated more of the dark colored blood

will be present in the skin than when they are constricted. In the former instance cyanosis will of course be more pronounced. Increased carbon dioxide tension in the peripheral blood causes capillary dilation, therefore, when retention of this gas accompanies oxygen want, as in venous congestion of superficial regions, etc. the cyanosis is intense. If the peripheral vessels are strongly constricted, as in shock, cyanosis may be inconspicuous.

(b) *Pigmentation and thickness of the skin.* These factors obviously will modify the depth of the cyanotic color. Cyanosis is more clearly evident in regions where the skin is thin and unpigmented. The yellow discoloration of the skin caused by an excess of bilirubin in the blood (jaundice) tends to modify the cyanotic tint but since the former stains the skin itself, while the discoloration due to reduced hemoglobin is confined to the capillary vessels, jaundice is likely to be just as intense in regions where the skin is thick as in those where it is thin. The cyanotic discoloration can be temporarily abolished by pressure upon the skin whereas the icteric staining cannot. Cyanosis does not appear in the conjunctivae but these are deeply colored in jaundice.

OXYGEN THERAPY

Oxygen administration is of great value in combating acute arterial anoxia as may occur in pneumonia, pulmonary edema, or obstruction to breathing as well as in states such as congestive heart failure, or coronary thrombosis when though the arterial blood contains the usual amount of oxygen, the tissues, owing to impairment of the peripheral circulation, suffer from a deficiency of oxygen.

The chronic anoxia due to anemia, in which the hemoglobin is saturated with oxygen to the normal degree, is treated preferably by measures directed to the disease itself rather than by oxygen therapy. In failure of the peripheral circulation, the inhalation of 100 per cent oxygen will increase the oxygen content of the blood to revive a flagging respiratory center. But the anoxia due to a shunt of blood from the right to the left side of the heart (p. 522) or through a similarly completely anaerated portion of the lung will not be much benefited by oxygen inhalations, it is not possible to make the blood supplying healthy and well aerated alveoli absorb any important amount of extra oxygen and so compensate for the shunted blood.

When, however, the diffusion coefficient of oxygen (ch. 29) through the alveolar membrane is

reduced as a result of edema, thickening or a coating of fluid, oxygen administration by raising the pressure of the gas in the alveolar air will increase its rate of diffusion across the pulmonary epithelium. The oxygen saturation of the blood flowing through the damaged pulmonary tissue is increased.

Consequently, in broncho- or lobar pneumonia when such changes are responsible for the anoxemia, in emphysema or in pulmonary edema whether from cardiac or pulmonary disease or from gas poisoning, the success of oxygen administration is often spectacular. Anoxemia increases the permeability of the pulmonary epithelium to fluids and, consequently, encourages edema formation. In other words, a vicious circle is established—edema inducing anoxemia and the latter increasing the edema—which is broken by oxygen administration.

Anoxemia due to rapid shallow breathing is relieved by oxygen treatment since the oxygen tension of poorly ventilated alveoli is raised thereby. The shallow breathing itself is likely to persist since it is primarily due to the local process in the lung acting upon the nerve endings rather than to the anoxemia. Therefore this type of breathing could, no more than the pulmonary lesion itself, be expected to be abolished by oxygen treatment.

It has been said that when the arterial blood contains the normal quantity of oxygen, namely about 19.5 volumes per cent (saturation 97.5 per cent) as in the hypokinetic type of anoxia of congestive heart failure, oxygen inhalation cannot be of any great value, since the oxygen saturation can be raised only to 100 per cent, and the total oxygen content increased by 2.2 volumes per cent (an increase of 1.7 volumes in simple solution together with 0.5 volumes combined with hemoglobin). That is, the total oxygen content of a person breathing 100 per cent oxygen will be 21.7 volumes per cent. But this increase of 2.2 volumes per cent (representing an increase in O_2 content of 11 per cent) is as pointed out by Comroe and Driggs of the highest importance in anoxia, for it raises very considerably the pressure at which oxygen is delivered to the tissues. For example, when a patient is breathing ordinary air, every 100 cc. of blood in passing through the capillaries loses 7 volumes of O_2 (normal about 5 vols.), and, therefore, leaves the venous end of the capillary with a content of 12.5 vols. per cent, is 63 per cent saturated, and has a pO_2 of around 32 mm. Hg. Now when 100 per cent oxygen is breathed the extra 2.2 volumes per cent in the arterial blood is given up on entering the capillaries, which re-

duces the oxygen saturation only to that existing under ordinary conditions in the arterial blood, namely, 97.5 per cent. But the tissues owing to the slowing of the circulation abstract a further 4.8 volumes per cent to satisfy their need of 7 volumes per cent. The venous blood, therefore, contains 14.7 volumes per cent of oxygen, and is over 73 per cent saturated, instead of about 63 per cent without oxygen administration, the pO_2 is nearly 40 mm. Hg. Thus the tissues are supplied with oxygen at a virtually normal head of pressure. In congestive heart failure, therefore, especially if there is generalized edema, the administration of oxygen is often of great benefit.

METHODS OF ADMINISTRATION

Oxygen is given usually by means of a nasal or oral nasal catheter by a specially designed face mask, or the patient is placed in a hood tent or airtight cabinet in which the O_2 percentage is maintained at the required concentration. Carbon dioxide (5 to 10 per cent) is sometimes added especially in CO poisoning, persistent hicough and postoperative atelectasis, in order to encourage lung expansion. In an oxygen tent the patient's own breath may raise the CO_2 to the range of 1 to 2 per cent.

In normal persons the breathing of 100 per cent oxygen often causes a slight initial reduction of breathing of about 3 per cent. If the administration is continued the respirations are stimulated possibly as a result of afferent impulses set up in the respiratory tract by the inhalation and conveyed to the medullary center. In anoxia, a much more pronounced depression or even complete cessation of breathing may occur. This so-called oxygen apnea may be very alarming, especially during anesthesia. But it is a sure indication of the existence of anoxia and the need for oxygen therapy, for it shows that the respiratory center has been profoundly depressed to the direct stimulating action of CO_2 . Before oxygen administration the center had been driven by impulses from the peripheral chemoreceptors, the relief of the anoxia has abolished this source of stimulation. In chronic anoxia, such as may be seen in congestive heart failure and pulmonary emphysema, especially when there is also carbon dioxide retention, the patient may pass into coma when oxygen is administered. The unfavorable effects following administration of O_2 under these conditions are attributable to the further rise in pCO_2 which occurs as a result of the depression of breathing.

Another effect of oxygen inhalation is the climi-

nation of nitrogen. A man of average weight (70 kg) breathing oxygen eliminates about 18 ml of nitrogen per minute. The rate of removal of the gas from all tissues is not however the same, it is removed most rapidly from the blood and the most vascular parts of the brain. Pure oxygen is, therefore, administered to divers to prevent decompression sickness, and to pilots before high altitude flights.

Helium (atomic weight 4, $\frac{1}{8}$ density that of nitrogen) is lighter than any other gas except hydrogen. Barach has applied this physical fact to reduce the respiratory effort in asthmatic attacks, in those suffering from laryngeal or tracheal obstruction and in certain other types of dyspnea. A gas mixture is used in which helium is substituted for nitrogen (oxygen, 21 per cent, helium 79 per cent). For the relief of anoxemia the oxygen percentage may be increased to 60 or 70 per cent.

Effects of prolonged breathing 0.5 to 1 atmosphere of O₂. Ill effects other than the "oxygen apnea" described above may result from prolonged administration of oxygen. Commonly subjects complain of substernal distress in 4 to 16 hours after beginning to breathe 100 per cent O₂ at sea level. The symptom usually persists for some hours after the patient resumes breathing of atmospheric air. The pain evidently is related to tracheobronchitis, and it is not a problem unless oxygen tension in inspired air is in excess of 0.5 of an atmosphere. Other manifestations of toxicity produced by breathing 70 to 100 per cent O₂ at a pressure of 1 atmosphere include fatigue, paresthesias in the hands and feet, joint pain, anorexia, nausea and vomiting. The causes of these symptoms are unknown (Comroe and Driggs 1950).

In the ordinary clinical management of patients when oxygen is given in a tent or by nasal catheter oxygen toxicity does not become a factor since the O₂ content in inspired air is rarely, if ever, increased to above 50 per cent. Higher levels can be achieved if a close-fitting mask is used in the absence of rebreathing or if the subject is placed in an enclosure into which oxygen is introduced.

Effects of oxygen pressures greater than one atmosphere. When oxygen is breathed at pressures around 2 to 4 atmospheres severe symptoms indicating dysfunction of the higher central nervous system are experienced. These include mood swings, indifference, loss of judgment, somnolence, irrational apprehension and finally convulsions of the grand mal type. The latter are fol-

lowed by automatism and amnesia. Vertigo also is a common symptom of oxygen poisoning. The cause of the symptoms is not clear. Reduction in the CO₂ carrying capacity of the blood, with a corresponding rise in CO₂ tension and pH in the tissues and venous blood, has been shown to occur in experimental animals, but it is not known if the symptoms in man are related entirely to these changes (Bean, 1945).

Mice die within 20 to 25 minutes when exposed to an oxygen tension of 8 atmospheres, whereas a pressure of 8 atmospheres of air is tolerated well.

Effects of breathing air at very high pressures (nitrogen narcosis). The inert gases, including nitrogen, at certain pressures display the typical properties of anesthetic agents. Whereas surgical anesthesia is produced in patients breathing 80 per cent of an atmosphere of nitrous oxide or xenon, about 38 atmospheres of nitrogen has been calculated to be necessary to have this effect. In experimental animals a pressure of 30 atmospheres of nitrogen is required to abolish righting reactions. However, symptoms referable to impairment of function of the central nervous system occur in an individual exposed to 6 atmospheres of nitrogen (the equivalent of about 200 feet below the surface of water). Helium-oxygen mixtures have less anesthetic action than nitrogen-oxygen mixtures, hence divers breathing helium-oxygen can descend to much greater depths without the development of mental aberrations. The theories of how anesthesia is produced by nitrogen are the same as for the anesthetic actions of other gases. These are discussed in textbooks of pharmacology.

Resuscitation

Until the last few years Schafer's prone pressure method of artificially inflating the lungs was most widely practiced. But today either the *Holger Nelson* or the *mouth-to-mouth method* is preferred.

HOLGER NIELSON OR BACK PRESSURE-ARM LIFT METHOD. After loosening the clothing around the neck and chest, drawing the tongue well forward, and wiping fluid, mucus, etc., from the mouth and throat in order to allow free passage of air, the subject is laid in the prone position (chest down). The arms are abducted at the shoulders to lie at right angles to the trunk and bent at the elbows (see fig. 33.9). The head is turned to one side with a cheek resting on the hands. The operator places himself in front of the subject with one knee resting beside his head and near his forearm. The

FIG 33 9 Illustrating the Holger Nielsen method of resuscitation (From *First Aid* Metropolitan Life Insurance Company)

foot of the operator's other side is planted near the subject's opposite forearm. Then the operator places his hands, with fingers spread apart, upon the subject's back, thumbs touching, and on an imaginary line joining the axillae. He then sways forward, bringing his weight to bear through his arms and hands upon the subject's back. The operator should hold his arms straight at the elbows. This movement compresses the chest and imitates natural expiration. The operator then seizes the subject's arm above the elbows and draws them forward, at the same time as he himself straightens up. This position which expands the chest and simulates natural inspiration is held for two seconds. He then swings forward again and repeats the first phase. The double movement is repeated about 12 times a minute.

MOUTH-TO-MOUTH METHOD In a symposium published in the May, 1958 issue of the *Journal of the American Medical Association* it is stated that mouth-to-mouth resuscitation is superior to all manual methods for all age groups. It is reported to be the only technique which produces adequate ventilation in all cases. The single most important factor in this and other methods in assuring adequacy of the ventilation is proper extension of the neck and elevation of the jaw. To perform mouth-to-mouth resuscitation the subject is placed in the supine position with the head extended and the rescuer at the side of the head. The rescuer grasps the lower jaw of the subject between his thumb and index finger and

lifts it vertically upward. The other thumb and index finger are used to clamp off the nostrils. The rescuer then places his mouth over the subject's mouth and exhales into the airway a volume about two times the normal tidal volume (fig 33 10). Volume and pressure required are easily judged by the rescuer. He inflates the subject's

FIG 33 10 Mouth to mouth method of artificial respiration (Courtesy of Dr. John Henderson and Duell Sloan, Pierce and Company Publishers, New York)

lungs and thorax and notes the expansion of the chest. The rescuer then removes his mouth from that of the subject to allow him to exhale. The procedure should be performed about 12 to 20 times per minute.

The effectiveness and ease of performance of this type of resuscitation is improved by the use of an anesthesia face mask, or an oropharyngeal airway or an endotracheal tube.

During recent years several methods have been developed for the long continued application of artificial respiration by various mechanical devices. This work was begun by Thunberg in Lund who devised an apparatus called the barospirator. The subject was placed inside a metal chamber in which the pressure was raised and lowered rhythmically by means of the stroke of a large piston. The interchange of air within the lungs was caused by a rise and fall of pressure of the air in the external atmosphere. This apparatus was effective and a model was built large enough to accommodate patient, nurse and doctor. All three were ventilated without movement of the chest. A certain amount of discomfort was experienced in this cabinet due to the change in pressure on the two sides of the eardrum during the increase and decrease of air pressure. A more generally applicable model was produced by Drinker at Harvard. In this type the patient's head remains outside the cabinet (fig. 33-11). The chest is expanded by reducing the pressure within the cabinet and as the pressure is raised again, the natural elasticity of the lung causes expiration. Forced expiration, however, may be produced by raising the pressure above atmospheric. Patients have been adequately ventilated with this apparatus for many months. Some difficulty is occasionally encountered in the regulation of the rate and depth of respiration, but by determining the

oxygen saturation of the arterial blood or watching for signs of cyanosis an observer can usually regulate the ventilation quite satisfactorily.

Two other types of apparatus should be mentioned, (1) the jacket model of Sahlin which operates like the Drinker machine but is applied only to the chest, and (2) the Bragg Paul pulsator which consists of a hollow elastic bandage placed around the chest. The bandage, when inflated by an electrically driven bellows, compresses the chest, which returns to the midposition by virtue of its own elasticity during the intervals between the compressions.

The pulmotor and other similarly devised resuscitators, which force air into the chest and suck it out again as though the lungs were rubber bags, though so appealing in their mechanical efficiency, are physiologically unsound. They are not only less effective than other methods but may be actually harmful. The pulmonary tissue may be torn. Those machines which inflate the lungs with an oxygen-carbon dioxide mixture, and permit expiration to take place simply by interrupting the air current and thus permitting collapse of the thorax, are much sounder in principle.

A mixture of oxygen and carbon dioxide (5 per cent or 10 per cent of the latter) commonly is used for resuscitation. The high tension of CO_2 combined with the rhythmical inflation and deflation of the lungs, which presumably cause the discharge of afferent impulses, encourages the return of spontaneous breathing.

Resuscitation of the newborn. Asphyxia in the newborn infant is usually due to the failure of the lungs to expand fully, alveoli in areas of the pulmonary tissue remaining in the fetal state (atelectasis). The methods of resuscitation which may be effective in the adult are likely to fail. Cutaneous stimulation, e.g., slapping, hot or cold

FIG. 33-11 The Drinker respirator. 1, pumps, 2, motor, 3, vents, 4, alternate, 5, valves, 6, manometers, 7, external shutters, 8, adjustment for head rest, 9, adjustable ring to hold collar in place. (After Shaw and Drinker)

water, are time honored devices which are usually unsuccessful. The object aimed at should be the expansion of the collapsed alveoli, and when the infant makes no respiratory effort this is best accomplished by the insufflation of the lungs with a carbon dioxide-oxygen mixture, carried out by the passage down the trachea of a tube, to the outer end of which a rubber bag filled with the gas mixture is attached. When the breathing is not completely suspended but is weak, and the infant cyanosed, inhalations of a carbon dioxide-oxygen mixture are employed. Also mouth-to-mouth resuscitation is quite effective in infants.

URINE FORMATION

The Structure of the Kidney, Theories of Renal Function

THE STRUCTURE OF THE HUMAN KIDNEY

The functional unit of the kidney is the *nephron*, each kidney being composed of approximately one million such units. The nephron begins at a blind end enclosing a leash of capillaries. In this structure, known as the *glomerulus* (*renal corpuscle*, *Malpighian corpuscle*), urine formation begins by the separation, from the blood perfusing the glomerular capillaries, of an essentially protein free filtrate of plasma. The glomerular space or *Bowman's capsule* is continuous with the lumen of the *renal tubule*, a long coiled structure structurally and functionally divisible into three segments: proximal convoluted tubule, loop of Henle and distal convoluted tubule. The nephron as an individual unit ends with the distal convoluted tubule but groups of distal convoluted tubules empty into a series of *collecting tubules*, which in turn coalesce to form *collecting ducts*. The collecting ducts in turn empty into the *short papillary ducts of Bellini* which open into the renal calyces at the tips of the papillae.

THE GLOMERULUS consists of a leash of capillaries interconnected by short anastomatic channels. These capillaries are invaginated into and covered on their outer surfaces by the visceral layer of the epithelium of Bowman's capsule. This layer of flattened cells is continuous with the parietal layer of epithelium and with the lining cells of the renal tubules. Blood enters the glomerulus from the short afferent arteriole, and the coalescence of the glomerular capillaries forms the efferent arteriole, the glomerular capillaries are thus unique in being interposed between two arterioles.

The glomerulus averages about 200μ in diameter and the total surface of glomerular capillaries in the two human kidneys is estimated to be about 1.5 square meters. The glomeruli are found only in the cortex.

THE PROXIMAL CONVOLUTED TUBULE is a tortuous structure averaging about 55μ in diameter and 14 mm in length. It lies in the renal cortex usually in close proximity to the glomerulus to which it is conjoined. It is lined with a single layer of cuboidal cells, each interdigitated with the adjoining cells in a highly complex manner. The border facing the tubule lumen is characterized and distinguished from that of other segments by delicate striations perpendicular to the free edge and known as the brush border. The terminal portion of the proximal tubule becomes straight and dips toward the medulla to become the loop of Henle.

THE LOOP OF HENLE commences with a descending limb which dips down into the medulla. As it does so, the cuboidal cells are suddenly replaced by the flattened cells of the thin segment. The loop penetrates into the medulla for a varying distance, the depth depending upon the location of the glomerulus from which the tubule is derived. Those loops derived from tubules with glomeruli situated near the surface of the kidney penetrate only a short distance into the medulla before turning back toward the cortex, those arising from tubules with glomeruli close to the cortico-medullary junction (*juxtamedullary glomeruli*) penetrate deeply to near the tip of the papilla before turning back. (see fig. 34.1) The first part of the ascending limb does not differ in appearance from the thin portion of the descending limb, but as the ascending limb reaches the

outer medullary zone it widens and becomes lined with a cuboidal epithelium which continues into the distal tubule. The tubule continues into the cortex and comes into contact with the glomerulus from which it arose, this contact being marked by a region of closely packed nuclei designated as the *macula densa*.

THE DISTAL CONVOLUTED TUBULE may be defined as beginning at the macula densa. Like the proximal tubule with which its loops are generally entwined, the distal convoluted tubule lies in the cortex. It is distinguished by the fact that its lining epithelium is somewhat lower, less complex

and lacks the brush border. The distal convoluted tubules empty into collecting tubules. The collecting tubules empty into collecting ducts which pass through the medulla and papilla to empty into the pelvis.

BLOOD SUPPLY The renal artery upon entering the hilum of the kidney breaks up into numerous branches, the *interlobular arteries*, which pass outward between the renal pyramids to the junction of the cortex with the medulla. Here they turn to follow a more horizontal course and form arterial arches (the *arcuate arteries*) across the bases of the pyramids. From the arcuate arteries arise

Fig 342 Diagrammatic representation of the glomerulus

the interlobular arteries which run outward through the cortex. From the interlobular arteries the afferent arterioles carry blood to the glomeruli.

The short muscular afferent arteriole enters the glomerulus and breaks up into the leash of glomerular capillaries. The latter again coalesce to empty into the efferent arteriole which is usually appreciably smaller in diameter than the afferent arteriole (fig 342).

The efferent arterioles derived from most glomeruli break up into a network of capillaries surrounding the convoluted tubules as they lie in the cortex. This capillary network is drained by veins which follow a course close to the arteries and empty into the renal vein (fig 343).

The efferent arterioles derived from the juxtamedullary glomeruli close to the cortico-medullary junction do not feed into the peritubular capillary plexus. Instead each divides into a group of straight vessels, the vasa recta which descend into the medulla, following a course similar to the loops of Henle, and then turn to return to the cortex and enter the venous system. As they pass through the cortico-medullary junction, the vasa recta tend to become gathered into groups, the vascular bundles, and in these groups the descending and ascending limbs of the vasa recta lie closely intermingled in an arrangement ideally suited for diffusional exchanges between inflowing and outflowing blood.

SUMMARY OF DEVELOPMENT OF CURRENT CONCEPTS

The development of our present understanding of the function of the kidney can be considered

to date from 1842 when Bowman described the structure of the glomerulus, particularly showing the continuity of the space of the Malpighian corpuscle with the lumen of the tubule. Bowman recognized the structural characteristics which suggested its function as a filter. He supposed that the filtration process provided only the urinary water and that the solutes of the urine were added by the secretory activity of the cells of the renal tubules. The process of glomerular filtration thus served merely to wash through the solutes.

Ludwig in 1844 proposed that glomerular filtration provided all of the water and solutes of the urine and that the function of the tubules was to concentrate the solutes by the reabsorption of water. It was recognized that this concentration would lead to some loss of solute by diffusion. Heidenhain (1874) from observations on the accumulation of dyes in the renal tubule cells returned to a theory close to that of Bowman placing the burden of urinary excretion on secretion of solutes by the tubule cells.

In 1917, Cushny in an attempt to simplify what had by then become a complex and confused subject, proposed what he termed the 'modern theory of renal function'. Totally rejecting any secretion by the renal tubules, Cushny hypothesized that urine formation began with the formation of a protein free ultrafiltrate of plasma in the glomeruli. From this flow of fluid the tubules were assumed to reabsorb a solution of constant and unvarying composition. This solution was presumed to have the composition of an ultrafiltrate of normal plasma and Cushny proposed that the

'fluid reabsorbed is always the same, whatever the needs of the organism at the moment'

The development of knowledge concerning the function of the kidney has shown that each of the above theories contains some parts which are correct and others which are not. The existence of secretion by the tubules was definitively shown by Marshall and his associates.

In the development of renal physiology which has taken place in the last 25 years leading to the physiological picture presented in the following pages, two experimental techniques have played a central role. The micropuncture techniques developed by A. N. Richards and his many important associates provided means for collecting fluid from accurately located regions of the nephron and for the analysis of this fluid by microchemical methods. This has provided invaluable information on the nature and localization of events in the renal tubule. The clearance methods, with measurement of the rate of glomerular filtration, in connection with which the names of Rehberg, Homer Smith and Shannon stand out, has provided a tool for the evaluation of many processes in the intact unanesthetized animal or in man, under conditions approaching normal.

General Nature of Urine Formation

Although the two human kidneys are made up of some two million nephron units, it is convenient for most purposes to consider the two kidneys as constituting a single huge nephron. Such a model is accurate to the extent that each nephron is similar in its functional proportions to every other and to the extent that each nephron functions in parallel with and independent of every other. These assumptions may be accepted as first approximations. The consequences of heterogeneity of nephron function and of interdependence of nephrons will be considered in subsequent sections. For present purposes we may speak of the glomerulus and the proximal convoluted tubule, etc., as if the kidneys represented a single unit, and referring to the sum of the functions of the several million units.

The processes of renal function are initiated in the glomerulus by the separation from the plasma of an essentially protein free ultrafiltrate. The ultrafiltrate delivered from the glomerular capillaries into the space of Bowman's capsule enters the lumen of the proximal tubule. As the result of the net filtration pressure the separated fluid flows through the tubule. As it passes through the various tubule segments, the fluid is drastically modified both in volume and composition by a

series of operations performed upon it by the lining epithelium of the tubules. Many of the constituents of the fluid originally filtered into the glomerular space are removed from the fluid as it traverses the renal tubules and are returned to the blood to be retained within the body. Some components of the glomerular filtrate such as glucose and the amino acids are virtually completely reabsorbed appearing in the final urine only under unusual circumstances. Other constituents such as urea are reabsorbed to only a limited extent while still others are excreted and reabsorbed to an extent which is regulated so as to maintain the normal composition of body fluids. Among the substances reabsorbed to a major but variable extent is water itself so that the volume flow of urine is always but a fraction of the flow of glomerular filtrate. In addition to reabsorbing many substances from the fluid flowing through the tubule the tubule epithelium also removes certain substances from the peritubular blood and deposits them in the fluid within the lumen. Thus three individual processes: glomerular filtration, tubular reabsorption (from lumen to blood) and tubular secretion (from blood to lumen) are involved in the process of urine formation. These three processes will be considered in detail in subsequent sections.

GLOMERULAR FILTRATION

The idea that the glomerulus is a device for filtering fluid from the blood perfusing the glomerular capillaries goes back to Bowman who in 1842 first described the relationship of the glomerular capsule to the renal tubules. Bowman believed that only the water of the urine was contributed by this filtration process the solutes being added by secretion in the tubule. Shortly thereafter Ludwig (1844) offered the view, which has since been amply confirmed, that the glomerulus acts as an ultrafilter, separating from the plasma a solution which contains all of the solutes of plasma except the proteins and each at a concentration identical to that in the plasma water, except as modified by the absence of protein. The cornerstones of the evidence indicating that the glomerulus is indeed an ultrafilter were supplied by A. N. Richards and his associates who showed that the composition of fluid collected from glomeruli in amphibians was, with respect to an extensive list of constituents that required of a plasma ultrafiltrate. (The studies were later extended with respect to a limited number of substances, to fluid collected directly from mammalian glomeruli by Walker, Bott, Oliver and

MacDowell) In addition it was shown that the hydrostatic pressure in the glomerular capillaries is sufficient to supply the driving force for the filtration process

As in the case of other capillary beds, and in accord with the Starling hypothesis, the rate of filtration through the walls of the glomerular capillaries is determined by a balance of forces favoring and opposing filtration. The main driving force is the hydrostatic pressure—the intracapillary blood pressure (P_c). Opposing filtration is the osmotic pressure exerted by the plasma proteins (π) and the hydrostatic pressure of the fluid in Bowman's capsule (P_a). The rate of glomerular filtration (GFR) may thus be expressed as

$$\text{GFR} = K_f(P_c - P_a - \pi) \quad (1)$$

where K_f is a constant relating net filtration pressure to filtration rate and thus related to the area and the permeability of the glomerular capillary walls

The glomerular capillaries differ from those of other capillary beds in being interposed between two arterioles, in maintaining a higher hydrostatic pressure, and in having a higher permeability. Pappenheimer and his associates have estimated that the permeability of glomerular capillaries is approximately one hundred times that of the capillaries in the limbs (muscles), the difference is presumably largely in the fraction of the total capillary surface occupied by the pores through which filtration actually occurs. The membrane which constitutes the significant filtration resistance and which is penetrated by the pores of critical size is probably the capillary basement membrane

Some idea of the size of the pores can be obtained from the characteristics of those solutes which are filtered through the glomerular capillary membrane as compared with those which are not. The normal glomerular membrane is virtually completely impermeable to the proteins of plasma. The smallest of these, albumin, has a molecular weight of about 70,000 and appears in the glomerular filtrate either not at all or at a concentration too low (less than 1 per cent of its concentration in plasma) to have been measured in the samples of mammalian glomerular filtrate which were examined. Hemoglobin (molecular weight 68,000) on the other hand is excreted at a rate which would indicate that it appears in glomerular filtrate at a concentration equal to about 5 per cent of its concentration in the plasma. (The concentration referred to is that not combined, in the plasma, with larger protein molecules.) The

hemoglobin molecule is somewhat less elongated than the albumin molecule, but the difference is relatively small. In any case, it is clear that the pores in the glomerular membranes can not be far removed in size from the dimensions of these molecules.

Also pertinent is the passage through the glomerular membrane of certain polysaccharides. Most important among these is inulin, a polymer of fructose, which has found a central role in the study of renal function. Its molecular weight is usually estimated to be 5200, but different inulin molecules probably differ in size, some being smaller, others larger. In addition, the molecule is greatly elongated, a characteristic which reduces its diffusibility and filtrability compared to a compact molecule of the same molecular weight. Nevertheless, the glomerular membrane appears to offer no hindrance to the passage of inulin, and its concentration in glomerular filtrate is the same as in the plasma from which the filtrate is derived. Dextrans (polysaccharides composed of glucose) of a molecular weight approximately equal to that of inulin have been found to pass the glomerular membrane freely, but their passage is progressively restricted as their molecular weight increases and those with molecular weights above 55,000 do not appear in the urine from normal kidneys (i.e., kidneys producing protein free urine).

Although different theoretical treatments will yield different dimensions for the size of the pores in the glomerular membrane, the permeability can be interpreted as attributable to pores approximately 100 Å in diameter.

Equation (1) indicates that glomerular filtration is a function of three variables as well as the area and permeability of the glomerular membrane. It is important to consider the possible contribution of changes in each of these to the physiological regulation of glomerular filtration.

1. **THE GLOMERULAR MEMBRANE (a) Permeability** The permeability of the glomerular membrane per unit of functioning surface is presumably fixed by its anatomical nature and not subject to physiological variation. Although changes do occur with disease, the effect of change in permeability as opposed to change in effective filtering area is difficult to evaluate. The diseased membrane may permit the passage of molecules larger than those which normally penetrate, but the predominant effect appears to be a decreased permeability.

(b) **Area** The effective area available for filtration depends upon the number of glomeruli active at any time and the number of functioning capil-

lanes in each glomerulus. The weight of evidence favors the view that, in the mammalian kidney under physiological conditions, all glomeruli are continuously active. This interpretation is not universally accepted and there are those who believe that variation in the number of glomeruli contributing to urine formation is a major factor in determining the rate of glomerular filtration. Subsequent treatment of the subject in this section will be based on the assumption that all the glomeruli are continuously involved in the formation of glomerular filtrate.

2. CAPILLARY BLOOD PRESSURE (P_b) The major variable in the regulation of the rate of glomerular filtration is the pressure within the glomerular capillaries. The pressure at which blood enters the afferent arterioles is not much lower than that in the aorta; the decrease in pressure between aorta and glomerular capillaries is largely determined by the resistance of the afferent arterioles. Thus, other factors remaining equal, constriction of the afferent arterioles will decrease and dilatation will increase glomerular filtration. The effect of changes in the caliber of the efferent vessels is in general the converse of parallel changes in the afferent vessels.

It is to be noted that it is the *pressure, not the blood or plasma flow*, in the glomerular capillaries which determines glomerular filtration rate. Thus the rate of glomerular filtration need not bear any particular relationship to the cardiac output. A low level of cardiac output is, at least in theory, quite compatible with a normal rate of filtration provided this output is sufficient to maintain a normal blood pressure and provided that renal vasoconstriction is not a part of the general vasoconstriction necessary to maintain the normal arterial pressure.

Although the renal nerves play a role in the regulation of the renal arteriolar resistances and thus in the maintenance of a stable rate of glomerular filtration (and particularly in man, this function is maintained at a remarkably constant level under normal conditions), the nerves are not essential to this stability. The kidney even when totally isolated shows only slight changes in glomerular filtration rate (and blood flow) as perfusion pressure is varied over a wide range. This process, frequently designated by the term *autoregulation*, has attracted considerable interest among physiologists. It is probably attributable to spontaneous adjustments of the arteriolar resistances.

3. INTRACAPSULAR HYDROSTATIC PRESSURE (P_c) Under ordinary conditions variations in the

pressure within Bowman's capsule probably contribute little to changing glomerular filtration rate. With ureteral obstruction this pressure may rise until the rate of filtration is reduced to negligible levels, but such obstruction does not, of course, occur under normal circumstances. It is also likely that in the extremes of solute diuresis produced experimentally the pressure required to drive the greatly increased flow of urine against the resistance offered by the tubules may be sufficient to reduce filtration.

4. COLLOID OSMOTIC PRESSURE OF THE PLASMA PROTEINS (π_c) The osmotic effect of the plasma proteins is the equivalent of a hydrostatic pressure of some 25 to 30 mm. Hg opposed to glomerular filtration. Glomerular filtration must therefore cease when the net hydrostatic pressure across the capillary membrane falls to this level. Although this osmotic effect is large enough for changes to exert appreciable effects on net filtration pressure, it is doubtful whether such changes contribute significantly to the physiological regulation of glomerular filtration. Experimentally it can be shown that sudden dilution of the plasma proteins by the administration of isotonic sodium chloride solution produces an increase in glomerular filtration and urine flow (dilution diuresis) but the changes are small compared to those which can be produced experimentally in other ways.

The Measurement of Glomerular Filtration Rate

The difference between the rate at which a substance is filtered at the glomeruli and the rate at which it is excreted in the urine represents the rate at which the substance is removed from or added to the urine as the latter traverses the renal tubules. The rate at which a substance is filtered is given by the product of its concentration in the plasma (or more accurately the concentration of unbound substance in the plasma water) and the rate of formation of glomerular filtrate. The rate of excretion is easily determined as the product of urine flow and the concentration in the urine of the substance in question. Thus the measurement of glomerular filtration rate plays a central role not only in the evaluation of glomerular filtration itself, but in the assessment of the processes of reabsorption and secretion as well.

The rate of glomerular filtration can be determined if there is some substance which is neither reabsorbed nor secreted by the tubules and if the concentration of this substance in the glomerular filtrate can be deduced from its concentration in the plasma. If a substance is neither reabsorbed nor secreted as the urine flows through the tu-

hules, then, in the steady state, the rate of excretion of the substance must be the same as the rate at which it is filtered. Given the rate at which the substance is filtered and its concentration in the filtrate, the volume of the filtrate can be calculated.

For example, consider some substance X which we will assume has the requisite characteristics of (1) being freely filterable at the glomeruli, (2) being neither reabsorbed from nor excreted into the tubule lumen. Suppose we measure the flow of urine over a 10 minute period during which 20 ml of urine are collected to yield a flow (V) of 2 ml per minute.

The concentration (U_x) of substance X in the urine is determined and found to be 120 mg per ml.

The rate of excretion, then, is given by the product of flow and concentration

$$U_x V = 120 \text{ mg/ml} \times 2 \text{ ml/min} \\ = 240 \text{ mg/min}$$

Since for substances which are neither reabsorbed nor secreted the rate of excretion is equal to the rate of filtration, the rate of filtration of substance X is also 240 mg per minute. But the rate of filtration of a substance is equal to the product of the rate of formation of filtrate (GFR) times the concentration of the substance in the filtrate which, in this case, is defined above as being the same as the concentration in the plasma (P_x). Assume the concentration in the plasma in this case is determined and found to be 2 mg/ml.

Thus the rate of filtration of X is the product GFR $P_x = U_x V$ and

$$\text{GFR} = \frac{U_x V}{P_x} = \frac{240 \text{ mg/min}}{2 \text{ mg/ml}} = 120 \text{ ml/min}$$

The desirability, for the evaluation of renal function, of a substance which fulfills the criteria for measuring glomerular filtration is apparent. It is now generally accepted that *inulin*, a starchlike polymer of fructose obtained from dahlia tubers, has the requisite characteristics and can be used for the measurement of glomerular filtration in all vertebrates including man.

THE USE OF THE TERM CLEARANCE The expression $U_x V/P_x$ denotes a quantity which is generally referred to as the *clearance* of substance X and abbreviated C_x . As can be seen, it is the volume of plasma needed each minute to supply the substance in question at the rate at which it is excreted in the urine. It is thus a measure of the efficiency of the kidney in the excretion of a par-

ticular substance, the larger the value of its clearance, the more effectively it is excreted. The term is derived from the fact that one may consider the clearance to be that volume of plasma which completely yields its content for excretion and is thus cleared of the particular substance each minute. Some confusion arises when the latter concept of clearance is used since the volume cleared of a particular substance is usually virtual rather than real. The same clearance is obtained if 50 ml of plasma yield all of their content, if 100 ml lose half or 200 ml yield one fourth.

The clearance of a substance such as inulin is the volume flow of glomerular filtrate. By comparison of the clearance of any other substance with that of inulin we may infer the nature of the processes involved in its excretion. If it is filtered but neither reabsorbed nor excreted by the tubules, its clearance must be identical with that of inulin. If its clearance is lower, it must be reabsorbed from the tubules, if higher, it must be secreted by them.

Thus if P_x is the concentration of X filterable in the plasma, T_x the amount of X which is secreted into or reabsorbed from the tubule each minute and C_{in} the inulin clearance taken as equal to the rate of formation of glomerular filtrate, then,

$$C_{in} P_x = \text{filtered X}$$

$$C_{in} P_x + T_x = \text{excreted X} = U_x V$$

(where T_x will have a negative value if X is reabsorbed from the tubules)

Then

$$C_{in} + \frac{T_x}{P_x} = \frac{U_x V}{P_x} = C_x \quad (2)$$

It can be seen from equation (2) that if for any reason the capacity of the tubule (T_x) to reabsorb or secrete a particular substance is limited, the clearance of that substance will approach the rate of glomerular filtration as the plasma concentration is progressively increased, since as P_x approaches infinity, the term T_x/P_x approaches zero. It will be shown that this is the case with most substances transported by the renal tubules.

THE RATE OF GLOMERULAR FILTRATION IN MAN The clearance of inulin in a man of average size under normal basal conditions (except for the water usually administered during the determination of such clearances) averages slightly in excess of 125 ml per minute. It is customary, in order to compare individuals of varying size, to normalize the clearance values by 'correcting' them to

what is generally considered an average normal value of body surface area, 1.73 square meters. Women have glomerular filtration rates some 10 per cent lower than those found in men even after "correction" to the same value of surface area.

The large value for the rate of formation of glomerular filtrate emphasizes the similarly great magnitude of many of the processes of reabsorption carried on by the renal tubules. Thus if we assume that the rate of 125 ml per minute is maintained throughout the day, we may calculate that some 7.5 liters are filtered each hour or 180 liters per day in an individual of normal size. Since ordinarily such an individual will excrete only a liter or two of urine, it is clear that an amount approaching 180 liters is also reabsorbed. The total body water of a 70 kilogram man is of the order of 45 liters, so that on the average all of the body water is filtered into the renal tubules and reabsorbed four times each day. On the same basis we may calculate that the extracellular fluid (approximately 12 liters) is filtered and reabsorbed some 15 times per day, the plasma volume (roughly 3 liters) some 60 times.

We may further multiply this volume by its content of the various filtrable solutes of plasma to estimate the amounts of these filtered and by comparison with the amounts excreted in the urine, calculate the amounts of each reabsorbed. Illustrative data are indicated in table 34-1. It is apparent from this table that very large quantities are turned over by the kidney each day and that only a small percentage departure from normal in the process of reabsorption could result in very large changes in excretion.

OTHER MEASURES OF GLOMERULAR FILTRATION
In man, except for inulin, no substance has been found which can be considered to give an accurate and reliable value for the rate of glomerular filtration. Approximations can be made using one of several substances, and such approximations are useful for comparative purposes but not for the evaluation of tubular reabsorptive and secretory processes. Most commonly the creatinine clearance is used and gives a value, under most conditions, not too different from the clearance of inulin.

This is probably the result of compensating errors, since creatinine is excreted into the lumen by the tubules of the human kidney. It is possible that it is also reabsorbed and in addition the methods usually used for determining the concentration of creatinine in plasma are not specific and include small amounts of other substances which apparently are reabsorbed. Under some

conditions, particularly in the presence of renal disease, the departure of the creatinine clearance from the rate of glomerular filtration may be considerable.

Other substances which have been used to approximate the rate of glomerular filtration in man are certain hexitols (mannitol, sorbitol, dulcitol), particularly mannitol, and allantoin. The mannitol clearance is about 10 per cent lower than the clearance of inulin, indicating that about 10 per cent of the filtered mannitol is, on the average, reabsorbed.

In many lower mammals, as well as in amphibians, the creatinine clearance does not have the limitations which reduce its usefulness in man. The clearance of creatinine is, for practical purposes, identical with that of inulin in the dog, cat and rabbit.

TUBULAR REABSORPTION

The quantitative importance of the process of reabsorption in the renal tubules has been indicated above by the magnitude of the amounts of material involved. An understanding of the nature of the mechanisms by which this reabsorption is effected is essential to a grasp of the function of the kidney.

The processes involved in tubular reabsorption are divided into two categories, passive and active.

1. Passive reabsorption. It is clear that the volume of the urine is greatly reduced as it flows through the tubules. If, in the course of this re-

duction in volume, some solute is retained in the lumen to a greater extent than water, its concentration will rise above that in the glomerular filtrate and above the concentration in the plasma and interstitial fluid which surround the tubules. A concentration gradient for the substance is thus created between the lumen and the environment of the tubule and, provided the tubule is permeable to some extent to the substance in question, it will diffuse from the lumen of the tubule to interstitial fluid and blood. This type of process is designated by the term *passive reabsorption* and is typified by the reabsorption of urea, the excretion of which will be considered in more detail later.

More generally, the movement of any substance across a biological membrane (in this case the complex membrane is the renal tubule epithelium) is considered *passive* when it can be explained entirely by gradients of concentration and/or (in the case of charged particles) gradients of electrical potential. In such a context, the movement of urea is a passive process requiring no mechanism in the tubule cells specific for urea and no expenditure of energy by the tubule cells for the movement of urea itself. However, it should be noted that work must be done to raise the urea concentration so that it may diffuse out passively. It will be shown that in this instance the primary active process is the removal of salt from the lumen by the activity of the tubule cells, the movement of water is the passive consequence of the transport of salt and the movement of urea is in turn secondary to the movement of water.

2 Active reabsorption. The reabsorption of many substances from the renal tubules can not be explained by gradients of concentration or electrical potential. The process involved in the movement of these solutes is designated as *active reabsorption*. The best known and possibly simplest example of an active reabsorptive process is probably that for glucose. A consideration of glucose reabsorption will illustrate the characteristics of these mechanisms.

Active Reabsorption. The Reabsorption of Glucose

Under normal conditions approximately 100 mg. of glucose are filtered at the glomerulus each minute. Of this, none but the merest trace is excreted in the urine. Clearly, the transport of glucose is effected against a *concentration gradient* and, since glucose carries no electrical charge, its transport is, by definition, *active*.

If the concentration of glucose in the plasma is progressively increased, it is found that, for a time, the urine remains free of glucose. However,

when a sufficiently high plasma glucose concentration is reached, glucose appears in the urine in appreciable quantities. Further increments in plasma glucose concentration are then accompanied by proportional increments of glucose excretion. The basis for the relationship of plasma glucose concentration and glucose excretion becomes clear when the glomerular and tubular events are analyzed by the simultaneous determination of glomerular filtration rate (inulin clearance). From the product of inulin clearance and plasma glucose concentration,¹ the filtered glucose is calculated, the difference between filtered and excreted glucose is the amount reabsorbed. It is then found that as the plasma glucose concentration increases (the filtered glucose, of course, increasing proportionately) the reabsorbed glucose increases, remaining equal to the filtered, until a limiting value of glucose reabsorption is reached. As the filtered glucose increases beyond this level there is no further increase in glucose reabsorption and the excess glucose is excreted in the urine. These relationships are illustrated in figure 34.4. The relationship among the various quantities is expressed by the equation

$$U_G V = C_{12} P_G - T_0$$

where T represents the amount reabsorbed per minute from the tubule and the subscripts G and I refer to glucose and inulin respectively.

T_0 is seen to increase, remaining equal to the filtered glucose (frequently referred to as the *load* or *filtered load*), until T_0 reaches a maximum. This maximum, which represents the capacity of the tubules to transport glucose, is conventionally designated as the glucose T_m or T_{mG} . The existence of such a limited capacity subject to saturation is a characteristic feature of active transport processes and is one of the criteria by which they may be identified.

The limitation which characterizes the transport mechanism involved in glucose reabsorption and other similar mechanisms is believed to derive from the involvement of a "carrier" in the process. In this view, the tubule cell membrane is virtually impermeable to glucose in the free state. However, the membrane contains certain molecules which can combine reversibly with

¹ In determining the amount filtered in the case of substances, such as glucose, which are rapidly metabolized by the tissues, it is important to measure the arterial plasma concentration, since the venous concentration may be appreciably lower and since it is arterial plasma from which glomerular filtrate is derived.

glucose, and in this state the glucose, now in combination with its carrier, is able to penetrate the membrane. Having reached the inside of the tubule cell, the carrier glucose complex dissociates releasing free glucose which, we may assume, is free to diffuse out of the cell into the peritubular fluid and blood. The carrier is then available to repeat the process.

The reactions involved may be represented

where A is glucose in the tubule lumen, B the carrier, AB the glucose carrier complex and T the glucose which has been transported (e.g., into the tubule cell). Some step in the process requires an input of energy since the expenditure of energy is necessary to drive the reaction "uphill" from the low concentration in the lumen to the higher one in the cell. This energy might be involved in driving reaction (2) or possibly the carrier might be modified in the transport process and require activation before it can again combine with glucose in the lumen. When the mechanism is saturated all of the carrier is interpreted as in the combined state AB and the maximum rate of transport (T_m) reflects the total amount of carrier in the tubule cells and the rate constant for the dissociation of AB to yield B and T. Although, theoretically, the rate of such transport processes could be limited by the amount of energy available to drive them, there is no evidence that this actually occurs, and the same tubule cells are able simultaneously to carry out the transport of a number of solutes among which there is no mutual interference.

Although the existence of carriers with the properties described is fairly generally accepted, it should be noted that none has ever been isolated or identified chemically. The interaction between carrier and transported substance may be considered analogous to that between an enzyme and its substrate, in fact the reactions suggested above correspond to those to which the kinetic behavior of enzymatic reactions are attributed. Transport reactions also show certain other characteristics of enzymatic reactions, particularly in being subject to inhibition, both competitive and noncompetitive.

The glucose transport mechanism is fairly specifically inhibited by the glycoside, *phlorizin*. The administration of this inhibitor in adequate dosage completely abolishes glucose transport so that the clearance of glucose becomes equal to the glomerular filtration rate. This property is also

FIG 34.4 Diagrammatic and idealized representation of the relationship among filtration, reabsorption and excretion of glucose. The figures are calculated on the assumption that glomerular filtration rate was 100 ml per minute.

shared by the glycoside of the adrenocortical steroid desoxycorticosterone. Several monosaccharides (e.g., xylose, fructose and galactose) are reabsorbed to some extent apparently by the same transport mechanism responsible for the reabsorption of glucose, and their reabsorption is also inhibited by *phlorizin*.

Micropuncture studies have clearly shown that the reabsorption of glucose occurs high in the proximal convoluted tubule and that when the plasma glucose concentration is normal the glucose has largely been removed before the urine reaches the middle of the proximal tubule.

In human beings, the normal capacity to reabsorb glucose (glucose T_m) averages approximately 375 and 300 mg per minute per 1.73 M² of body surface area in men and women respectively. If we compare the capacity to reabsorb glucose with the rate of glomerular filtration we may deduce what concentration of glucose in the plasma would be required to yield enough filtered glucose to saturate the glucose T_m . Since the average normal rate of glomerular filtration is 125 ml per minute it is apparent that a plasma glucose concentration of 3 mg per ml or 300 mg per cent is required to yield a filtered load equal to reabsorptive capacity of 375 mg per minute. From the idealized and oversimplified diagram of excretion and reabsorption versus load plotted in figure 34.4 it would be predicted that no glucose should appear in the urine until the plasma glucose is 300 mg per cent, at that point, filtered load should be exactly equal to reabsorptive capacity and reabsorptive capacity should be fully saturated. Further increases in plasma glucose should give no increase in glucose reabsorption. In actual

FIG 34.5 Titration of the capacity to reabsorb glucose. Based on average data from ten normal individuals. The ordinate (T/T_m) is the ratio of glucose reabsorbed at a particular value of filtered glucose to the maximum capacity to reabsorb glucose in the same individual. It is thus the fractional saturation of glucose reabsorptive capacity. The abscissa (load/T_m) is the amount of glucose available for reabsorption again related to the capacity of the individual to reabsorb glucose.

The frequency distribution curve shows the proportion of nephros having various ratios (r) of filtration rate to reabsorptive capacity as related to the average of this ratio (R) for the two kidneys as a unit.

The data are those of Smith, Goldring, Chasis, Ranges and Bradley (J. Mt. Sinai Hosp. 10: 59, 1913).

In practice this is not the case. In figure 34.5 is reproduced the observed relationship between plasma glucose (filtered glucose) and excretion and reabsorption in normal man. It is seen that glucose begins to appear in the urine when the filtered glucose is only about three-fourths of the capacity of the tubules to reabsorb and that the reabsorption does not reach its maximum rate until the amount filtered is some 50 per cent greater than this maximum.

The departure from the idealized relationship is due to two factors. Two assumptions are implicit in the construction of the idealized relationship, and neither is completely valid. (1) Each tubule reabsorbs all the glucose presented to it until its capacity is fully saturated, and none of the filtered glucose escapes reabsorption until saturation is achieved, and (2) all of the tubules are functionally identical so that the kidney may be looked upon as a single nephron. We may now consider why these assumptions are valid only as first approximations.

1. The hypothetical basis of transport in terms of the formation of a substrate-carrier complex was presented above. The initial reaction is visualized as the reversible formation of the complex

If we write the mass action expression for this reaction, we obtain

$$K = \frac{[A][B]}{[AB]}$$

where the brackets signify concentration and K is the dissociation constant for the substrate carrier complex. The smaller the value of K , the greater the affinity of the carrier for the transported substance.

It is apparent from this that the residual (unreabsorbed) substrate will be very small only (1) if the value of K is very small or (2) when there remains an appreciable concentration of unsaturated carrier (B). Conversely (once the total A available is equal to the total transport capacity) there will be negligible unutilized transport capacity only (1) when K is very small or (2) when there remains a considerable amount of unreabsorbed substrate. Thus, the relationship will approach the ideal as the value of K becomes infinitely small and for any finite value of K there will be some departure from the ideal (fig. 34.4). Actually among the various substances actively reabsorbed by the renal tubules there are varying degrees of departure from ideality presumably reflecting differences in the value of K . The departure from ideality in the case of glucose is small compared to that for many other substances suggesting a low value for the dissociation of the glucose carrier complex.

The type of relationship plotted in figure 34.5 is commonly referred to as a *titration curve*, and the departure from the sharp break of the ideal relationship is called the *splay* of the titration curve.

2. The nephrons are clearly not all identical nor is it reasonable to expect them to be so. The heterogeneity of the nephron population which is pertinent to the shape of reabsorptive titration curves is heterogeneity of what is called *glomerulotubular balance*, that is, the relationship between the filtering capacity of the glomerulus and the reabsorptive capacity of the tubule attached to that particular glomerulus. Thus if we deal with a tubule with an average capacity to reabsorb glucose but a filtration rate of twice the average it will become saturated with glucose when the plasma glucose concentration is only half that required to saturate the average nephron. Conversely nephrons with small glomerular filtering capacity and large reabsorptive capacity will be come saturated only when the plasma glucose is much higher than that which would saturate the average nephron.

The titration curve in figure 34.5 can be analyzed to yield the distribution of glomerular activity in relation to glucose reabsorptive capacity if it is assumed that the titration curve in each individual nephron is ideal (that is, if the kinetic contribution to splay is disregarded). What is obtained is a distribution of the ratios of filtration to reabsorption for the nephron population as these ratios relate to the average ratio for the kidneys taken as a unit. This distribution curve, included in figure 34.5 indicates that in the normal human kidney no appreciable number of nephrons has a ratio of filtration to reabsorption of glucose departing more than 50 per cent from the average.

The earlier literature on the physiology of the kidney divides substances which may appear in the urine into *threshold* and *no threshold substances*. A threshold substance was one which did not appear in the urine until its concentration in the blood exceeded some value, this value being designated as the renal threshold. No-threshold substances were those which appeared in the urine at all concentrations in the plasma. Clearly glucose (and most other substances actively reabsorbed by the tubules) would fall in the category of 'threshold' substances. However, with improvements in the methods of study of renal function, this terminology has in large measure lost its usefulness, and it is greatly preferable to consider the specific mechanisms involved in the excretion of a particular substance and the quantitative aspects, formerly subsumed in the 'threshold,' in terms of the rates of filtration, reabsorption and secretion.

OTHER SUBSTANCES ACTIVELY REABSORBED BY THE TUBULES The reabsorption of glucose is the prototype of a number of reabsorptive processes which are qualitatively similar. In several instances the site of reabsorption has been identified, and in each case the proximal tubule is the segment concerned. It is probable that, except for those mechanisms involved in the movements of the more important monovalent electrolytes and water (these will be considered separately later), the active reabsorptive (and secretory) processes are confined to the proximal convoluted tubules.

The normal urine contains only traces of *amino acids* although, of course, a number of amino acids are present in plasma. Several separate transport mechanisms are involved in their reabsorption. The basic amino acids arginine, lysine and histidine appear to share the same mechanism since

elevation of the plasma concentration of any one depresses the reabsorption of the others. *Reabsorptive T_m 's* have been demonstrated for lysine and arginine but not for histidine, the reabsorption of which is still increasing at the highest levels produced experimentally. A second transport mechanism is responsible for the reabsorption of leucine and isoleucine which compete, but the capacity for reabsorption is so high that no T_m has been demonstrated. Glycine appears to be reabsorbed by a separate mechanism. In those instances in which T_m 's have been demonstrated, there is considerable excretion of the amino acid when the reabsorptive capacity is far from saturated. Presumably this represents a relatively high degree of dissociation of the carrier substrate complex. *Creatine* is reabsorbed by a mechanism closely related to if not identical with, that involved in glycine reabsorption.

Phosphate is reabsorbed by an active process which can be saturated on elevation of the plasma concentration. The transport mechanism seems to be modified by a number of factors. It is probable, although not clearly established, that parathyroid hormone depresses the phosphate transport system. *Acidosis* increases phosphate excretion in part by what appears to be an increase in the splay of the titration curve.

Sulfate reabsorption is effected by a mechanism which becomes saturated with only a slight increase in the plasma concentration above the normal level. The reabsorption of sulfate can be depressed by the administration of thiosulfate which competes for reabsorption by the same mechanism.

Uric acid reabsorption is remarkable for the number of substances known to inhibit it. These include other reabsorbed compounds such as glycine, and a number of drugs which inhibit the secretion of organic anions by the tubules (carnitide, probenecid, phenylbutazone). The reabsorptive capacity for uric acid is so great that it is certainly never saturated in the normal individual. Excretion occurs by virtue of the great splay in the titration curve. The excretion of urate at levels far below saturation of reabsorption has been attributed to the existence of a mechanism of low capacity capable of secreting urate into the tubules, the evidence for such a process is as yet inconclusive.

Among other substances actively reabsorbed by the tubules are *ascorbic acid* and *beta-hydroxy butyric and acetoacetic acids*.

FIG 346 Relationship between plasma concentration and filtered secreted and excreted amounts of a substance excreted by tubule secretion. See text for details.

TUBULAR SECRETION

The processes by which materials are removed from the peritubular fluid and transferred to the tubule lumen are designated by the term *tubular secretion*. The term *tubular excretion* is often used synonymously. In the present section the secretion of the monovalent ions potassium, hydrogen and ammonium will be omitted and the discussion will be concerned with the somewhat simpler transport processes involved in the secretion of certain organic electrolytes.

The first substance for which tubular secretion was demonstrated was phenol red (phenolsulfon phthalein PSP). The critical experiment was that of Marshall who showed that as much as 75 per cent of the phenol red contained in the arterial blood could be removed as the blood traversed the kidney whereas because of a high degree of binding of phenol red to plasma proteins only 20 to 25 per cent of the phenol red in the arterial plasma is free and filterable. Clearly no matter what fraction of the plasma was converted to glomerular filtrate, filtration alone could not account for the excretion of phenol red. These experiments put an end to a prolonged controversy over the existence of tubular secretory processes.

A large number of substances are now recognized to be transported into the tubules by the same mechanism responsible for the secretion of phenol red. Among these are *hippuric acid* and a variety of its iodo-, hydroxy- and amino derivatives, *penicillin*, 5-hydroxyindoleacetic acid (a metabolite of serotonin), a number of *sulfon phthaleins* in addition to phenol red, several of the iodinated compounds which have been used for X-ray contrast study (intravenous pyelography) of the urinary tract (Diodrast, Iopax,

Neopax Skiodan).² Also although their tubular secretion in man has not been identified it has been shown that glucuronides and ethereal sulfates are so transported in other animals and the same is probably true in man. It is notable that the list contains no normal constituents of the body but under normal conditions it seems likely that the mechanism serves for the rapid excretion of the conjugates of ingested foreign substances these conjugates being in the form of hippurates glucuronides and sulfates.

The tubular secretory process which is also located in the proximal tubule resembles those involved in reabsorption in many respects except for the reversal of direction.

At low concentrations of the transported substance the mechanism is able to transport all of the material presented to it. The most commonly studied substance p-aminohippuric acid (PAH) may be used as an example. If PAH is administered intravenously in small amounts so as to maintain a low concentration in the arterial plasma it is found that the blood leaving the kidney in the renal vein may be almost free of PAH. An average of some 90 per cent of the PAH reaching the kidney in the plasma is removed. Since some of the blood reaching the renal vein has probably perfused tissue which does not transport PAH it is apparent that very little can be left over from that plasma which passes through the active areas. This extremely effective *extraction* of PAH is the basis of the use of this substance for the estimation of renal plasma flow which is considered below.

As the plasma concentration of the transported substance is increased the rate of tubular excretion increases until a maximum is reached and no further augmentation of secretion occurs. The relationship between plasma PAH concentration and PAH excretion in the urine is illustrated in figure 346. The dotted line passing through the intercept is the amount of PAH filtered at the glomeruli calculated from the product of inulin clearance and the plasma concentration of free PAH. (Since PAH is to a small extent bound to plasma albumin the total concentration must be corrected for this binding to obtain the filtered amount.) At every level of plasma PAH the rate of excretion exceeds the rate of filtration.

² While the iodine is important for X-ray density it is not related to the susceptibility to transport which undoubtedly derives from the organic structures to which the iodine is attached. The first three of those mentioned are derivatives of pyridine N-acetic acid; the last is an organic sulfate.

$$U_{PAH}V = C_{12}P_{PAH}f + T_{PAH}$$

where f is the fraction of the plasma PAH which is filterable. As the plasma PAH is increased the rate of excretion at first increases sharply, the slope of the line relating excretion to plasma concentration being equal to the renal plasma flow. When the plasma concentration is further increased, the rate of excretion increases less rapidly, and it is found that the excess of excreted over filtered has become constant. This excess represents the maximum rate of tubular secretion and is designated as T_{PAH} .

If the rate of tubular secretion is determined by subtracting the filtered from the total excretion the relationship shown in figure 34-6 is obtained. Again, the actually observed titration curve differs from the idealized intersection of two straight lines and for reasons analogous to those involved in tubular reabsorption: (1) the dissociation of substrate-carrier complex and (2) heterogeneity of nephron function. The pertinent heterogeneity in this case, however, is in the ratio of perfusion to transport capacity since it is blood supply, rather than glomerular filtration, which along with plasma concentration will determine the amount available for secretion by the tubules.

Any of the various substances listed above as being secreted by this particular transport mechanism can be shown to compete with the others. Thus a high concentration of one will reduce the secretion of another and vice versa. Presumably they share a common carrier, and when some of the carrier sites are occupied by one, it has less capacity for the transport of another.

Several more or less specific inhibitors of this transport mechanism have been discovered (carbamide, probenecid, phenylbutazone). Actually these substances are probably also competitive inhibitors but are so poorly transported themselves that they occupy sites on the transport mechanism to the exclusion of the other transported substances. (It is interesting to note that these inhibitors have found their major practical application as inhibitors of the reabsorption of urate in the treatment of gout.)

The mechanism is inhibited noncompetitively by dimetrophenol and by mercurial diuretics. The effect of dimetrophenol, which has the property of uncoupling oxidation from phosphorylation, suggests that phosphate bond energy is important in the transport process. The effect of mercurial diuretics is striking in man, but, for unknown reasons, entirely absent in the dog.

The transport of PAH is enhanced by acetate

and lactate and inhibited by a number of the dicarboxylic acid intermediates of the Krebs cycle.

All of the substrates of the secretory process responsible for the tubular excretion of PAH are weak organic anions. A separate and distinct mechanism is capable of transporting a variety of organic bases including N-methylnicotinamide, tetraethylammonium ion and priscoline. These compete with each other but show no interaction with the organic anions. The normal substrate for this mechanism has not been recognized.

The Utilization of Tubular Secretion for the Measurement of Renal Blood Flow

As was noted above, several substances which undergo tubular excretion are very nearly completely removed from the blood which perfuses the kidney. This has made them singularly useful for the estimation of renal blood flow. Diodrast and *p*-aminohippurate (PAH), because they are well adapted to chemical analysis, have particularly been used for this purpose, and we will consider the use of PAH as an example.

In accord with the Fick principle, if the rate of removal of a substance from the blood as it flows through an organ is known, and if the concentration in the blood entering and leaving the organ can be determined, the blood flow can be calculated.

$$F = \frac{R}{A - V}$$

where F is the flow, R the rate of removal and A and V the concentration in arterial and venous blood respectively.

In applying this to the measurement of renal blood flow using PAH, the following experimental facts are important: (1) there is no metabolism, production nor storage of PAH in the kidney, all of the PAH removed from the blood is excreted in the urine, (2) all of the PAH removed from the blood is removed from the plasma, the concentration in the red blood cells does not change significantly as blood passes through the kidney. Then the above equation can be modified to yield

$$RPF = \frac{U_{PAH}V}{P_{PAH}^A - P_{PAH}^{RV}}$$

where RPF represents renal plasma flow and P_{PAH}^A and P_{PAH}^{RV} represent concentrations of PAH in arterial and renal venous plasma respectively.

Now, as it stands in this form the determination of renal plasma flow would require measurement of the rate of excretion of PAH and the concen-

trations in arterial and renal venous blood plasma. All of these are feasible in man, but the collection of renal venous blood is considerably more difficult than the remainder of the procedures. However, since we know that at low concentrations of PAH in the arterial plasma the removal of PAH as blood passes through the kidney is very nearly complete, we may as a first approximation consider the concentration in renal venous plasma to be zero and write

$$\text{ERPF} = \frac{U_{\text{PAH}}V}{P_{\text{PAH}}} = C_{\text{PAH}}$$

or that the *effective renal plasma flow* is equal to the PAH clearance. In practice it is not necessary to measure arterial plasma PAH since, when arterial concentration is constant, there is no measurable removal of PAH by peripheral tissues, and the PAH in peripheral venous plasma is the same as that in arterial plasma. Therefore, the effective renal plasma flow can be simply estimated by measurement of the plasma PAH clearance when the plasma PAH is maintained at a low level. (As plasma PAH is increased, the extraction becomes less complete and the clearance falls further below the true plasma flow.) From the effective renal plasma flow the corresponding renal blood flow can be calculated if the hematocrit is known

$$\text{ERBF} = \frac{\text{ERPF}}{1 - H_c}$$

It is interesting to note that Homer Smith and his associates deduced that the clearance of diodrast could be used to measure renal plasma flow in man before the technique for obtaining renal venous blood by venous catheterization had been devised and the virtually total extraction of diodrast confirmed.⁴ This was based on the very high value (approximately 650 ml per minute) of the diodrast clearance, thus plasma flow of at least 650 ml per minute was required to supply the diodrast at the rate it was excreted. It was reasoned that this was already such a large volume flow that the true plasma flow could not be much higher.

* It should also be noted that if, for some reason, renal venous blood is collected so that true plasma and blood flow can be determined, PAH and similar substances lose their unique value. Then any substance which is removed by, but not produced, metabolized or stored in the kidney can be used for the measurement, since the Fick principle can be applied directly. A high degree of extraction under these conditions has only the virtue of minimizing experimental error.

Renal Blood Flow and Filtration Fraction in Man

The remarkably high value of the renal plasma flow has been mentioned above. A plasma flow of 650 ml per minute corresponds to a blood flow of about 1200 ml per minute, an amount approximately equal to one-fourth of the cardiac output under basal conditions. The ratio of the renal blood flow to cardiac output is frequently referred to as the *renal fraction* of the cardiac output.

The demonstrated equivalence of PAH clearance and (effective) renal plasma flow has made it possible to measure the renal blood flow in man with a minimum of manipulation and disturbance. Thus it has been possible to measure changes in blood flow with disease as well as to determine the effects of various changes in physiological state and the effects of drugs, etc.

In considering changes in the renal plasma and blood flows, it is pertinent to take account of the fraction of the plasma lost as glomerular filtrate as the plasma flows through the glomerular capillaries. Since all of the renal blood flow under normal conditions passes through the glomeruli, the volume given up as glomerular filtrate is derived from the total plasma flow and the ratio of filtration rate to plasma flow (inulin clearance to PAH clearance) is a measure of the extent to which, in the average glomerulus, the plasma volume is reduced, and the plasma protein concentration increased by the process of glomerular filtration. The ratio of filtration rate to plasma flow is known as the *filtration fraction*.

While, as was noted in an earlier section, the rate of glomerular filtration is a remarkably stable function, the renal blood flow manifests a fairly marked degree of lability, and may be modified by any of a number of stimuli. Most of the changes are mediated via the sympathetic nerve supply and are in the direction of decreases. In fact, although the subject has long been debated and no consensus has been achieved, the only physiological effects clearly shown to be mediated by the nerve supply to the kidneys are vasoconstriction and the renal nerves have not been shown to play a significant role in the regulation of transport processes in the renal tubules.

The renal blood flow is diminished by fright, pain, exercise, epinephrine, norepinephrine and stimulation of several areas of the central nervous system, and by a number of other stimuli. In general, anything which lowers blood pressure will reduce renal blood flow, not so much because of the reduction in perfusion pressure, but because the kidney takes part in the general vasoconstriction.

tion which is the homeostatic response to a lowering of blood pressure. Thus there may be a marked decrease in renal blood flow with only a trivial reduction in aortic blood pressure. Drugs which reduce blood pressure also reduce the renal blood flow. However, in general, the reduction in flow is less than with equivalent reductions in blood pressure due to, for instance, hemorrhage or orthostasis, since the blood pressure reducing drugs usually inhibit renal as well as peripheral vasoconstriction. A special case appears to be hydrazinophthalazine which may increase renal blood flow while reducing systemic blood pressure, probably through a specific renal vasodilator action.

A more or less unique phenomenon is the marked renal vasodilation and hyperemia produced by the pyrogenic reaction. The latter phenomenon, the most striking clinical feature of which is chills and fever, is most often a response to bacterial products (certain bacterial polysaccharides, typhoid vaccine). It is accompanied by intense hyperemia of the kidney, and the renal blood flow may reach twice its normally very high value. Interestingly the renal response to pyrogenic materials is not abolished by the administration of antipyretic drugs although the latter may completely suppress the chills and fever.

With all of the above changes in renal blood flow there are frequently only slight changes in glomerular filtration rate and such changes are frequently entirely absent. Thus the changes in filtration fraction are the inverse of the changes in blood flow.

THE REABSORPTION AND EXCRETION OF WATER

One of the most striking features of the function of the mammalian kidney is the capacity to excrete urine differing in osmotic pressure from the blood from which it is derived. It is through this capacity to excrete concentrated or dilute urine that the solute concentration (osmotic pressure) of the body fluids is maintained within remarkably narrow limits despite wide variation in the intake of solute and water. When, because of water loss or solute gain, the solute concentration of body fluids rises, the urine becomes concentrated; solute is excreted with less than the equivalent amount of water, and the solute concentration of the body fluids is restored to normal. Conversely, when the body fluids become diluted by water intake or solute loss, a dilute urine containing an excess of water is excreted, and the osmotic pressure of body fluids is returned to normal. Before considering the mechanisms by

which the renal tubules effect these changes, it may be helpful to digress briefly to review the concept of osmotic pressure and its measurement.

If two solutions containing different concentrations of solute are separated by a membrane permeable to the solvent (water in all cases with which we are concerned) but not the solute, there will be a movement of water from the more dilute to the more concentrated of the solutions. The movement of water is due to the fact that the presence of solute reduces the chemical activity of water, and water will move from the solution in which its activity (analogous to concentration) is high to one where it is lower. Water will move from dilute to concentrated solution until both have the same solute concentration or, if the movement of water is opposed by the application of a hydrostatic pressure until the hydrostatic pressure balances the concentration difference. The hydrostatic pressure which would be required to maintain a solution at constant volume when it is separated by an ideal semipermeable membrane⁴ from pure water is the osmotic pressure of that solution. The term osmotic pressure is applied although the osmotic pressure is never actually determined. Instead some other property of the solution dependent upon total solute concentration is measured: most commonly the freezing point, occasionally the vapor pressure.

The *colligative properties* (osmotic pressure, freezing point depression, vapor pressure depression) depend on the ratio of the total number of solute particles to the number of moles of solvent. The nature of the solute is, to a large extent, indifferent; ideally, a protein molecule of molecular weight 100,000 has an effect equal to that of a sodium ion of weight 23 and a mole of sodium chloride, since it dissociates to yield two particles, has twice the effect of a mole of urea or glucose. One mole of ideal solute dissolved in a kilogram of water depresses the freezing point of the solution by 1.86°C. Such a solution is defined as an *osmolal solution* and is said to contain one *osmol* per kilogram of water. Since most biological fluids are considerably more dilute, it is convenient in order to avoid decimals, to deal with *milliosmols* or *micro-osmols*, one milliosmol being one one-thousandth of an osmol, one micro-osmol one thousandth of a milliosmol. The milliosmolality of a solution is defined as its freezing point depression divided by 0.00186. Thus normal plasma

⁴An ideal semipermeable membrane is one permeable to solvent but impermeable to all solute.

is about 285 milliosmolar (abbreviated 285 mOs) and has a freezing point of about -0.53°C *

It will facilitate consideration of the processes which take place between the filtration of an isotonic fluid (one which has the same osmotic pressure as blood plasma) and the excretion of dilute and concentrated urine, if we first consider the gross behavior of water excretion and its extrarenal control. Under basal conditions the urine is usually moderately concentrated and the urine flow is small. If under such conditions an individual ingests a moderately large volume of water, e.g., one liter, it is found that after an interval of some 15 to 20 minutes the urine flow begins to rise. The flow increases rapidly to reach a peak of some 12 to 15 ml per minute at 40 minutes to 1 hour, and, when an amount approximately equal to that ingested has been excreted, returns to the same low level as obtained before the water ingestion. (Of course, if the water ingestion is continued so that a positive balance is maintained, the high rate of flow may continue for prolonged periods.) If these events are analyzed more carefully, it is found (1) that the osmotic pressure of the blood shows a distinct drop (though only a few per cent) well before the onset of the increase in urine flow (*diuresis*), (2) that the change in urine flow is almost entirely due to a change in the amount of water excreted, manifested by a shift in urine osmolality from hypertonic to markedly hypotonic to plasma, solute excretion shows little or no change, (3) if glomerular filtration has been measured it is found that the increase in urine flow occurs without or with only trivial changes in the rate of formation of glomerular filtrate, the change in water excretion is due to a change in the absorption of water in the renal tubules, (4) if at the peak of the urine flow, additional water is ingested the urine flow does not increase further but remains at a value of some 12 to 15 per cent of the volume of the glomerular filtrate, (5) if, at any point in the course of the diuresis, vasopressin, the antidiuretic hormone of the posterior pituitary, is administered, the diuresis is immediately interrupted, and the urine again becomes more concentrated than the blood.

The concentration of the urine is normally

* Note that osmotic pressure depends on the number of solute particles per unit of solvent. The amount of water in a given volume of solution will vary with concentration as well as with the nature of the solute. There is therefore, no simple way to convert from osmolality to a number of solute particles per unit volume of solution. It is, however, the practice to disregard the inaccuracy involved and multiply volume by osmolality to obtain the approximate amount of solute in a given volume.

continuously regulated by the secretion of antidiuretic hormone (ADH) by the posterior lobe of the pituitary gland. This hormone is believed to be produced in the supraoptic nuclei of the hypothalamus and to migrate via the supraopticohypophyseal tracts to the posterior lobe of the pituitary where it is stored and released into the blood in response to stimuli mediated from the hypothalamus via the same tract system. Within the supraoptic nuclei certain cells (*osmoreceptors*) are believed to behave as tiny osmometers, taking up water and swelling when the osmotic pressure of the surrounding body fluids is reduced and giving up water as the osmotic pressure of the bathing fluid rises. The swelling and shrinking of these cells is believed to lead to the transmission of nervous impulses which modulate the release of antidiuretic hormone from the posterior pituitary. Thus a reduction of the osmotic pressure of the blood leads to inhibition of ADH release,* an increase of osmotic pressure stimulates ADH secretion. In turn the ADH is carried by the blood to the kidney, and in the kidney ADH regulates the reabsorption and excretion of water.

The work of Verney, to whom we owe much of our understanding of the pituitary control of water excretion, showed that injection into the internal carotid artery of the dog of enough sodium chloride to raise the osmotic pressure of the blood by about 2 per cent resulted in immediate inhibition of water excretion. Injection of the same amount into a peripheral vessel had no such effect since it was then diluted with a large volume of blood before being delivered to the sensitive area in the brain. Injection of the osmotically equivalent amount of urea into the internal carotid was also virtually without effect. In this case the ineffectiveness is presumably due to the fact that urea readily penetrates cells. When the urea concentration of their environment is raised, the osmoreceptor cells take up urea rather than lose water. Since the receptors do not shrink, there is no induction of ADH secretion. Thus, *only those solutes to which cells are relatively impermeable make up the effective osmotic pressure in response to which ADH secretion is regulated*†.

Our knowledge of the location in the renal tu-

* The latent period from water ingestion to onset of diuresis is attributable 1) to the time required for water absorption to produce sufficient dilution of the body fluids and thus inhibit ADH secretion, 2) for the circulating ADH to disappear.

† The above describes the normal control of ADH secretion. A number of other stimuli such as fear, trauma, nausea, certain drugs, and many others may produce secretion of ADH under conditions unrelated to the osmotic pressure of the body fluids.

bule and the nature of the processes by which water excretion is regulated is due largely to the application of the micropuncture technique—in amphibians by Richards and his associates and in mammals by Walker, Bott, Oliver, and MacDowell and more recently and extensively by Wirz and Gottschalk.

The glomerular filtrate has the same osmotic pressure as the plasma except for the absence of the plasma proteins.³ As the fluid flows through the proximal tubule, its volume is reduced to a fraction of that which enters the glomerular space. Although, because of inaccessibility from the kidney surface no samples have been collected from the last 40 per cent of the proximal tubule, it is generally estimated that approximately one-fifth of the filtered volume reaches the end of the proximal tubule and enters the loop of Henle. This reduction of volume occurs *without change in osmotic pressure* whether the urine being produced is dilute or concentrated. Thus the large fraction of fluid reabsorbed in the proximal tubule does not take part in the concentration and dilution processes, and, in fact is lost to the process of osmoregulation. The water thus reabsorbed in the proximal segment has been termed by Smith *obligatory water reabsorption* to distinguish it from the *facultative water reabsorption* in the more distal portions of the nephron where water reabsorption is subject to regulation in accordance with the excess or deficit of water in the body fluids.

A considerable body of evidence indicates that the water reabsorption in the proximal tubule is entirely a passive process and that the active process which underlies it is the transport of salt (predominantly sodium salts) out of the tubule lumen. As sodium salts are transferred from lumen to peritubular fluid there is a tendency to produce dilution of the tubule contents and hypertonicity of the surroundings. The proximal tubule is highly permeable to water and in response to the osmotic gradient, water follows the salt out of the tubule. Within the limits of the determinations the proximal tubule contents are always isotonic with the blood.

The exact course of events in the loop of Henle

³ It is important to make a clear distinction between the total osmotic pressure with which we are concerned in the processes of urine dilution and concentration, and the colloid osmotic pressure or oncotic pressure due to the plasma proteins which play such an important role in the distribution of fluid across capillary membranes (because the latter are so highly permeable to all the other solutes). The colloid osmotic pressure of plasma is equivalent to about 25 mm Hg (1 to 2 mOs) while the total osmotic pressure is of the order of 6 atmospheres (285 mOs).

is not completely established because of inaccessibility to direct puncture (except at the tip). However, from more indirect evidence it is quite probable that the descending limb of the loop retains the high water permeability which characterizes the proximal tubule and that the fluid within the descending limb retains the same osmotic pressure as the surrounding interstitial fluid. The high water permeability is, however, lost in the ascending limb and now the continued removal of salt leaves the fluid dilute. The urine emerges into the distal convoluted tubule with its osmotic pressure reduced to about half that of plasma whether the final urine is to be dilute or hypertonic.

The changes which take place in the distal tubule depend upon whether a dilute or concentrated urine is to be produced. In the *formation of dilute urine* the dilute fluid which enters the distal tubule is further diluted by the continued removal of salt, and the salt removal probably continues through the collecting system. The urine is thus rendered hypotonic by the active reabsorption of salt in a region which clearly has a low permeability to water (Other wise the osmotic gradient would be dissipated, as it is in the proximal tubule by the escape of water to the more concentrated surroundings.) The low permeability to water which characterizes the distal convoluted tubule and collecting system during the *formation of dilute urine* is dependent upon the absence of ADH.

In the *formation of concentrated urine*, the events are similar up to the point at which the fluid enters the distal convoluted tubule. In the presence of antidiuretic hormone, however, the distal convoluted tubule and collecting ducts become permeable to water.⁴ Consequently, as it flows through the distal tubule the osmotic gradient, established by the reabsorption of sodium and chloride, is dissipated and, despite additional salt removal in the distal tubule the dilute character of the urine is lost so that it regains isotonicity before it enters the collecting system. It is important to emphasize that it enters the collecting system isotonic, never hypertonic. The additional water loss which renders the urine more concentrated than blood occurs in the collecting system.

The nature of the mechanism by which urine is rendered hypertonic to the body fluids has long

⁴ Antidiuretic hormone has been shown to have the property of increasing water permeability in isolated membranes (frog skin, toad skin, toad bladder) by causing the dilation of water-filled pores. Presumably the effect on the distal tubule epithelium is similar.

been one of the more intriguing problems of renal physiology, and its apparent elucidation, largely through the efforts of Wirz and his associates, is one of the more important recent achievements. Although some of the details of the mechanism are relatively complex, the essentials are quite simple and directly related to the anatomical organization of the kidney. The convoluted tubules are cortical structures; the loops of Henle and the collecting tubules and ducts lie in the medulla. The latter structures are thus relatively isolated from the cortical structures in which most of the transport activity of the kidney takes place. In addition, the blood supply of medulla and papilla forms a looplike system derived from the efferent vessels of the juxtamedullary glomeruli, running down into the medulla and looping back to the cortex. Thus both loop of Henle and the blood supply of the medullary region form *countercurrent* systems in which the outflowing fluid flows counter to and in proximity to inflowing fluid. We will for the moment defer consideration of the importance of this particular arrangement.

As was noted above, as fluid flows through the ascending limb of the loop sodium and chloride are removed while the water remains behind in the tubule lumen and the urine becomes diluted. The sodium and chloride removed are transferred to the interstitial fluid of the medulla, increasing the osmotic pressure of this fluid. The diluted urine emerges into the cortex where, in the pres-

ence of ADH, it loses its excess of water and is further reduced in volume as solute is removed in the distal tubule. Thus water loss occurs in the cortex, spatially separated from the salt left behind in the medulla and in an area where, because of the very large flow of blood, the excess water produces only a minimal change in osmotic pressure. Now the remaining urine, greatly reduced in volume and isotonic with the blood, enters the collecting system and flows through the medulla. The interstitial fluid of the medulla, however, has a high osmotic pressure because of the salt transported by the loop and, the collecting duct being permeable to water in the presence of ADH, the urine loses water to attain the same osmotic pressure as the interstitial fluid. Thus the hypertonicity of the urine is produced. These events are illustrated diagrammatically in figure 347. Because the volume flow through the loop is several times larger than that in the collecting ducts, a relatively small change in concentration in the loop is sufficient to yield enough solute to raise the concentration of the urine in the collecting ducts severalfold.

If the sodium salts transported into the medullary interstitial fluid are to raise the osmotic pressure of the latter, they must not be immediately carried away by the blood flowing through the area. The retention of excess solute in the medullary interstitial fluid is made possible by the arrangement of the blood flow which constitutes a *countercurrent exchanger*. The principle

FIG. 347. Diagrammatic representation of changes in the tonicity of fluid in the tubules during the formation of concentrated and dilute urine. Dark and light arrows indicate movements of sodium chloride and water respectively, and the relative permeability of the tubule wall to water is indicated by its thickness.

FIG 34.8 Principle of the countercurrent exchanger. A and B 100 calories per minute raise the temperature of 10 ml per minute of water 10 degrees in both A (straight flow) and B (countercurrent flow). However, since the incoming water is heated by the outgoing water in B, the maximum temperature attained in the countercurrent system is considerably higher than with straight flow. The graph compares the temperature along the flow tubes in each system. C, countercurrent flow as applied to the capillary loop showing that it is not necessary for the limbs of the loop to be in direct contact. In the hypothetical illustration given, both limbs are in contact with the same interstitial fluid, of progressively increasing concentration. Sodium salts (arrows) at first enter the capillary blood, later partly return to the interstitial fluid. Note the analogy between B, in which heat is recirculated and C, in which sodium salts are similarly retained in an area.

of the countercurrent exchanger is illustrated in figure 34.8. Outflowing blood tends to lose its solute to the inflowing blood. As a result, solute is recirculated in the medulla. This characteristic makes it possible not only to retain sodium salts but to trap urea as well, the special role of urea in the concentration process is considered with the excretion of urea.

The loop arrangement has an additional physiological advantage. As the fluid flows down the descending limb of the loop of Henle into an environment made hypertonic by the activity of the ascending limb, it loses water so as to retain the same osmotic pressure as the environment. The loss of water raises the concentration of sodium salts in the loop contents so that the transport of sodium salts out of the ascending limb is against only a small gradient of concentration despite the very high concentration of sodium salts in the interstitial fluid surrounding the loop. This arrangement is that of a *countercurrent multiplier*, so called because the small concentration gradient from the loop contents to environment is multiplied in the longitudinal direction from cortex to tip of papilla.

The highest concentration achieved by the human kidney is generally about 1200 to 1400 mOs (a relatively modest maximum compared with some other mammals, e.g., dog 2300 to 2500 mOs, rat 3000 to 3200 mOs, kangaroo rat over 5000 mOs), the lowest concentrations observed are of the order of 30 to 40 mOs. Thus the kidney is able to produce urine four to five times more concentrated than or one-seventh to one-tenth as concentrated as the blood (roughly 300 mOs).

In clinical practice, the specific gravity, rather than the osmolality, is generally used as an index of concentration and dilution. Urine of specific gravity 1.008 to 1.010 is approximately isotonic with plasma, but the two scales are not directly interchangeable since the specific gravity depends not only on the concentration of solute but also

on the latter's nature. The chief value of the specific gravity lies in the simplicity of its determination.

The highest and lowest concentrations are produced only when solute excretion is at a relatively low level, as solute excretion increases dilute urines become less dilute and concentrated urines less concentrated. The basis for this change can be deduced from the mechanisms for dilution and concentration described above and is more easily understood if the urine flow is considered to be divided into two parts as suggested by Smith. One fraction is considered to contain all of the solute excreted at the same concentration as plasma, the other fraction is the amount of water contained in excess of this isotonic fraction. The isotonic fraction is calculated by dividing total solute excretion by the osmolality of plasma. Solute excretion is given by the product of urine flow and urine osmolality $U_o \cdot V$ and when this is divided by the plasma osmolality, the resulting value has the dimensions of a clearance and is generally called the osmolal clearance (C_o).

$$C_o = \frac{U_o \cdot V}{P_o}$$

When the urine is dilute the flow exceeds the osmolal clearance by an amount which Smith has designated the *free water clearance* (C_{H_2O}). This is the volume of water which must be removed from one minute's flow of urine to return the urine to isotonicity. Thus

$$V - \frac{U_o \cdot V}{P_o} = C_{H_2O}, \quad C_{H_2O} = V - C_o$$

From the mechanism described above it may be seen that, provided no water has escaped from distal tubule or collecting duct, C_{H_2O} is the volume of water which originally contained the salt reabsorbed in ascending limb, distal tubule and collecting duct. The capacity of these segments to reabsorb sodium salts, therefore, sets the limit on the amount of water which can be excreted above that containing the urinary solutes in isotonic solution. It is this limited capacity to excrete water freed of solute which accounts for the increasing concentration of dilute urine as solute excretion increases, the isotonic portion of the urine flow (C_o) constituting an ever larger fraction of the total flow (V). Actually C_{H_2O} may be less than maximal 1) because insufficient sodium salts are delivered to the distal portions of the tubule to saturate the reabsorptive capacity or 2) because some of the water "freed" by salt removal diffuses out of the distal tubule. Even in

the total absence of ADH some permeability to water persists, and thus permeability may be increased by amounts of ADH which are too small to yield a maximal effect and thus a concentrated urine.

When the urine is concentrated the flow is smaller than the osmolal clearance, that is,—water must be added to the urine to render it isotonic. Thus C_{H_2O} assumes a negative value, this has been designated as $T_{H_2O}^*$ by Smith. The driving force for the removal of water from urine flowing through the collecting ducts is provided by the salt transported out of the ascending limb of the loop of Henle. Therefore the amount of water thus removed ($T_{H_2O}^*$) can not be greater than the osmotic equivalent of the salt deposited in the medulla by the loop.¹⁰ Since the value of $T_{H_2O}^*$ is limited, as solute excretion increases the urine concentration falls again because the isotonic portion of the urine (C_o) constitutes an even greater fraction of the total (V) ($V = C_o - T_{H_2O}^*$). The flows and concentrations of dilute and concentrated urines as solute excretion is varied are illustrated in figures 34.9a and 34.9b.

In considering the effects of antidiuretic hormone and the change from dilute to concentrated urine, it is important to emphasize that by far the most important effect is that in the distal tubule which involves the change from dilute to isotonic urine. The relative quantitative importance of the dilution and concentration processes can be illustrated in a person excreting enough solute to require the excretion of 2 liters of isotonic urine in 24 hours. If he were to produce maximally dilute urine for this period, he would excrete approximately 20 liters of urine. Therefore, if ADH were to effect a rise in urine concentration only to isotonicity with plasma, some 18 liters of water would be conserved. If, on the other hand, the same solute were to be excreted in a maximally concentrated urine, the volume would be reduced to about 500 ml, a further saving of about 1.5 liters. Clearly, the water saved in not putting out a dilute urine is quantitatively much more important than that conserved in forming a concentrated urine.

THE REABSORPTION AND EXCRETION OF SODIUM AND CHLORIDE

The regulation of the osmotic pressure of body fluids tends to adjust the amount of water in the

¹⁰ This is equivalent to saying that the production of a concentrated fluid (urine) in the medulla must be just balanced by the production of a dilute one (the fluid emerging from the ascending limb of the loop).

FIG 34 9a (left) Relationship between urine flow and solute excretion in water diuresis and during the formation of concentrated urine

FIG 34 9b (right) Relationship between urine flow and urine osmolality when urine flow is modified by changing solute excretion. See text for explanation

body to the amount of solute in the body fluids. Thus, so long as osmotic pressure regulation remains normal, the volume of the body fluids will depend on the amount of solute in the body. Since sodium salts constitute some 90 per cent or more of the solute of extracellular fluid, the volume of the extracellular fluid is largely dependent on the regulation of renal sodium excretion.

We have already considered, in relation to the regulation of water excretion, how sodium reabsorption is distributed in the renal tubule. It has been pointed out that a major fraction of the filtered solute and water are reabsorbed in the proximal tubule. Since most of this solute is composed of sodium salts and since the fluid remains isotonic in the process of this reabsorption, there is ordinarily little reduction of sodium concentration in the proximal tubule. However, the reabsorption involves active sodium transport since (1) the reabsorption occurs despite an electrical potential (20 mv, lumen negative to interstitial fluid) opposing the movement of sodium, and (2) if some nonreabsorbable solute (e.g., mannitol) is present, the sodium concentration does fall well below that of the peritubular fluid as sodium is reabsorbed. (However, because of a relatively high permeability the gradient of sodium concentration which can be established is limited because of diffusion from peritubular fluid.) Since chloride reabsorption is favored by the electrical potential, there is no reason to believe any specific transport mechanism for chloride is present. In essence, the chloride is pulled by its electrical charge as a result of the active transport of sodium.

The reabsorption of sodium in the more distal

segments of the nephron does result in the establishment of gradients of sodium concentration which may, indeed, be very steep since sodium may be virtually absent from the urine. The difference between proximal and distal tubules probably resides not in the character of the transport mechanism, but in the passive permeability of the tubule epithelium; there is less tendency, in the distal area, for the sodium to diffuse back into the lumen and dissipate the gradient.

In addition, in the distal tubule not all of the reabsorption of sodium is accompanied by reabsorption of anion. Some of the sodium reabsorbed in the distal segment is replaced by potassium, and some is replaced by hydrogen and ammonium ions. These aspects of the sodium reabsorptive mechanism will be considered in relation to potassium excretion and the renal regulation of acid base balance in later sections of this chapter.

The mechanism by which sodium is transferred from lumen to peritubular fluid is poorly understood. It is probably very closely related to that mechanism (also poorly understood) common to virtually every cell of the body, by which sodium is extruded from and potassium maintained at a high concentration in the intracellular fluid. The process probably involves a negatively charged carrier and an exchange of sodium ions for other cations (potassium and/or hydrogen), but no entirely satisfactory and generally applicable model is available.

The Regulation of Sodium Excretion

A number of circumstances are known to influence the rate of sodium excretion. The way in which these factors are integrated to determine

and regulate the rate of sodium excretion is not so well known. To say that the rate of sodium excretion is determined by the balance between filtration of sodium at the glomeruli and reabsorption of sodium by the renal tubules is merely to state the obvious. What is required is a knowledge of how these two processes are interrelated and modified to maintain a normal body sodium content. Although we can indicate qualitatively some of the determinants of sodium excretion, they can not be put together as, for instance, in the case of glucose, to predict the rate of salt excretion.

1 GLOMERULAR FILTRATION Under average normal conditions only a very small fraction of the sodium contained in the glomerular filtrate is excreted in the urine—a person on an average salt intake puts out only about one half of one per cent of the amount filtered. It is clear, therefore, that an increase of only one per cent in the rate of glomerular filtration¹¹ supplies enough additional sodium in the filtrate to double or triple the sodium excretion were none of the extra sodium reabsorbed by the tubules. It is also clear, however, that when the glomerular filtration rate increases, the increment of filtered sodium is never quantitatively excreted. In fact, unlike the situation with respect to the reabsorption of such substances as glucose and phosphate, changes in the rate of glomerular filtration are attended by parallel changes in the rate of sodium reabsorption. When glomerular filtration increases, sodium reabsorption increases; when filtration decreases, reabsorption likewise decreases. However, because these changes are not exactly proportional, changes in glomerular filtration are not accompanied by proportional changes in excretion. As a matter of fact, acute changes in the filtration of sodium produce relatively very large changes in sodium excretion. However, if the filtration rate changes are maintained for a protracted period, compensatory changes in reabsorption occur so as to restore sodium balance.

These circumstances are very clearly demonstrated by the experiments of Mueller and his associates. In dogs operated upon to make it possible to collect the urine from each kidney separately, these investigators placed constricting clamps on one renal artery. It was found that if the artery was constricted so as to produce a

barely detectable decrease in glomerular filtration rate, there was a marked drop in the amount of sodium excreted by the affected kidney. Such a kidney might excrete only 10 to 20 per cent of the daily sodium intake, the remainder being excreted by the normal control kidney so as to maintain sodium balance. This situation might persist indefinitely. If, however, the normal kidney was then removed there was a prompt increase in the salt excreted by the kidney with the constricted artery. When the full load of maintaining sodium balance was placed on the experimental kidney, compensatory adjustments of reabsorption overcame the effects of reduced glomerular filtration.

2 ADRENOCORTICAL STEROIDS The best known of the influences which modify tubular reabsorption of sodium is that exerted by the steroid hormones of the adrenal cortex. The natural hormone with the greatest effect on sodium reabsorption is aldosterone, but similar effects are produced by desoxycorticosterone, cortisol, cortisone and others, as well as a number of synthetic steroids. All of the active steroids exert qualitatively identical effects on sodium transport by the renal tubules, increasing reabsorption in all its forms—that is, sodium reabsorption accompanied by chloride reabsorption as well as sodium exchange for potassium and hydrogen ions. However, the various steroids may produce differing effects on sodium excretion not only because they differ in potency with respect to their capacity to modify sodium transport, but because glucocorticoid activity is associated with the specific property of increasing the rate of glomerular filtration.

The control of salt excretion by the adrenal cortex is probably mediated by the secretion of aldosterone. The control of aldosterone secretion *in turn is dependent upon some as yet unidentified receptor probably responsive to changes in effective intravascular volume and mediated by a trophic hormone probably secreted somewhere in the hypophyseal hypothalamic area.* Contraction of blood volume leads to increased secretion of aldosterone, increased reabsorption of sodium (and chloride) and secondarily, by an increase in the retention of water, to expansion of volume.

The mechanism by which the steroids modify sodium transport is unknown. It should be clearly understood that the transport process proceeds very well in the absence of the corticosteroids; the effect of the hormones is, in a sense, the fine adjustment of a process which is largely autonomous.

When adrenal salt-retention hormones are administered to normal animals there is a brief

¹¹ Changes in the amount of sodium filtered are generally due largely to changes in the rate of glomerular filtration since the plasma sodium concentration is normally maintained within a very narrow range, reflecting the constancy of osmotic pressure to which sodium salts contribute such a major share.

period of salt retention but the decreased salt excretion is relatively short-lived. After retaining a modest amount of salt, the animal comes back into balance. This does not indicate the development of resistance to the effect of steroid on sodium transport but compensation for this effect by other factors including, but probably not limited to, an increase in glomerular filtration.

3 Osmotic diuresis. The excretion of sodium is increased by any circumstance which leads to an increase in the excretion of solute. Perhaps the most common such event is elevation of the blood glucose to levels where the reabsorptive capacity of the tubules is saturated and glucose is excreted in the urine. The same effect may be produced by the administration of poorly reabsorbed substances such as urea or mannitol. This phenomenon is known as *osmotic diuresis*. Sodium excretion is increased because the presence of the other solute depresses sodium reabsorption in the proximal tubule. As sodium is reabsorbed, the other solute, which remains behind in the tubule, forms a larger and larger fraction of the total solute. Since the fluid retains the same total solute concentration as the blood, the sodium concentration must fall, the decrease in concentration impairs reabsorption.

4 EXCRETION OF POORLY REABSORBED ANIONS OR ANIONS SUBJECT TO TUBULAR EXCRETION. When large amounts of some anion are excreted in the urine, there must be an equivalent amount of cation excreted. To some extent sodium may be substituted for by potassium, ammonium or hydrogen ions, but the capacity to do this is limited. Thus under conditions where large amounts of sulfate, phosphate, p-aminohippurate (PAH), etc., are excreted, sodium excretion is increased.

5 SPECIFIC INHIBITION OF SODIUM TRANSPORT. The commonly used diuretics,—organic mercurials, chlorothiazide and related compounds, carbonic anhydrase inhibitors, etc., all owe their efficacy to the capacity to depress sodium transport by the renal tubules.

THE EXCRETION OF POTASSIUM

Potassium holds a unique place among the normal constituents of the blood and urine in being subject to both reabsorption and secretion by the tubules. The average rate at which potassium is excreted in the urine is only about 15 per cent of the rate at which it is filtered at the glomeruli, on the other hand, if large amounts of potassium salts are administered, or if the secretion of hydrogen ion is inhibited, the rate of excre-

tion of potassium may rise to levels equivalent to twice the rate at which it is filtered. There is considerable evidence to support the view that, even when the amount excreted is less than that filtered, the potassium in the urine is derived from tubular secretion.

The site and mechanism of potassium reabsorption are incompletely established, beyond the fact that reabsorption occurs more proximally than tubular secretion. It seems most likely that potassium reabsorption occurs in the proximal tubule and involves a specific active transport process since the urine potassium concentration may be considerably lower than the concentration in plasma and since all the electrical potential measurements which have been made have shown the lumen to be negative to the peritubular fluid. (An electrical potential oriented in the opposite direction would be required to produce passive movement against a concentration gradient.) It seems fairly certain that the reabsorptive mechanism is able to reabsorb all of the potassium delivered to it and that the filtered potassium makes no contribution to potassium excretion.

The potassium secretory process is located in the distal convoluted tubule, possibly extending into the collecting system. The tubular secretory mechanism operates by reabsorbing sodium ions in exchange for secreted potassium ions. Thus potassium excretion is limited to the amount of sodium which reaches the distal tubule segment in which exchange occurs.

The rate of potassium excretion is determined by several factors.

1 The concentration of potassium in cells, particularly the renal tubule cells. The concentration of potassium in the plasma has little influence on potassium excretion except insofar as cell potassium concentration tends to vary with plasma concentration. Such an arrangement is highly reasonable since potassium is primarily an intracellular ion, and it is, therefore, the cell potassium to which excretion should be related.

2 The amount of sodium delivered to the tubule site of sodium-potassium exchange is an important factor. Thus paradoxically, since sodium is reabsorbed as potassium is secreted, sodium and potassium excretion frequently vary in parallel rather than inversely.

3 The rate of tubular secretion of hydrogen ion or, possibly, the acidity of the secretory cells. The mechanism by which potassium is exchanged for sodium is also involved in exchanging hydrogen for sodium and there is competition between potassium and hydrogen in the process. Anything

which tends to enhance the secretion of hydrogen ion, depresses tubular excretion of potassium, anything which inhibits tubular secretion of hydrogen ion, enhances excretion of potassium

4 The capacity of the exchange mechanism. Provided sufficient sodium is delivered to the exchange mechanism potassium excretion is enhanced by conditions which enhance sodium reabsorption (adrenocortical steroids) and depressed by inhibitors of the mechanism (mercurial diuretics)

5 Tolerance to potassium. For reasons that are not entirely clear potassium excretion is facilitated by repeated administration of potassium

RENAL REGULATION OF ACID-BASE BALANCE

Under normal conditions the diet provides a number of sources of potential acid. The organic phosphorus of proteins and phospholipids is converted to phosphoric acid, the sulfur of the sulfur-containing amino acids is converted to sulfuric acid. When ammonium chloride is ingested, the ammonium ion is converted to urea and hydrogen ion leaving hydrochloric acid as the end product. If calcium chloride is ingested the calcium may be excreted in the stool as the insoluble salts of organic acids (such as fatty acids) and hydrochloric acid is absorbed. Under abnormal conditions (starvation, diabetic ketosis) large amounts of organic acid may be produced well beyond the capacity of the body to oxidize this acid to carbon dioxide.

In the usual dietary circumstances the dietary sources of acid predominate over the sources of alkali, but the latter may be in excess with certain intakes. Fruits and vegetables abound in the salts of organic acids. The organic anions are oxidized to CO_2 leaving the bicarbonates of sodium and potassium. In addition the intake may include sodium or potassium bicarbonate as such.

Acid or alkali entering the body fluids react with the buffers of these fluids and the pH change which occurs is thereby minimized. The most abundant buffer system of extracellular fluid is that made up of bicarbonate and carbonic acid and the bulk of the extracellular buffering is therefore involved with this system. Because it must provide the major part of the alkali to neutralize any acid gaining access to the extracellular fluid, the bicarbonate concentration has been designated the *alkali reserve* and can be considered a measure of the degree of acidosis or alkalosis (even though, by respiratory compensation, changes of

bicarbonate concentration may be accompanied by only minimal changes in pH).

Acid added to extracellular fluid reacts chiefly with bicarbonate to yield carbonic acid and the salt of the acid. The carbonic acid in turn yields CO_2 which is excreted in the lungs.

The result is the replacement, in the extracellular fluid, of one equivalent of bicarbonate with one equivalent of the anion of the acid. The anion (A^-) will eventually be excreted in the urine. If it is excreted as the sodium salt, the form in which it exists in plasma, the overall result will have been the disappearance from the extracellular fluid of one mol of sodium bicarbonate for each mol of H^+ added.

The buffer capacity of the extracellular fluid can be restored only by regaining a mol of sodium bicarbonate. This might be done if, instead of excreting the sodium salt (NaA) in the urine, the kidney were able to dispose of the free acid HA thus regenerating sodium bicarbonate. This would amount to a reversal of the reactions above.

This, in fact, the kidney is able to do by virtue of its capacity to produce urine considerably more acid (down almost to pH 4) than the blood (pH 7.40). Thus, to the extent that any acid is unionized at the pH of the urine, that acid may be disposed of directly, with regeneration and recovery of the bicarbonate by which it was temporarily buffered in the extracellular fluid.

The extent to which an acid is unionized at a given pH can be deduced from the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK} + \log \frac{[\text{A}^-]}{[\text{HA}]}$$

This may be rearranged in the form $\text{pK} - \text{pH} = \log [\text{HA}] - \log [\text{A}^-]$ to indicate more clearly that when the pH is lower than the pK of the acid concerned there will be more unionized acid than salt. Thus any acid which has a pK higher, or *not much lower* than the pH of the urine,¹² can be excreted to an appreciable extent in unionized form. Acids with pK's high enough to appear in

¹² Although more acid urine can be formed, the urine pH is not often below 5.0 and is more commonly around 6.

the urine in undissociated form to an appreciable extent are monobasic phosphate ($\text{H}_2\text{PO}_4^- \rightleftharpoons \text{HPO}_4^{2-} + \text{H}^+$), $\text{pK } 6.80$, β hydroxybutyric acid, $\text{pK } 4.7$

For most acids which enter the extracellular fluid, excretion as the undissociated acid is impossible. Hydrochloric and sulfuric acids are completely dissociated at all pH's. At a urine pH as low as 4.0, the concentration of hydrochloric or sulfuric acid would be only 10^{-4} N or $0.1 \text{ meq per liter}$. Even weak acids having $\text{pK}'s$ much below 5 must be excreted almost entirely as salts. In the excretion of such acids, then, some other mechanism is required if bicarbonate is to be regained to replace that originally lost in neutralizing them. This is accomplished by the generation of ammonium ion from neutral precursors and the substitution of ammonium ion for sodium ion in the urine. The acids are excreted as ammonium salts, the sodium is returned to the extracellular fluid as sodium bicarbonate. The overall reaction may be considered to be the following:

$\text{RNH}_2 + \text{HOH} \rightarrow \text{NH}_3 + \text{ROH}$ (which may then be oxidized to CO_2 and H_2O)

$\text{NH}_3 + \text{Na}^+\text{A}^- + \text{H}_2\text{CO}_3 \rightarrow$

$\text{NH}_4^+\text{A}^- \text{ (to urine)} + \text{Na}^+\text{HCO}_3^-$

Neither of these reactions nor those indicated above should be interpreted as indicating the actual processes which take place in the kidney. They represent the net results of a series of reactions.

Thus acids are disposed of without loss of alkali reserve (1) by excretion of weak acids in their unionized form and (2) by the substitution of ammonium ion for sodium ion in the excretion of their salts. The disposal of excess alkali is more direct. Alkali appears in the extracellular fluid as bicarbonate ($\text{B}^+\text{OH}^- + \text{CO}_2 \rightleftharpoons \text{B}^+\text{HCO}_3^-$) and is excreted in the urine as that bicarbonate which escapes reabsorption in the tubules. This background concerning the nature of the overall processes will serve as an introduction to the renal mechanisms which determine the excretion of acid or alkali.

Three processes are important in regulating the amount of acid or alkali excreted: (1) the filtration of bicarbonate at the glomeruli, (2) the transport mechanism by which bicarbonate is reabsorbed and the urine rendered acid, and (3) the synthesis of ammonia by the cells of the renal tubule.

The glomerular filtrate contains bicarbonate at a concentration essentially identical to that in

plasma.¹³ Micropuncture studies by Gottschalk have shown that as the fluid flows through the proximal tubule in the mammal, its pH tends to fall somewhat (to as low as about 6.5).¹⁴ Although the bicarbonate concentration of these fluids has never been measured, these pH determinations indicate that bicarbonate is extensively reabsorbed in the proximal tubules since some 80 per cent of the glomerular filtrate is reabsorbed, and the bicarbonate concentration of the fluid which remains is lower than that of plasma.

The latter is inferred from the Henderson-Hasselbalch equation, $\text{pH} = 6.1 + \log \frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]}$ and the assumption that the denominator, $[\text{H}_2\text{CO}_3]$, remains constant. The assumption is justified by the very high diffusibility of carbon dioxide through all known biological membranes which would indicate that the carbon dioxide tension (concentration) and therefore the carbonic acid concentration must be very nearly equal to those of plasma.

In the distal tubule the urine is further acidified, and the process continues into the collecting ducts. The major reduction in pH occurs in the distal parts of the nephron, but this does not necessarily indicate that the reabsorption of base occurs predominantly in the latter segments. As bicarbonate is removed from the tubule lumen, changes in the pH of the remaining fluid will depend upon the changes in volume of the remaining fluid. If bicarbonate removal proceeds more rapidly than volume decreases, the bicarbonate concentration falls and the pH likewise falls since the concentration of carbonic acid remains constant (see above). If the volume of the remaining tubular fluid diminishes more rapidly than does the amount of bicarbonate remaining, the pH of the fluid will rise. Thus, the degree to which the urine is acidified depends not only upon the rate of bicarbonate removal, but on the relationship of the removal rate to the rate of removal of water. Consequently, the production of urine more alkaline than plasma requires only that a greater fraction of the filtered water than of the filtered bicarbonate be reabsorbed.

¹³ Because the plasma proteins are nonfilterable anions, a Donnan equilibrium is set up across the glomerular membrane and all monovalent filterable anions, including bicarbonate, are about 5 per cent more concentrated in glomerular filtrate than in plasma water. All monovalent filterable cations, including H^+ , are about 5 per cent less concentrated.

¹⁴ Measurements have been made only under conditions in which the fully elaborated urine was acid. It is not unlikely that when the final urine is alkaline, the pH does not decrease but may even rise in the proximal tubule.

FIG 34 10 Hypothetical cellular processes in the secretion of hydrogen ion in exchange for sodium

Mechanism of Urine Acidification

Largely as the result of the studies of Pitts and his associates the process by which bicarbonate removal is effected is generally accepted as being one in which hydrogen ion is secreted by the cells of the renal tubule in exchange for sodium ions. The mechanism may be conveniently depicted as follows (fig 34 10). In the renal tubule cell as a result of energy requiring processes, hydrogen ion and hydroxyl ion are generated from water in spatially separated loci. The hydrogen ion enters the tubule lumen in exchange for a sodium ion which is taken into the cell. Meanwhile the hydroxyl ion is buffered within the cell by reacting with carbonic acid to yield bicarbonate ion and water. The bicarbonate and sodium ions are extruded into the extracellular fluid. The carbonic acid is regenerated by the hydration of carbon dioxide, the latter may be derived from either the metabolic processes within the cell or from the carbon dioxide of the blood and extracellular fluid.

The regeneration of the carbonic acid proceeds rapidly only in the presence of the enzyme *carbonic anhydrase* and this step may become rate limiting in the overall process. When the production of carbonic acid is unpaired by inhibition of the enzyme the concentration of carbonic acid in the cell falls and with it the hydrogen ion concentration. Since the rate at which hydrogen ion is extruded in exchange for sodium ion is related to the hydrogen ion concentration in the cell the rate of secretion of hydrogen ion is diminished. Thus inhibition of carbonic anhydrase diminishes the secretion of hydrogen ion and all of the processes dependent upon the secretion of hydrogen ion.

It should be noted that in the above process, for each hydrogen ion extruded one equivalent of

sodium as the bicarbonate is added to the extra cellular fluid and this result is independent of the fate of the hydrogen ion in the tubule lumen (fig 34 11). The fate of the hydrogen ion which enters the lumen in exchange for a sodium ion depends upon the composition of the fluid which it enters.

Acid added to any buffered solution is distributed among the buffers of that solution in a predictable way depending upon the relative concentrations of the buffers and their pH values. Any change in hydrogen ion concentration must affect all the buffers present since all must satisfy their ionization constants. The amount of hydrogen ion distributed to each buffer will be directly proportional to the concentration of the buffer and inversely related to the difference between the pH of the solution and the pK of the buffer.

We may consider as an example the secretion of hydrogen ion into the proximal renal tubule. The buffers contained in the glomerular filtrate may be considered to be bicarbonate (pK' 6.1) at a concentration of about 27 mmole per liter and phosphate (pK 6.8) at a concentration of about 1.5 mmole per liter. Because it is present in much higher concentration, bicarbonate will take up most of the hydrogen ion secreted even though the pH of the fluid (7.4) is closer to the pK of phosphate. Thus in the proximal tubule most of the added hydrogen ion reacts with bicarbonate.

The result of hydrogen ion addition then is the conversion of bicarbonate ion to CO_2 and water.

FIG 34 11 Fate of hydrogen ion secreted into tubule lumen in exchange for sodium. a) Formation of titratable acid, b) formation of ammonium ion, c) reabsorption of filtered bicarbonate. Modified from figure of Orloff (Yale J Biol & Med, 29: 211, 1956).

and the CO_2 diffuses out of the tubule lumen to extracellular fluid. Thus the exchange of a mol of sodium ion for a mol of hydrogen ion has resulted in the removal of a mol of sodium bicarbonate from the glomerular filtrate even though no bicarbonate ion has crossed the membrane separating lumen from tubule cell. Instead, the bicarbonate ion which enters the extracellular fluid is generated independently in the tubule cell.

In the distal tubule the situation may be quite different. Suppose that the proximal tubule capacity for phosphate reabsorption has been saturated so that half of the filtered phosphate has escaped reabsorption and reaches the distal tubule. At the same time the volume of the fluid flowing through the tubule has been greatly diminished by the processes of reabsorption, so that we may assume that at some point in the distal tubule only 5 per cent of the glomerular filtrate remains. The phosphate concentration in the fluid will then have reached a value ten times that in the glomerular filtrate or 15 mmole per liter. Now the hydrogen ion secreted into the fluid will to a very considerable extent react with dibasic phosphate, converting it to monobasic phosphate

As the pH falls, the concentration of bicarbonate diminishes rapidly, a greater proportion of the hydrogen ion will be taken up by other buffers. At pH 6.1, the bicarbonate concentration will be only about 1.4 m eq per liter, at 5.1 about 0.14 m eq per liter.

It is important to note that as hydrogen ion reacts with bicarbonate the resulting undissociated acid (H_2CO_3) disappears from the urine (as CO_2). The hydrogen ion which reacts with other weak acids, however, remains and can be detected in the final urine in the form of titratable acid. The amount of the latter can be determined as the amount of alkali required to titrate the urine back to the pH of plasma, and is equal to the amount of hydrogen ion expended and sodium bicarbonate regenerated in the conversion of the buffer salt (as it existed in plasma) to the buffer acid as it appears in the urine. The titratable acid, therefore, is a very poor measure of the amount of hydrogen ion secreted by the renal tubules since most of the acid produced by this secretion is carbonic acid which is dissipated.

However, from the standpoint of the regulation of the acid base balance of the body, the situation is reversed. That part of the secretion of hydrogen ion which is expended in reabsorbing bicarbonate from the glomerular filtrate serves an important

conservative role in preventing loss of bicarbonate from the body, but its overall effect is only to return to the extracellular fluid that which it previously had lost for a time into the glomerular filtrate. The excretion of titratable acid, however, represents the addition of extra sodium bicarbonate to the extracellular fluid, replacing the neutral salt (Na^+A^-) which it had previously contained. Thus, then, is an addition to the alkali reserve and as such can be used to balance off the acid products of ingestion and metabolism.

The excretion of titratable acid is a process in which there is a net gain of alkali reserve, but it is a process of limited potentiality, limited by the capacity of the kidney to reduce the pH of the urine and by the amount of weak acid of suitable pK excreted in the urine. This process alone would be unable to maintain the alkali reserve against the continued addition to extracellular fluid of even most of those acids which can be excreted to a considerable extent in an ionized form. Thus β -hydroxybutyric acid can be excreted about half as the free acid, half as the salt. The excretion of titratable acid can therefore diminish the attrition of body buffer by about one half, but the continued production of this acid would eventually exhaust the extracellular bicarbonate supply. Of course, the production of titratable acid contributes nothing to balancing off the effects of the ingestion or production of strong mineral acids. The latter effects are overcome by the production and excretion of ammonium ion in place of so-called "fixed cation" (largely sodium and potassium).

EXCRETION OF AMMONIA. The source of urinary ammonia was the subject of debate for many years. That the ammonia is produced in the kidney was established by the studies of Nash and Benedict who showed that more ammonia left the kidney in renal venous blood than entered in the arterial blood. The experiments of Van Slyke and his associates demonstrated that a major fraction of the urinary ammonia was derived from the amide nitrogen of glutamine.

Ammonia is also produced by the oxidative deamination of a number of amino acids (glycine, alanine, leucine, aspartic acid).

Ammonia, produced in the cells of the renal tubules, enters and accumulates in the renal tubules by simple diffusion. The nature of the process by which this accumulation takes place may be understood from a consideration of the

nature of cell membranes and the solubility characteristics of weak electrolytes

Most cell membranes that have been studied have the characteristics of lipid layers permeated by aqueous pores which occupy only a very small part of the total surface area. Substances which are highly soluble in lipid can penetrate the entire surface of the cell, while those which are highly water soluble and lipid insoluble can penetrate only through the aqueous pores. Lipid soluble materials, therefore, diffuse in and out of cells very much more rapidly than water soluble substances. Among the latter are most ions, ionized compounds are, in general, highly water soluble and poorly soluble in lipid. On the other hand many un-ionized substances are highly soluble in lipids (provided they are not highly polar compounds, e.g., sugars, urea, short-chain alcohols etc.) In accord with these generalizations, the ammonium ion (NH_4^+) is highly water soluble and would be expected to penetrate cell membranes poorly, on the other hand, free ammonia (NH_3) is highly lipid soluble and penetrates cells quite readily.

Now suppose we have two aqueous solutions of different pH separated by a membrane having the characteristics of the lipid layer discussed above. To such a system ammonia is added. The ammonia, being highly lipid soluble, will penetrate the membrane readily and will reach equilibrium when the concentration of the free ammonia (NH_3) is the same on both sides of the membrane. However, in each solution ammonia will react with hydrogen ion to yield ammonium ion.

This reaction will be continuously at the equilibrium required by the dissociation equation

$$K_A = \frac{[\text{H}^+][\text{NH}_3]}{[\text{NH}_4^+]}$$

or

$$\text{pH} = \text{p}K_A + \log \frac{[\text{NH}_3]}{[\text{NH}_4^+]}, \quad \text{p}K_A = 8.9$$

Since $[\text{NH}_3]$ is the same on both sides of the membrane, the numerator of last term may be considered a constant and the $\log [\text{NH}_4^+]$ will vary inversely with the pH. Thus a decrease in pH of one unit will yield a tenfold increase in ammonium ion concentration. Since the free ammonia constitutes a very small part of the total ($\text{NH}_3 + \text{NH}_4^+$) the total will vary pretty much the concentration of ammonium ion.

This model may be considered to approximate the situation in the kidney where the solution on one side of the membrane represents the contents of the renal tubule cells in which ammonia is produced and the other side of the membrane, the fluid in the lumen. We may consider the pH of the intracellular fluid and its ammonia concentration to be maintained relatively constant and ammonia to accumulate in the lumen until the free ammonia concentration is approximately the same on both sides and the ammonium ion concentration in the lumen that required by the urinary pH. The concentration of ammonium ion will therefore increase as urine pH decreases.

Because several assumptions involved in this model are only approximations, the actual ammonia excretion varies with pH appreciably less than would be predicted. A urinary pH change of two to two and a half units is required to yield a tenfold change in ammonia excretion. (The idealized model would indicate a tenfold change with each pH unit.) It should be noted that as NH_3 diffuses into the urine, hydrogen ion is titrated and the pH of the urine tends to become elevated, the pH difference would disappear if it were not maintained by the continuous secretion of hydrogen ion.

The formation of ammonia is believed to be a function of the distal portions of the nephron. In any case it is unlikely that the urine pH is low enough, in earlier parts of the tubule for ammonia to play any essential role in the hydrogen ion secretion process. However, as urine pH approaches its minimum in the distal nephron, each hydrogen ion secreted into the lumen must be neutralized by capture of NH_3 to form an ammonium ion before another hydrogen ion can be secreted.

The excretion of ammonia like the excretion of titratable acid represents replenishment of the body's alkali reserve. Quantitatively it represents, under most conditions, the more important contribution to the maintenance of the acid base balance of the body. The sum of titratable acid and urinary ammonium ion represent the net gain of sodium bicarbonate for the body fluids as a result of the process of urine formation. (In estimating body balance, it is necessary to subtract from this total any bicarbonate excreted in the urine.)

A striking and unique feature of ammonia formation and excretion is the phenomenon of adaptation. If an individual is given an acidifying regimen (such as the administration of ammonium or calcium chloride or the feeding of a strongly

acid ash diet), there is a gradual increase, over a period of three to five days, of the excretion of ammonia in the urine. This increase is independent of changes in urinary pH (which occur very much more rapidly) and the amount of ammonia in the urine is eventually greater at each pH than it was before the acidifying stimulus was started. The administration of alkali has an effect exactly the reverse of the administration of acid. Neither the osmure nor the immediate stimulus to this adaptation are too clearly established. It undoubtedly involves a modification in the enzymatic mechanism by which ammonia is produced and presumably a rise in the concentration of ammonia in the cells in which it is produced.

In the rat, but not in the dog, it can be shown that glutaminase activity is increased. The overall behavior of ammonia excretion in man resembles that in the dog more closely than in the rat. For instance, if acidosis is produced by the administration of inhibitors of carbonic anhydrase which cause massive loss of bicarbonate in the urine, ammonia excretion and glutaminase activity increase markedly in the rat, but ammonia excretion remains at a level related only to urine pH in both man and dog. There is no evidence of adaptation of the sort produced by the administration of acidifying salts.

The stimulus to adaptation is also not clear. It is obviously in some way related to the intake of acid, but it does not appear to depend on the degree of acidosis, ammonia excretion remaining high when, as a result of the adaptation, plasma bicarbonate has been restored essentially to normal.

QUANTITATIVE ASPECTS OF URINE ACIDIFICATION As with all processes of urinary excretion, the urinary acidification is dependent upon the balance between glomerular filtration and tubular reabsorption. In this case, the important characteristic of the filtrate is its bicarbonate concentration. We will postpone consideration of those factors which modify the secretion of hydrogen ion by the renal tubules and consider first the effect of changes in plasma bicarbonate concentration.

We must first take note of the fact that for reasons that have not been determined, the capacity of the tubules to reabsorb bicarbonate varies with the rate of glomerular filtration but not with the plasma bicarbonate concentration. The concentration of bicarbonate in the glomerular filtrate is therefore a far more important determinant of bicarbonate excretion than the total amount of bicarbonate filtered. To take this

into account and to present the reabsorption and excretion of bicarbonate as an orderly, predictable phenomenon, it is the practice to divide the amounts filtered, reabsorbed and excreted by the rate of glomerular filtration and to present the data as the amount reabsorbed, etc., per 100 ml or per liter of glomerular filtrate.

When the plasma bicarbonate concentration is low the urine is acid and essentially free of bicarbonate, all of the filtered bicarbonate is reabsorbed. As the plasma bicarbonate concentration is increased, the urine remains essentially free of bicarbonate until the concentration approaches approximately 28 m eq per liter. Bicarbonate then begins to appear in the urine and as the plasma concentration increases further bicarbonate reabsorption remains virtually constant at 28 m eq per liter of glomerular filtrate and the excess is excreted in the urine. This is illustrated in figure 34-12. This tends to produce stabilization of the plasma bicarbonate concentration at its normal level of 27 to 28 m eq per liter. When the plasma bicarbonate falls below this level, the filtered bicarbonate is completely reabsorbed and conserved. If the plasma bicarbonate rises appreciably above 28 m eq per liter, the excess is excreted and the plasma bicarbonate tends to return rapidly to normal.

It should be noted that to the extent that the capacity of the tubule to secrete hydrogen ion is expended in the reabsorption of bicarbonate no appreciable amount is available to appear as titratable acid or ammonia. Thus when the plasma bicarbonate is close to 28 m eq per liter, essentially all of the filtered bicarbonate will be reabsorbed but there will be little titratable acid and ammonia in the urine (reflecting the fact that the urine pH will not be very low). However, when the plasma bicarbonate drops lower the bicarbonate of the glomerular filtrate may be exhausted before the capacity to secrete hydrogen ion is fully utilized and a variable part of the remaining capacity will appear as titratable acid (depending on the rate of excretion of buffer acid) or as ammonium ion (depending upon the rate of production of ammonia).

It is also noteworthy that the amount of titratable acid and ammonia in the urine is a poor indication of the capacity of the tubules to secrete hydrogen ion because, if plasma bicarbonate is low, hydrogen ion secretion stops when the urine pH gets too low and before all the capacity for hydrogen sodium exchange is utilized. Thus the capacity to secrete by hydrogen ion can be evaluated

FIG 34-12 Relationship between plasma bicarbonate and reabsorption and excretion of bicarbonate in man (Pitts Ayer and Schiess J Clin Invest 28 35 1949)

only when there is bicarbonate left over from the process—that is when the urine is alkaline

FACTORS MODIFYING THE RATE OF SECRETION OF HYDROGEN ION Under ordinary conditions of acid base balance, with a normal carbon dioxide tension in the blood, a normal cell potassium concentration, etc the capacity to secrete hydrogen ion in exchange for sodium is about 28 m eq per liter of glomerular filtrate as indicated in the preceding discussion. This tends to maintain the plasma bicarbonate concentration at about 28 m eq per liter. The capacity to secrete hydrogen ion may be varied in response to several factors.

1 Carbon dioxide tension When the carbon dioxide tension is increased (respiratory acidosis) the plasma bicarbonate concentration increases by titration of the blood buffers, and the pH change attributable to the increased carbonic acid concentration is minimized. The elevated plasma bicarbonate concentration persists, and the maintenance implies an increase in bicarbonate reabsorption (hydrogen ion secretion) by the renal tubules. Indeed, such an increase in bicarbonate reabsorption is demonstrable immediately upon elevation of the carbon dioxide tension. If elevation of the carbon dioxide tension is maintained for extended periods there is a further increase in the capacity to secrete hydrogen ion, the nature of this further adaptation is unknown. Decreases in carbon dioxide tension (respiratory alkalosis) have exactly the opposite effects, reducing renal bicarbonate reabsorption¹, hydrogen ion secretion) and causing stabilization

of the plasma bicarbonate concentration at a reduced level.

The effects of changes in carbon dioxide tension on hydrogen ion secretion are readily interpreted in terms of the hypothesis that the rate of secretion of hydrogen ion is directly related to the hydrogen ion concentration of the tubule cells. The concentration of dissolved CO_2 is directly related to the carbon dioxide tension (pCO_2) and the concentration of carbonic acid (H_2CO_3) is directly proportional to the pCO_2 . Since cell membranes have a very high permeability to CO_2 , all changes in extracellular pCO_2 are reflected by similar changes in intracellular pCO_2 . Thus intracellular pH falls when extracellular pCO_2 is elevated and vice versa. (On the other hand, changes in extracellular bicarbonate concentration are probably *not* regularly reflected by parallel changes in intracellular bicarbonate and pH.)

2 Potassium metabolism The secretion of hydrogen ion is depressed when potassium is administered so that the urine frequently becomes alkaline even though the plasma bicarbonate concentration is low. Conversely in the presence of potassium depletion the rate of secretion of hydrogen ion is enhanced so that the plasma bicarbonate concentration becomes stabilized at an elevated level.

The effects of potassium on urine acidification reflect the fact that the mechanism by which hydrogen ion is secreted in exchange for sodium can also exchange potassium for sodium and that, as

a result, there is competition between potassium and hydrogen ion for secretion. It may be that this apparent competition involves changes in cell hydrogen ion concentration rather than mutual exclusion from sites on a carrier. There is reason to believe that when cells lose potassium, they become more acid, and that when they gain potassium, they lose hydrogen ion. This interpretation has the advantage of placing the effects of potassium and of CO_2 tension on a similar basis,—the modification of cell hydrogen ion concentration.

3 *Carbonic Anhydrase* The role of carbonic anhydrase and the effect of inhibition of this enzyme have been discussed earlier. Under normal conditions the activity of carbonic anhydrase is not rate limiting in hydrogen ion secretion although it may become so when inhibited. There is no evidence that adaptation to acid loads involves an increase in kidney carbonic anhydrase.

4 *Adrenal steroids* The secretion of hydrogen ion participates in the enhancement of sodium reabsorption produced by aldosterone and other steroids with similar effects on electrolyte metabolism.

PASSIVE REABSORPTION, THE EXCRETION OF UREA

Because passive reabsorption is the result of the active reabsorption of other constituents of the glomerular filtrate, it is appropriate to consider this relatively simple mechanism last. The reabsorption of urea has long been considered a typical example of this process.¹³ Certainly as the most abundant constituent of the urine and as one which fits in unique fashion into the formation of highly concentrated urine, urea requires separate consideration.

Cell membranes generally have a high permeability to urea. It is therefore not surprising that as the filtrate is reabsorbed from the renal tubules, tending to concentrate the urea in the remaining fluid, urea tends to diffuse out of the lumen. What is more remarkable is the very considerable extent to which the urea concentration can be raised in the urine. This appears to be due to two factors: (1) an unusually low permeability to urea of some or all of the cells lining the renal tubules (it is to be remembered that much of the tubule lining

membrane also has a uniquely low permeability to water, especially in the absence of antidiuretic hormone), and (2) a mechanism for maintaining a high urea concentration in the interstitial fluid (of the medulla) surrounding those portions of the nephron containing fluid with the highest urea concentrations (the collecting ducts), in the latter case the concentration gradient driving the diffusion of urea out of the urine is minimized.

As is characteristic of substances excreted by mechanisms involving passive reabsorption, the fraction of the filtered urea excreted in the urine varies with the urine flow. The fraction of the filtered urea excreted is given by the ratio of the urea clearance (C_U) to the glomerular filtration rate. At urine flows in excess of about 2 ml. per minute in individuals with normal renal function, there is relatively little further increase in the urea clearance with further elevation of urine flow up to the limits of water diuresis. At this time the urea clearance averages about 60 to 70 per cent of the inulin clearance, i.e., about 30 to 40 per cent of the filtered urea is reabsorbed. If *osmotic diuresis* is superimposed the urine flow can be further increased, and under these conditions the excreted fraction of filtered urea increases further along a curve which may be extrapolated to suggest that no urea would be reabsorbed when no water was reabsorbed. Conversely, as urine flow decreases in antidiuresis the excreted urea diminishes to what may be only 15 or 20 per cent of the filtered. These phenomena are illustrated in figure 34-13 from the data of Shannon obtained in the dog.

As was noted earlier, in the discussion of water excretion and reabsorption, the change from the low flow of concentrated urine to the high flow of water diuresis involves primarily modifications in the flow in the distal portions of the nephron. The reabsorption of water which occurs in the proximal tubule is relatively unaffected. Thus, the additional urea which is reabsorbed when water diuresis is interrupted is logically considered to be reabsorbed in the distal tubule and collecting system. Furthermore, since in the absence of an antidiuretic hormone these portions of the nephron have a low permeability to water they may be expected to have a low permeability to urea as well. It is thus logical to attribute the reabsorption of some 30 to 40 per cent of the filtered urea to losses from the proximal tubule as water is reabsorbed from that segment and to consider the losses from the distal portions of the nephron to be negligible in water diuresis. As the fraction of the filtrate reabsorbed in the proximal tubule is

¹³ There is evidence that in ruminants (sheep, camel) there is some sort of active renal conservation of urea when the animal receives a low protein intake. While it has also been suggested that there is a similar mechanism in man, the evidence is not convincing and for the sake of didactic clarity, any such process will be disregarded.

FIG. 34.13 The ratio of urea clearance to creatinine clearance (Fraction of the filtered urea excreted in relation to the reabsorption of water as indicated by the U/P ratio of creatinine) (Shannon *Am J Physiol* 122:782, 1938)

diminished in osmotic diuresis the urea is concentrated to a lesser extent and less than the usual 30 to 40 per cent is reabsorbed.

In antidiuresis the reabsorption of water in the distal tubule is markedly increased at the same time it is highly probable that the permeability to urea is also enhanced. Both of these factors lead to an increase in the diffusion of urea out of the urine in the distal portions of the nephron and account for the rapid falling off of the urea clearance as urine flow decreases to low levels.

Because the arrangement of the blood supply in the medulla constitutes a countercurrent exchanger, urea escaping from the collecting ducts is not easily carried away in the blood as it is in the cortex. Instead, even a relatively slow leak of urea from the collecting ducts is sufficient to yield a high urea concentration in the peritubular region. As a result the urea concentration in the interstitial space of the papilla is almost as high as in the urine. This has two important consequences: (1) the amount of urea lost from the urine is reduced because the concentration gradient is small, and (2) the osmotic effect of the urea in the collecting duct urine is counterbalanced largely by urea in the interstitial space. The sodium chloride of the interstitial space which initiates the urine concentrating process can be utilized to balance the osmotic effect of the non-urea solute, the urea being simply added to both sides of the intervening membrane. Consequently the urine can be made considerably more concen-

trated when urea is a major part of the excreted solute and urea the major product of protein catabolism and in fact by far the most abundant product of metabolism requiring urinary excretion can thus be excreted largely in water already obligated for the excretion of other urinary solutes.

Because the level of the blood urea and the urea clearance are frequently used for the clinical evaluation of renal function a brief discussion of these clinical indices is warranted. Since the concentration of urea in red blood cell water is the same as in the plasma, the concentration of urea in whole blood is only slightly lower than in plasma, the difference being due to the larger fraction of solids in the red cells. Consequently it has been the usual practice to base the clinical estimation of urea clearance on the measurement of urea in whole blood (although glomerular filtration operates only on plasma). Because of the variation of urea clearance with urine flow some account must be taken of this factor. The convention which has been adopted has been to arbitrarily divide urea clearances into two classes. When the urine flow exceeds 2 ml per minute the clearance of urea is calculated in the conventional fashion except for the substitution of B for the concentration in whole blood for P, the concentration in plasma. The figure (UV)/B obtained is called the *maximal urea clearance* and a value of 75 ml per minute is accepted as the average normal. It is customary to divide the clearance

obtained by 75 and express the result as a per cent of normal

When the urine flow is less than 2 ml per minute, some correction is necessary to take into account the marked effect of urine flow change on urea excretion. It has been found empirically that, in normal individuals, if the clearance is divided by the square root of the urine flow ($\sqrt{V}$) the value obtained is relatively independent of urine flow provided the latter is less than 2 ml per minute. This figure is referred to as the *standard urea clearance* and is equal to

$$\frac{UV}{B} \times \frac{1}{\sqrt{V}} = \frac{U\sqrt{V}}{B}$$

It has an average normal value of 54 and again, the result obtained is expressed as a per cent of the normal value

When urea clearances are measured, every attempt should be made to assure a urine flow in excess of 2 ml per minute since the maximal urea clearance is more clearly related to the value which one wishes to estimate, the rate of glomerular filtration

The blood urea concentration is also, in a rough way, related to the rate of glomerular filtration. However, it is subject to modification by factors which do not affect the urea clearance, namely the intake and metabolism of protein and other nitrogen sources. For this reason the urea clearance is a much more reliable index of renal function.

For the individual in nitrogen balance, almost the entire nitrogen intake is excreted in the form of urea. The excretion of urea is in the long term equal to the formation of urea. Therefore, if we were to consider the daily excretion of urea as a sort of 24 hour determination of urea clearance we would have

$$C_u = \frac{UV}{B} = \frac{\text{rate of nitrogen turnover}}{B}$$

and

$$B = \frac{\text{rate of nitrogen turnover}}{C_u}$$

Thus we see that the blood urea is inversely related to the filtration rate to the extent that the urea clearance is related to the filtration rate, but in addition it is also directly proportional to the nitrogen turnover. The latter factor is eliminated when the urea clearance is determined.

NON IONIC DIFFUSION The excretion of weak electrolytes is frequently modified (or totally affected) by diffusion dependent upon the dissociation characteristics of the substance concerned.

The phenomenon is entirely analogous to that involved in the entrance of ammonia into the urine, a process which was discussed in some detail above. It was pointed out that un-ionized weak electrolytes frequently penetrate cell membranes very much more readily than their ions. As a result when cell membranes separate two aqueous phases of differing pH, the weak electrolyte accumulates in that phase in which the pH requires that the ratio of ionized to un-ionized weak electrolyte is higher. The same considerations apply to a number of other weak electrolytes, not only weak bases such as ammonia but weak acids as well. Most of the substances the excretion of which has been shown to involve this type of mechanism are foreign to the body, but it is highly probable that a number of normal constituents are also involved although they have not been studied in detail. Some of these drugs which have been shown to be excreted by mechanisms involving, entirely or in part, processes of non-ionic diffusion are bases (quinine, atabrine, neutral red, mecamylamine) and acids (salicylates, phenobarbital). As opposed to the situation with respect to ammonia, which is produced in the tubule cells, the two phases of differing pH involved in excretion of these foreign materials are the urine and the peritubular interstitial space.

The effect of pH on the excretion of weak acids is exactly the opposite of its effect on that of weak bases. This is due to the fact that the ratio of ion to un-ionized fraction increases with pH in the case of weak acids, as indicated by the equation

$$\text{pH} = \text{pK}_A + \log \frac{[\text{A}^-]}{[\text{HA}]}$$

while in the case of weak bases the ratio of ionized to un-ionized decreases with rising pH as indicated by the dissociation equation for a base

$$\text{pH} = \text{pK}_A + \log \frac{[\text{RNH}_2]}{[\text{RNH}_3^+]}$$

The effect of pH on the excretion of weak bases is appreciable only when the pH of the urine is lower than the pK_A of the base, since it is only when pH is less than pK that the amount of ion is the major fraction of the total. For similar reasons pH change has an appreciable effect on acid excretion only when the urine pH is higher than the pK of the acid.

It should be noted that the effect of changing pH is so great as to be compatible with net reabsorption (excretion of less than the filtered) at one

urine pH and net secretion (excretion of more than the amount filtered) at another urine pH. It should also be noted that a substance may undergo active tubular secretion in the proximal tubule and nonionic diffusion in the distal, as appears to be the case with salicylates, and may be the case with a number of other weak electrolytes.

THE PATHOLOGICAL PHYSIOLOGY OF THE KIDNEY: MICTURITION

The Clinical Evaluation of Renal Function

Examination of the Urine

The first step in the evaluation of the functional status of the kidney and frequently the source of the first clue to the presence of renal disease is usually the clinical pathological examination of the urine. This has the unique advantage of extreme simplicity, requiring only a minimum of time and the simplest of equipment. Furthermore, the presence of renal disease is usually manifested by some abnormality of the urine. However, it is important to note that an apparently normal urine does not exclude the presence of certain diseases of the kidney nor impairment of renal function of even very marked degree.

Although the full routine examination of the urine includes several other tests usually intended to detect nonrenal metabolic abnormalities (diabetes, ketosis, etc.), those particularly related to diseases of the kidney itself are tests for protein and examination of the urinary sediment. In addition, determination of the specific gravity and acidity may, under certain conditions, be revealing of disorders of kidney function. Certain specific defects of renal function may be detected by analysis of urine for amino acids.

Tests Involving Examination of the Blood Only

The most commonly used test intended to evaluate the functional state of the kidney is the determination of the blood urea. (The results of this determination are commonly reported as the blood urea nitrogen, since nitrogen makes up just under half of the molecular weight of urea, the blood urea concentration is approximately twice the concentration of blood urea nitrogen.) The concentration of urea in the blood is directly proportional to the nitrogen turnover and inversely proportional to the renal clearance of urea. Its relationship to the nitrogen turnover and to glomerular filtration are fully discussed on page 565 of the preceding chapter.

Since the blood urea concentration is only partially related to the rate of glomerular filtration and to the functional status of the kidney, it is

hardly surprising that there is a wide range of normal values for the blood urea concentration and it is likely to be unequivocally elevated only when renal function is reduced by about half or more.

Nonprotein nitrogen Under normal conditions urea contributes about half of the nonprotein nitrogen of plasma (or serum). The remainder is made up of the nitrogen of a heterogeneous group of substances: creatine, creatinine, uric acid, amino acids, etc. As renal function is depressed the nonprotein nitrogen concentration of plasma rises, largely because of increasing urea concentration, though some of the other components also accumulate. The nonprotein nitrogen determination is thus subject to very much the same interpretation and qualifications as the blood urea analysis.

Creatinine The plasma creatinine concentration is a somewhat more reliable index of renal function than the blood urea concentration because the rate of formation of creatinine in the body is much more stable than the formation of urea. However, some reservation is required because the usual analysis of plasma for creatinine involves a chemical method affected by other constituents of the plasma.

Tests Involving Collection of Urine

A general comment and caution concerning these tests as a group is warranted. These tests (except for the concentration test) involve determination of the rate of excretion of some substance. They thus require a *timed collection of urine* and can be no more accurate than the timing and completeness of collection. In the case of substances such as urea or creatinine which are normal constituents of the urine, the urine formed before the actual period of the test will contain the test substance and it is, therefore, just as important that the bladder be completely emptied at the start of the test period as that all of the urine be collected at the end. Failure to empty the bladder before the test period will give a result that is misleadingly high just as failure to empty at the conclusion of the test will give an erroneously low value. Failure to give due care and consideration to this point frequently vitiates the usefulness of what is fundamentally a valuable method for assessing kidney function.

Urea clearance The mechanism of urea excretion has been considered in detail in the preceding

chapter, and little need be added here. The test is useful for the information it gives concerning the level of glomerular filtration. In contradistinction to the simple determination of blood urea, the urea clearance is not dependent upon the rate of formation of urea so that this source of variation is eliminated. The urea clearance depends only upon the rate of glomerular filtration and the urine flow. When the test is carefully performed it is a very useful index of glomerular filtration rate.

Creatinine clearance. The clearance of endogenous creatinine is frequently a valuable index of glomerular filtration. As compared with the urea clearance it has the advantage of being unaffected by the rate of urine flow.¹ However, for reasons that have not been fully elucidated, the clearance of endogenous creatinine is sometimes considerably greater than the glomerular filtration rate and sometimes lower. This is particularly true in the presence of renal disease. The creatinine clearance can therefore be considered only a rough approximation of the rate of glomerular filtration.

Excretion of phenolsulfonphthalein (PSP, phenol red). Phenolsulfonphthalein (PSP) is one of that group of organic acids rapidly secreted into the urine by the renal tubules (see preceding chapter). In contrast to some of the other substances in this group, PSP is not completely removed from the blood which perfuses the kidney. Nevertheless, the rate at which it is excreted by the kidney is determined largely by the rate at which PSP is delivered to the kidney by the flow of blood. The excretion of PSP is, therefore, reduced when the renal blood flow is diminished. The greatest virtue of the test in its simplicity, PSP is a dye which, in alkaline solution, has an intense red color, and its concentration in the urine is easily estimated.

A number of different procedures for the performance of the PSP test have been used involving various routes of administration of the dye and varying time periods for the collection of the urine. Procedures involving intravenous administration of the dye and relatively short periods for the collection of the urine are to be preferred as most sensitive to changes in kidney function. Low results can be obtained because of retention of PSP in the bladder as well as because of poor renal function.

Concentration test. The concentration test is a measure of the ability of the kidneys to form hypertonic urine. Because the test as usually performed involves determination of the urine specific gravity it can be considered only a rather crude index of this particular function.² The determina-

tion of specific gravity is, however, such a simple procedure that it is unlikely that it will soon be replaced by an estimation of osmolality by the determination of the freezing point depression.

In the performance of the test, it is usual to determine the specific gravity of the urine formed after all fluids have been withheld for 10 to 24 hours. Normally the specific gravity should be greater than 1.025 although a specific gravity between 1.020 and 1.025 can not be interpreted as a clear indication of abnormality.

Clearances of inulin and p-aminohippurate. Properly performed these measurements yield accurate estimates of glomerular filtration rate and renal blood flow and hence are highly valuable in accurately defining the status of renal function. The theoretical basis of the measurements is discussed in the preceding chapter. Unfortunately the determination of inulin and p-aminohippurate clearances requires the administration of continuous intravenous infusions at constant rate. The desired and attainable accuracy can be achieved only with meticulous care in the collection of the urine, usually with bladder catheterization and washout of the bladder at the termination of each collection period. Finally, the chemical analysis, particularly that for inulin, is relatively involved. For these reasons these tests are rarely used for routine clinical purposes. For most such situations one or more of the approximation procedures discussed above will suffice.

Measurement of Tubular Reabsorption and Secretory Capacity

These indices of renal function determined respectively, as the maximum capacity to reabsorb glucose (T_{mg}) and to secrete p-aminohippurate (T_{PAH}) are, like the measurement of inulin and PAH clearances, more or less definitive measurements of renal function (see preceding chapter). Like the latter determinations the procedures are involved, poorly suited to routine use, and rarely performed for purely clinical purposes.

Disturbances of Renal Function

CLASSIFICATION

Disturbances of renal function may be separated into two groups—those due to disease of the kidney itself and those due to nonrenal disturbances. In the latter group fall abnormalities of renal function due to circulatory disorders and to disturbed hormonal balance with loss or excess of endocrine factors which modify the function

modifying the urine osmotic pressure to which each solute particle, independent of its nature, contributes equally. However, each solute particle does not modify the specific gravity in the same way, one molar solution of different solutes may vary widely in specific gravity.

¹ However, as in any test involving the collection of urine, the errors due to incomplete or inaccurate collection of the urine are minimized if the rate of flow is high.

² In the formation of hypertonic urine the nature of the urinary solute is more or less a matter of indifference, the process being involved with

of the kidney. Among disturbances due to disease of the kidney itself two groups may be recognized: (1) disorders due to specific abnormalities of one or more of the transport mechanisms of the renal tubule, although these are particularly interesting from the point of view of clinicophysiological correlations, they are neither as frequent nor as important as (2) the inflammatory and degenerative diseases which involve the kidney more diffusely, affecting entire nephrons or nephron segments and their functions.

In the group of diseases which produce such diffuse involvement of the kidney, a few warrant brief discussion here to provide a background for some of the correlations between disturbances of physiology and renal disease. By far the most important of these from the standpoint of frequency of occurrence are glomerulonephritis, arteriolar nephrosclerosis, and pyelonephritis.

Glomerulonephritis

Glomerulonephritis is a diffuse inflammatory disease involving primarily the glomeruli and secondarily, with loss of glomerular function, degeneration of the conjoined tubules. A number of classifications of glomerulonephritis, based largely on pathological distinction, have been proposed and a number of variants are recognized by some workers. For present purposes it is sufficient to note that glomerulonephritis can be divided into two forms which may or may not represent different stages of the same disease.

ACUTE GLOMERULONEPHRITIS is characterized by a more or less sudden onset with proteinuria and hematuria and varying degrees of edema, hypertension and renal insufficiency. The onset of the disease can usually be related to an antecedent infection most often with Group A, β hemolytic streptococcus. Glomerulonephritis is generally believed to be a disease involving, in some still obscure fashion, an antigen-antibody reaction which produces damage to the glomerular capillaries. Acute glomerulonephritis has a relatively low mortality. The great majority of cases recover completely, with no residual evidence of renal disease or of significant functional loss. A small proportion do not recover, but show persisting evidence of active renal disease and progressive loss of renal function with an eventually fatal outcome.

CHRONIC GLOMERULONEPHRITIS is a progressive disease characterized by proteinuria, hypertension and diminution of renal function. Whether or not it is the progressive form of the same disease recognized as acute glomerulonephritis is dis-

puted. In most patients with the chronic form no episode of acute glomerulonephritis is recognized. The rate of progress of the disease is extremely variable, some patients have a rapid downhill course with a precipitous decline in renal function. Others may, for years, have proteinuria as the only evidence of smoldering disease.

The Nephrotic Syndrome

The nephrotic syndrome is characterized by massive proteinuria leading to a marked reduction of the plasma protein (particularly albumin) concentration, with edema frequently massive, and generally a marked increase in the concentration of lipids, particularly cholesterol in the plasma. Hematuria and hypertension are usually not prominent. A small proportion of instances of the nephrotic syndrome are clearly due to recognizable causes such as amyloidosis of the kidney, lupus erythematosus, syphilis, etc., but in most cases the underlying cause is not recognizable. No unanimity exists as to whether or not the idiopathic nephrotic syndrome represents a stage of chronic glomerulonephritis. A certain number of patients with the nephrotic syndrome do not recover, but show progressive loss of renal function with the development of hypertension and renal insufficiency in a fashion not distinguishable from chronic glomerulonephritis. On the other hand with antibiotic treatment and prevention of intercurrent infection and with control of the disease with adrenocortical steroids a considerable proportion of patients with the idiopathic nephrotic syndrome recover completely.

Whereas it was formerly believed that in true nephrosis the glomeruli were normal and the disease limited to degenerative changes in the tubule epithelium, this is now recognized as being the exact reverse of the true situation. The primary defect is in the capillary basement membrane, permitting the escape of protein into the glomerular filtrate. The striking changes in the appearance of the tubule cells on microscopic examination are probably secondary to the high concentration of protein in the glomerular filtrate with protein uptake from the tubule lumen.

Arteriolar Nephrosclerosis

Arteriolar nephrosclerosis is the manifestation of renal damage due to hypertension. It is characterized by thickening and hyalinization and sometimes necrosis of the renal arterioles. There is progressive loss of glomeruli and the function of the tubules to which they are attached. Clinically it is characterized by proteinuria and

progressive impairment of renal function which in some instances ("malignant nephrosclerosis") may be remarkably rapid. Some degree of nephrosclerosis occurs in most cases of hypertension of long standing. The progressive form leading to renal insufficiency occurs in some five to ten per cent of patients with so-called "essential" hypertension.

In contrast to the diffuse involvement of the kidney in arteriolarsclerosis (arteriolar nephrosclerosis) arteriosclerotic involvement of the larger vessels may lead to patchy ischemic degeneration of portions of the kidney. This type of involvement is relatively benign and rarely leads to significant functional disturbance.

Pyelonephritis

Pyelonephritis is an inflammatory disease of the kidney resulting from infection of the urinary tract (pelvis) with invasion of the kidney interstitium. Single acute attacks may subside without significant sequelae, but repeated or long-standing infections lead to scarring and contraction of the kidney and what may be extensive loss of renal tissue. The loss of renal function may be accelerated as changes due to hypertension (itself initiated by the chronic pyelonephritis) are superimposed on the results of infection and scarring. Proteinuria is usually not prominent and may be absent.

DISTURBANCES OF FUNCTION IN DIFFUSE RENAL DISEASE

PROTEINURIA (ALBUMINURIA) Perhaps the commonest manifestation of renal disease is the presence of increased amounts of protein in the urine. Normally only traces of protein are present in the urine, less than 100 mg. being excreted in a 24-hour period. In the presence of renal disease the amounts excreted may vary widely and reach figures of many grams. Whereas protein may gain access to the urine with exudation or bleeding into any part of the urinary tract, the glomeruli are the most pertinent source of urinary protein. Among the proteins of the urine albumin predominates, but despite the fact that urinary protein is frequently referred to as albumin, the other plasma proteins are also represented. However, it is true that the relative abundance of albumin is greater in the urine than the plasma.

An increased concentration of protein in the glomerular filtrate, the result of an abnormal increase in the permeability of the glomerular capillaries to plasma protein, is generally accepted as the cause of proteinuria in most instances of renal

disease and is one of the major features of the nephrotic syndrome, of glomerulonephritis and of arteriolar nephrosclerosis.

It is worth noting that decreased reabsorption of normally filtered protein has been seriously considered as a possibly significant factor in producing proteinuria. Such a possibility, although not generally accepted, is compatible quantitatively with what is known about the composition of mammalian glomerular filtrate. The method used for examination of the micropuncture samples of glomerular filtrate would not have detected a protein concentration of 25 mg. per cent or less. Thus 250 mg. might have been present in each liter of glomerular filtrate and escaped detection. With a filtration rate of some 175 liters per day this would involve filtration of close to 45 grams of protein in each 24 hours.

On the other hand, there is good evidence not only that there is an increased filtration of protein in the presence of proteinuria but that there is also an increase in the reabsorption of protein by the tubules under these conditions and that, in all probability, it is this increased protein uptake that is responsible for the histological changes in renal tubule cells in such disorders as the nephrotic syndrome.

Aside from its importance as a clue to the presence of renal disease, proteinuria may, when of sufficient intensity, lead to significant depletion of the plasma proteins. In the nephrotic syndrome as a result of urinary losses, the plasma albumin concentration may be reduced to 20 per cent or less of its normal value. This is a significant factor in the development of nephrotic edema.

The presence of proteinuria is not always a sign of significant organic disease of the kidney. It may be produced in otherwise normal individuals, for example, by fever or by violent exercise. Particularly likely to be misleading is the benign condition known as *orthostatic albuminuria* or *postural proteinuria*. This is characterized by the occurrence, especially in young people, of proteinuria when the individual assumes the upright position. The urine, after a night's rest in bed, is protein free. The production of proteinuria is presumably attributable to some sort of circulatory disturbance associated with the erect posture. It is important chiefly because it is frequently mistakenly interpreted as indicating the presence of latent glomerulonephritis.

CYLINDRURIA Casts are collections of protein which has precipitated in the tubules or ducts of the kidney and has been molded in the form of the structure in which it was precipitated. Cyl-

indruria or the presence of increased number of casts in the urine is commonly associated with proteinuria of glomerular origin. Aside from the diagnostic information derivable from the nature of the casts, the detection of casts is most significant as an indication that the protein in the urine has arisen from the nephrons. The casts may consist of protein only (hyaline casts) or may have incorporated into them red or white blood cells, epithelial cells, etc. The normal urine does not contain more than 2000 casts per 24 hours.

HEMATURIA. Red blood cells may be present in the urine in increased numbers (normal less than 130,000 per 24 hours) because of bleeding anywhere into the urinary tract. Of greatest importance in the present context is that, with inflammatory disease of the glomeruli, red cells as well as protein may penetrate the glomerular capillaries. Marked hematuria is particularly characteristic of acute glomerulonephritis.

IMPAIRMENT OF URINARY CONCENTRATION, POLYURIA, NOCTURIA. Two types of impairment of urine concentrating capacity are recognizable: (1) due to impairment of the process by which water is removed to produce urine hypertonic to plasma and (2) due to the excretion of increased amounts of solute per functioning nephron. Both types of defect contribute to the impairment of urine concentrating power observed in the presence of renal disease. Specific defects in the process which renders the urine hypertonic are present in *potassium depletion* and *hypercalcemia*. Since the processes responsible for rendering the urine more concentrated than plasma are located in the renal medulla, disease which disrupts the structure and/or function of this portion of the kidney, such as pyelonephritis and hydronephrosis, may be expected to have particularly marked effects on the concentrating process.

On the other hand, as renal function becomes progressively impaired by any nephron-destroying disease process, impaired ability to produce concentrated urine must inevitably result. Indeed, it has been shown experimentally that removal of one kidney and part of the other results in impaired ability of the remaining kidney to produce concentrated urine. The situation here is quite analogous to that observed as solute excretion is markedly increased (*osmotic diuresis*) in the individual with normal kidneys (see previous chapter, fig. 34.9b). As renal function becomes progressively diminished, the rate of excretion of solute must, over the long run, remain essentially unchanged reflecting the maintenance of salt balance and the excretion of products of metabolism.

However, as the number of nephrons involved in urine formation becomes smaller, the amount of solute excreted by each of those remaining becomes greater in proportion. Thus the volume of isotonic fluid in each nephron reaching the site of formation of hypertonic urine is increased and even the removal of a normal amount of water changes the concentration only to a limited extent.

As the ability to form concentrated urine is impaired, the volume of urine excreted must increase. The formation of increased volumes of urine is known as *polyuria*, a common manifestation of impaired renal function. The production of excessive amounts of urine may cause the patient to awake at night to void, a symptom designated as *nocturia*. (Of course, the ingestion of large volumes of fluid may lead to polyuria and nocturia in the absence of renal disease.)

OLIGURIA, ANURIA. Oliguria is the excretion of a markedly reduced volume of urine; anuria is the complete suppression of urine formation. Oliguria may, at times, be physiological—that is a normal response to dehydration and the characteristic manifestation of the formation of highly concentrated urine. A particularly low urine flow is found when dehydration is accompanied by a low rate of solute excretion. This combination is likely to be encountered in the individual who is excreting very little salt because of a low salt intake, because of antecedent salt loss (sweating, diarrhea, vomiting, induced diuresis) or because salt excretion is suppressed for other reasons as in the individual who is developing edema (see discussion of edema).

On the other hand, oliguria or its extreme, anuria, may be a manifestation of a severe disorder of renal function. It may occur as a complication of severe acute nephritis or as a terminal event in chronic glomerulonephritis or other chronic renal disease. Most often, however, anuria or severe oliguria is a manifestation of some acute renal insult—a circumstance commonly known as *acute renal insufficiency* or *acute renal failure*. Such severe acute damage may be produced by a variety of injuries and nephrotoxic substances, particularly with traumatic shock (in which circumstance it has been called the *crush syndrome*), hemorrhagic shock, incompatible blood transfusion, and mercury or carbon tetrachloride poisoning. This list is far from inclusive, and acute renal insufficiency may be caused by any condition which produces prolonged hypotension and/or intense renal vasoconstriction. Renal ischemia seems a major factor in the production

of acute renal insufficiency in those situations in which chemical nephrotoxins can not be implicated

The methods by which glomerular filtration is measured are not applicable in the presence of anuria, so that it is not possible to say with certainty whether, in acute renal failure, glomerular filtration ceases, or whether it continues but that complete reabsorption of the filtered fluid occurs through disrupted tubule walls. Both theories have their supporters. In either case, it is clear, *effective* glomerular filtration is zero.

It has also been proposed that in the anuria following trauma the renal blood flow is not reduced, but actually increased, the blood being shunted away from the cortex and through the juxtamedullary and medullary regions by dilation in the latter areas. This concept has been largely discredited. In the presence of anuria there is a marked reduction in the renal blood flow. The preferential injection of the juxtamedullary circulation which can be demonstrated under these conditions (Trueta) is due to the lesser involvement of this part of the renal circulation in the generally intense renal vasoconstriction.

EDEMA. The accumulation of sufficient excess of extracellular fluid to produce detectable swelling of distensible tissues (edema) is a common feature of many renal diseases. Since edema fluid is extracellular fluid, it has the composition of plasma except for its lower protein concentration. Like plasma, then, its major constituents are sodium chloride and water. Except for localized and limited amounts of edema which can be produced by redistribution of the normal volume of extracellular fluid, the production of edema requires that an excess of both salt and water be retained within the body and, conversely, edema may be produced by any circumstance which yields a sufficient increase of the salt and water content of the body. Actually in the production of edema, it is the salt retention which is primary, water being retained to maintain the normal osmotic pressure of body fluids, and, further, in the salt, it is specifically the sodium ion which plays the predominant role, in the edematous individual, edema is increased by sodium bicarbonate (or, of course, sodium chloride) but not by ammonium or potassium chloride.

In patients with renal disease, edema may be traced to three types of disturbance: (1) to impairment of sodium excretion due to the direct effect of disease on renal processes involved in salt excretion, (2) to hypoproteinemia, and (3) to cardiac insufficiency, a common complication of

renal disease particularly in the presence of longstanding hypertension.

The edema of acute glomerulonephritis is primarily of the first type, due to the effect of disease on the renal processes involved in salt excretion, salt intake exceeds the capacity of the kidney to excrete it, and edema results. The predominant mechanism is probably a sudden and sharp reduction in the rate of glomerular filtration without an equivalent impairment of the capacity of the tubules to reabsorb sodium salts, a condition frequently called "glomerulotubular imbalance." Through much of the course of chronic glomerulonephritis, a new balance is struck so that, despite reduction of the rate of glomerular filtration, sodium reabsorption by the tubules is reduced to an equivalent extent, and adequate excretion of salt is maintained. In the course of chronic glomerulonephritis, edema may appear as a result of any of the mechanisms noted above, because of the development of hypoproteinemia or, particularly late in the course of the disease, because glomerular filtration is reduced to such low levels that it is no longer possible to maintain more than a very low rate of salt excretion and finally because cardiac insufficiency may be superimposed.

In acute renal insufficiency the capacity to excrete salt may be entirely lost. Thus any salt and fluid intake is retained in the form of edema except to the extent to which they may be lost by extrarenal routes. This situation represents the extreme of edema formation due to impairment of the renal processes for salt excretion.

The classic example of edema resulting primarily from hypoproteinemia is that which characterizes the nephrotic syndrome. In this disorder the continuous loss of large amounts of protein, particularly albumin, in the urine taxes the capacity of the body mechanisms to synthesize albumin and the plasma protein concentration falls. As the plasma protein concentration is reduced, the colloid osmotic pressure is lowered, particularly since most of the colloid osmotic pressure of plasma is normally attributable to its albumin concentration. The lowering of the plasma colloid osmotic pressure favors redistribution of fluid volume from plasma to interstitial space in accord with the Starling hypothesis (see ch. 3). It is important to note that although this series of events favors expansion of the interstitial fluid volume at the expense of the intravascular volume, no significant quantity of edema can be attributed to this series of events *alone*, the intravascular volume is not large enough to yield a significant vol-

ume of edema without disastrously compromising the circulation. The production of hypoproteinemic edema, then, requires, as does all edema formation, retention of excess salt and water. The reduced intravascular volume favored by the reduction of colloid osmotic pressure is, in all probability, the stimulus for renal salt retention mediated largely by the secretion of salt retention steroid (aldosterone) by the adrenal cortex. A low rate of glomerular filtration may be a contributory factor.

That hypoproteinemia alone is not a sufficient cause of edema in the nephrotic syndrome is indicated by the results of steroid treatment in this disorder. When fully successful, treatment with large doses of adrenocortical steroids produces disappearance of proteinuria, restoration of the plasma protein concentration, and diuresis with disappearance of the edema. However, in a number of instances in which the steroid is without apparent effect on proteinuria or plasma protein concentration, withdrawal of steroid therapy is accompanied by diuresis and loss of the edema, although the plasma protein concentration remains at its previous low level. Spontaneous diuresis without increase of the plasma protein concentration may also occur.

The edema of cardiac failure, whether a complication of renal disease (hypertension) or not depends on renal retention of excess salt. Thus, edema of any origin is a manifestation of disordered kidney function, in the case of heart failure secondary to an abnormality of cardiac function. Although the sequence of events leading to edema in heart failure is disputed, the salt retention which occurs is the result of increased secretion of salt-active adrenocortical steroids, of some reduction of renal blood flow and glomerular filtration in many instances, and almost certainly, of an additional poorly understood factor or factors as indicated by the following observations. The administration of salt-active steroids to normal experimental animals leads to only very little retention of sodium (much of which replaces potassium which is lost) and no edema. If, however, because of borderline cardiac insufficiency or elevation of venous pressure in a major segment of the circulation the experimental animal is prone to the development of edema, sodium will be retained and edema will form—without reduction of the rate of glomerular filtration. The difference between edema formation and no edema formation in these two experimental situations is neither in glomerular filtration nor the amount

of adrenocortical steroid administered indicating involvement of additional unidentified factors.

Acidosis. Inability to maintain a normal level of plasma bicarbonate (alkali reserve) in the face of an acidifying intake is a common feature of advanced renal disease of any type. The most important factor responsible for the acidosis is deficient ability to form and excrete ammonia and thus maintain the plasma bicarbonate concentration in the face of the acid load provided by the acidifying components of the normal diet. Usually there is no defect in the ability of the kidney to render the urine acid and highly acid urines are frequently observed in even the most advanced renal failure. Since there is no major change in the excretion of weak acids, the output of titratable acid is not depressed. However, the reduced number of nephrons is not adequate to form and put out ammonia at a normal rate in the face of even the usual much less any increased demands. Thus the strong acids derived from dietary sources are excreted as the sodium or potassium, rather than the ammonium salt and the blood bicarbonate (alkali reserve) is depleted. In some cases an additional factor may contribute to the acidosis in the form of a deficient ability to reabsorb bicarbonate completely when the plasma bicarbonate concentration is at normal or only slightly lowered levels.

If bicarbonate is added to render the intake effectively neutral, the acidosis of renal failure may be absent. In fact, if bicarbonate intake is much more than that necessary for a neutral intake, alkalosis may be relatively easily produced since the capacity to excrete bicarbonate at a rapid rate is limited as a consequence of the reduction of the rate of glomerular filtration.

As opposed to the tendency to the development of acidosis which is almost universal in advanced renal disease of any type, *acidosis of renal origin* may occur as the result of a more or less specific defect of renal function with renal function remaining relatively intact in other respects. This relatively uncommon condition is known as *renal tubular acidosis*. In contrast to the acidosis of renal insufficiency it appears to be due specifically to an inability to render the urine normally acid and not to a deficient capacity to form ammonia. The maximum capacity to secrete hydrogen ion in exchange for sodium can be shown to be normal, since there is a normal maximum rate of bicarbonate reabsorption when bicarbonate is administered. Under these conditions the urine is alkaline and the secretion of hydrogen ion which effects bicarbonate reabsorption occurs against

ly a very limited concentration gradient (see 34, p 559) However, as the bicarbonate concentration is reduced to normal or below, the tubules are unable to effect the complete removal of bicarbonate, thus requiring that the urine be rendered highly acid. Hence bicarbonate escapes the urine. The defect appears to be in the ability to secrete hydrogen ion against any considerable concentration gradient. Since the urine does not become acid, the excretion of ammonia remains low despite what is probably a normal ability to produce ammonia in the renal tubules (p 559).

RENAL INSUFFICIENCY, UREMIA Renal insufficiency is the general term for reduction of the function of the kidney. It is manifested by many

of these physiological disturbances already described—impaired concentrating capacity, polyuria, nocturia, acidosis and a general loss of ability in the maintenance of normal body composition in the face of the stress of departure from the intake from ideal. *Uremia* is the complex of symptoms and signs which accompany advanced renal insufficiency. It is characterized by anemia, urea, vomiting, weakness, twitching, frequently convulsions and terminally stupor and coma. Although it derives its name from the elevated blood urea concentration which is a universal finding in the presence of the syndrome, the urea retention is not primarily responsible for the symptoms.

That urea itself is not responsible for the abnormalities associated with uremia is shown by several observations. Urea may be administered to normal individuals without producing significant disturbances. In the uremic individual, the blood urea can be considerably reduced by restriction of the protein intake without otherwise affecting the course of the disorder. The improvement which can be produced in the uremic patient by dialysis with the "artificial kidney" is not

when urea is included in the dialysis bath so that the blood urea is not removed by the dialysis. Disturbances of acid base balance and fluid and electrolyte metabolism are also commonly present in uremia, and may, at times, contribute or be responsible for certain of the symptoms. Nevertheless, these electrolyte imbalances cannot be considered to be the major contributor to the picture of uremia, and the factor or factors primarily responsible for the symptoms and signs remains unidentified. It is generally believed that toxic products of metabolism may, in the presence of depressed renal function, accumulate in the body fluids till toxic concentrations are reached.

These substances, if they exist, have never been adequately identified.

Intrinsic Defects of Renal Tubular Function

As opposed to the disturbances of renal function attributable to diffuse inflammatory or degenerative kidney disease, there are a number of abnormalities due to deficiency of certain transport mechanisms or groups of transport mechanisms. Many of these defects are familial or congenital though some may be acquired. They are for the most part uncommon, but warrant brief mention because of their unusual physiological interest.

One such defect, *renal tubular acidosis*, has been mentioned above and the impairment of sodium-hydrogen ion exchange described. The disorder is, at least in some instances, familial. It is frequently associated with nephrocalcinosis and pyelonephritis, but these are quite probably secondary rather than the cause of the renal abnormality.

NEPHROGENIC DIABETES INSIPIDUS is a rare congenital familial disorder most often encountered in males and characterized by the continuous obligatory excretion of dilute urine and consequently intense polyuria and secondarily polydipsia. The abnormality is apparently due to inability of the distal portions of the renal tubules to respond to pituitary antidiuretic hormone by a decrease in the permeability to water. Thus the urine, diluted by salt removal in the distal portions of the nephron, fails to give up the excess of water in the tubules and the water is lost in the urine. True or pituitary diabetes insipidus is characterized by the same symptoms and signs but is due to a lack of antidiuretic hormone secretion. The tubules are normally responsive to antidiuretic hormone in this disorder which is much more frequent than the nephrogenic type. Pituitary diabetes insipidus is usually an acquired abnormality secondary to injury to the pituitary and/or hypothalamus.

RENAL GLYCOSURIA is characterized by the excretion of glucose in the urine when the concentration in the plasma is normal or low. The abnormality is a defect in the mechanism by which glucose is reabsorbed in the proximal tubule; other proximal tubule functions may be normal. The specific nature of the derangement is not known. There is some depression of the maximum capacity to reabsorb glucose (Tm_G), but there is also considerable excretion of glucose when the concentration is below that required to saturate the reabsorptive mechanism. The possible interpretations of this "splay in the titration curve" are discussed on pages 540 to 543 of the preceding chapter.

RENAL HYPOPHOSPHATEMIA (or Vitamin D resistant rickets) is a familial disorder characterized by excretion of phosphate in the urine when the plasma concentration is low. It is attributable to a defect of the phosphate reabsorptive mechanism analogous to that for glucose in renal glycosuria.

AMINO ACIDURIA. Defects of amino acid reabsorption occur as specific defects of certain transport mechanisms and as part of more generalized disorders of renal tubular function. An example of the specific type is that known as *essential cystinuria* in which the abnormality is limited to diminished reabsorption of cystine, lysine, arginine and ornithine. The chief hazard derives from the formation of stones from the poorly soluble cystine. Abnormalities involving certain other specific amino acids or groups of amino acids are also known. In addition defects of amino acid reabsorption may occur in several other disorders including, among others, Wilson's disease (fundamentally a disturbance of copper metabolism), heavy metal poisoning, and the Fanconi syndrome in which amino aciduria is associated with defective reabsorption of glucose and phosphate and sometimes with renal tubular acidosis.

DISTURBANCES OF RENAL FUNCTION OF EXTRARENAL ORIGIN

The function of the kidney is dependent, for the maintenance of glomerular filtration, on the adequacy of the circulation. The effect of shock, leading as it may to sustained damage to the kidney, has already been discussed. In addition several of the renal transport systems for electrolytes and water are regulated by the activity of endocrine organs. The function of these systems is therefore subject to disturbance through abnormal activity of the endocrine organs in the form of either deficient or excessive secretion of hormones acting on the kidney. Two such abnormalities have already been described in relation to intrinsic renal disorders which they resemble or to which they are related.

1 **Primary diabetes insipidus** in which, because of deficiency of antidiuretic hormone secretion, renal water reabsorption is diminished and a dilute urine is continuously formed. The converse of this disorder may occur and a concentrated urine be formed when a reduced osmotic pressure of body fluids would ordinarily lead to the formation of dilute urine, most often this is due to the induction of antidiuretic hormone secretion by non-osmotic stimuli.

2 The excessive reabsorption of salt which characterizes *edema formation* and the contribution of hypersecretion of aldosterone have been discussed in relation to edema. Excessive secre-

tion of aldosterone leads to accumulation of edema only in the presence of factors predisposing to edema formation. In the absence of such factors, the increased sodium reabsorption is limited, and the major manifestation of hypersecretion of aldosterone is *potassium loss* resulting from stimulation of secretion of potassium ion in exchange for reabsorbed sodium. If potassium loss due to intrinsic renal disease with defective potassium reabsorption exists, it has not been demonstrated, and excessive renal potassium excretion appears to be due to excessive secretion of potassium by the renal tubules generally stimulated by excess adrenocortical hormone.

In the absence of adrenocortical hormones (*adrenal insufficiency*, Addison's disease) reabsorption of sodium and secretion of potassium by the renal tubules are defective. Sodium loss in the urine proceeds despite contraction of the extracellular fluid volume, which may become markedly reduced. The potassium concentration of body fluids becomes elevated. Abnormal loss of sodium in the urine despite sodium depletion may occasionally result from renal disease, and may be produced by inhibitors of sodium reabsorption (*diuretics*).

The reabsorption of phosphate by the renal tubules is regulated by parathyroid hormone. Excessive secretion of parathyroid hormone (*hyperparathyroidism*) is associated with loss of phosphate in the urine, loss of parathyroid function (*hypoparathyroidism*) leads to elevation of the plasma phosphate concentration without an equivalent increase in urinary excretion.

Micturition

Outline of the Anatomy of the Urinary Tract

The muscular coat of the *ureter* is arranged in three layers, an *external longitudinal*, a *middle circular* and an *internal longitudinal*.

The muscle of the *urinary bladder* is also disposed in three layers, an *external*, a *middle* and an *internal*. The fibers of the external layer run longitudinally, that is, in the long axis of the bladder. The fibers of the middle layer are thinly scattered, they have a circular arrangement and run both transversely and obliquely to the long axis of the viscus. The fibers of the internal layer follow a reticular pattern but for the most part run longitudinally.

The *vesical mucous membrane* is separated from the internal muscular layer by a submucous coat of loose areolar tissue. The mucosa is thin and, when the bladder is empty or contains only a small quantity of urine, has a corrugated appearance due to the presence of numerous folds or *rugae* which dis-

appear when the bladder becomes distended. The epithelium is of the transitional type. When the bladder is empty the mucosa shows several cell layers, but when distended only two strata of cells are to be seen, a deep stratum of cuboidal cells and a superficial one of large squamous cells.

The human bladder has a capacity of from 350 to 450 cc.

The peritoneum covers the superior surface of the bladder only.

The ureters pierce the wall of the fundus (or base) of the bladder very obliquely. From a half to three quarters of an inch of their lower ends is embedded in the vesical muscle. During contraction of the bladder wall these portions of the ureters are compressed by the muscle fibers, thus preventing the reflux of urine as the intravesical pressure rises. The urethral orifice which is situated at the most dependent part of the bladder is guarded by the vesical sphincter (*internal sphincter*), formed by the condensation of the muscle fibers of the circular layer. The triangular area marked out by the urethral orifice and the two ureteral orifices is called the *trigone* (*trigonum vesicae*). The muscle of the bladder wall is referred to as the *detrusor urinae*. The male urethra is embraced in its membranous portion by the *sphincter urethrae membranaceus*, a striated muscle which is frequently referred to as the *external sphincter*. The *bulbosacernous* muscle, which is applied to the urethral bulb and surrounds the corpora cavernosa penis, also exerts a constrictor action upon the urethra. The urethral wall itself contains two layers of smooth muscle, an outer circular and an inner longitudinal, in women (who do not possess an external sphincter of striated muscle) this serves to prevent the escape of urine after paralysis of the internal sphincter. The epithelial lining of the urethra is of the columnar type except near the bladder where it is of the transitional variety, and a short distance from the external urethral orifice where it is stratified and squamous.

FILLING OF THE BLADDER

The ureters exhibit rhythmical peristaltic contractions which travel at a speed of from 20 to 25 mm. per second (rabbit) and at a frequency from 1 to 5 per minute, according to the volume of urine formed by the kidney. The peristaltic waves serve to propel the urine from the pelvis of the kidney to the bladder. The urine therefore enters the bladder not in a continuous stream but in separate squirts synchronous with the arrival of the peristaltic waves.

The detrusor muscle exhibits two types of activity, a sustained contraction or tonus, and in intermittent contractions.

The bladder, in common with other hollow

viscera, is capable of adjusting its tone and so of adapting its capacity to changes in the volume of its contents with relatively little alteration in internal pressure. It thus differs in its behavior from an elastic hollow sphere composed of a non living material. For example, when a moderate quantity of fluids is run into the bladder through a catheter the intravesical pressure shows a transient rise, due to the tonic resistance offered by the bladder wall but then declines again to near its previous level as adaptation occurs. As successive volumes of fluid are introduced the curve of intravesical pressure therefore shows a gradual step-like ascent until the bladder contents are unusually large. From then on further additions of fluid cause a much more abrupt rise in pressure. The adaptation is not to a constant pressure (15 cm. of water), as was previously taught, but is always to a pressure a little higher than that existing before the fluid was introduced. In the experiments of Denny Brown and Robertson upon normal human subjects fluid was run into the bladder 50 cc. at a time. An increase in volume of the contents of the bladder from 50 cc. to 400 cc. caused little change in pressure (fig. 351). When completely paralyzed (as during the first two or three weeks following a transverse lesion of the cord) the bladder does not behave in this way, but simply as an inert elastic bag showing no tendency to respond to an increase in tension upon its walls or to adapt itself to its contents (Holmes), when successive quantities of fluid are introduced the curve of intravesical pressure rises along a smooth line.

Tension is the adequate stimulus for the sensory end organs in the bladder wall. When there-

FIG. 351. Curve of pressure changes in the human bladder during filling (upper curve) and emptying (lower curve) (After Denny Brown and Robertson).

fore the bladder becomes distended by the accumulation of urine and the intravesical pressure reaches a certain value, rhythmical contractions of the detrusor muscle are set up. As the pressure rises further these culminate in the movements constituting the micturition reflex, namely, a strong contraction of the detrusor muscle accompanied by relaxation of the internal sphincter, and followed by opening of the external sphincter. It is usually stated that the reflex occurs at an intravesical pressure of from 15 to 18 cm. of water, but it may be activated by a pressure considerably lower than this. The urine is expelled with considerable force, the pressure within the bladder rising during the contraction of the detrusor to around 130 cm. of water. Since adaptation requires a certain time to take place, the reflex is activated at a lower urine volume than usual if the accumulation of urine is rapid. At the average rate at which urine forms, micturition occurs, unless restrained, after from 250 to 300 cc. have collected.

THE VOLUNTARY CONTROL OF MICTURITION

The act of micturition, although essentially reflex in nature, is usually initiated by an effort of the will, it also can be voluntarily inhibited or be interrupted at any stage. The desire to urinate is accompanied by a vague feeling in the penis or perineum. The sensation appears when the urine volume is from 200 to 300 cc. If the act is long postponed a feeling of fullness and discomfort culminating in pain results. It is only in the infant or when, as a result of disease, the bladder is isolated from the control of the higher nervous centers, that micturition is a purely reflex act. Under ordinary circumstances in the adult when the desire to micturate arises, the act is restrained until an opportunity for emptying the bladder presents itself. The restraint is then lifted and the reflex occurs automatically.

The voluntary restraint exerted upon micturition consists, according to Denny Brown and Robertson, of inhibition of the detrusor with contraction of the external sphincter and perineal muscles. No evidence was obtained by these observers that the internal sphincter was under direct voluntary control, although a reciprocal increase in tone of the sphincter muscle accompanies inhibition of the detrusor. It was found that at a certain urine volume, contractions of the bladder and a consequent rise in intravesical pressure could be readily induced by an effort of the will, contraction of the abdominal muscles

was not necessarily associated with the performance of the act. The removal of restraint and the voluntary facilitation of the spontaneous bladder contractions are considered to be the important factors. At low urine volumes restraint is apparently exercised subconsciously. These observers therefore regard the act of micturition as being normally controlled through variations in voluntary and subconscious restraint of the reflex mechanism. Micturition therefore presents a very unusual feature in that movements innervated by autonomic nerves can be controlled by voluntary impulses. The higher centers from which the inhibitory impulses emanate are situated in the hypothalamus and cerebral cortex probably in area 4.

Although the abdominal muscles play a non-essential part in micturition, the act, under ordinary circumstances, is started by the contraction of these muscles, and it is well known that the bladder can be emptied although it contains only a few cubic centimeters of urine. The flow of urine is also accelerated during micturition by the rise in intra-abdominal pressure induced by the voluntary contraction of the abdominal muscles. Relaxation of the muscles of the perineum occurs as an associated movement at the commencement of micturition. After the bladder has been emptied the bulbocavernosus muscle (ejaculator urinae) contracts and expels urine which had been left in the urethra.

Contractions set up in a distended bladder by sudden increases of intra-abdominal pressure acting upon the viscus, as in coughing, sneezing, defecation, etc., may, by forcing a little urine past the sphincter into the urethra, cause micturition unless a strong effort of the will is exercised. Psychic influences may also induce bladder contractions which evoke the act unless opposed by restraint. The lifting of voluntary inhibition, unless the bladder is fully distended, may on the other hand be prevented and the power to micturate be temporarily lost, as when a shy or nervous examinee is asked for a specimen of urine in the presence of another person.

THE REFLEX MECHANISMS OF MICTURITION

Barrington describes six integrated reflexes as constituting the act of micturition in the cat, namely:

(1) *Contraction of the detrusor* evoked by distending the bladder: the afferent and efferent limbs of this reflex are in the pelvic nerves; its center is in the hind brain. Contraction of the detrusor is ac-

accompanied by reciprocal relaxation of the internal sphincter

(2) *Contraction of the detrusor caused by running fluid through the urethra* The afferent pathway for this response is in the pudendal (pudic) nerves, its efferent limb in the pelvic nerves and its center in the hind brain Through this reflex the contraction of the detrusor caused by the first reflex is sustained until the bladder is completely emptied

(3) *Contraction of the detrusor (transient and weak) when the proximal portion of the urethra is distended* The hypogastric nerves contain both afferent and efferent paths for this reflex, its center is in the sacral part of the cord

(4) *Relaxation of the external sphincter when fluid passes along the urethra* Afferent and efferent fibers are in the pudendal (pudic) nerves, the center is in the sacral part of the cord

(5) *Relaxation of the external sphincter when the bladder is distended* The afferent path is in the pelvic, the efferent in the pudendal nerves its center in the sacral part of the cord

(6) *Relaxation of the plain muscle in the proximal third of the urethra caused by distending the bladder* Both afferent and efferent paths of the reflex are in the pelvic nerves its center is in the sacral part of the cord

In the normal act of micturition the first of these reflexes, namely, contraction of the detrusor in response to distention of the bladder, brings the others, with the exception of the third automatically into action It is questionable whether the third reflex is called into play under ordinary circumstances

THE INNERVATION OF THE URINARY TRACT

The *ureters* in their upper part receive sympathetic fibers from the renal plexus, in their middle part from the spermatic (or ovarian) plexus and near the bladder from the hypogastric nerves The sympathetic fibers to the ureters exert a predominantly motor effect, although it appears that inhibitory fibers are also derived from the sympathetic It is thought by some that the ureter receives fibers from the parasympathetic as well, since certain parasympathomimetic drugs cause motor effects The existence of a parasympathetic innervation has not been demonstrated anatomically

The *efferent nerves to the bladder* are the sympathetic and parasympathetic The *sympathetic* furnishes inhibitory fibers to the detrusor muscle, and motor fibers to the trigone, internal sphincter, and the smooth muscle of the proximal part of the urethra³ These fibers arise from the lumbar

spinal segments and pass through the inferior mesenteric plexus, the superior hypogastric plexus (presacral nerve) and the inferior hypogastric plexus to reach the hypogastric ganglion (fig 35 2) Postganglionic fibers, which probably have their origins in the latter ganglion, enter into the formation of the vesical plexus, thus lies in relation to the fundus of the bladder (the hypogastrics in some species apparently contain motor as well as inhibitory fibers)

When the hypogastric nerves are stimulated electrically, a brief contraction of the detrusor muscle precedes the inhibitory effect (fig 35 3)

The *parasympathetic* supplies motor fibers to the detrusor muscle (which govern the tonus and contractile mechanisms) and inhibitory fibers to the internal sphincter The sympathetic and parasympathetic nerves are therefore reciprocal in their actions The parasympathetic fibers arise

FIG 35 2 To show innervation of the bladder (After Learmonth)

FIG 35 3 Kymographic records showing initial contraction followed by inhibition of the detrusor muscle in response to faradic stimulation of the hypogastric nerves in a dog in which the sacral preganglionic parasympathetic outflow had been interrupted (After Kuntz and Saccomanno)

³ The sympathetic also causes contraction of the ureteral orifices and of the muscle of the seminal vesicles, ejaculatory ducts and prostate

from the second and third sacral spinal segments and to some extent from the first and fourth. They are conveyed in the pelvic nerves (*nerve ingentes*) to connect with ganglion cells lying in close relation to the bladder wall (see also ch 71). According to Henderson and Roepke, the tonus mechanism is cholinergic (ch 71) but not the phasic contractions.

Both sets of autonomic nerves apparently exert a constant influence upon the tone of the detrusor and internal sphincter, the effect of one set being balanced against the other. Section of the sympathetic or parasympathetic causes, respectively, an increase or decrease in tone of the sphincter. In paresis of the bladder due to injury of the parasympathetic innervation, excision of the presacral nerve is sometimes performed with the object of removing the inhibitory influence of the sympathetic and thus enhancing the action of the pelvic nerves. Voluntary control of the detrusor is exerted apparently through the pelvic nerves.

The striated muscle constituting the external sphincter is innervated through the pudendal (pudic) nerves.

The afferent paths from the bladder travel in both pelvic and hypogastric nerves, those from the urethra in the pudendal nerves. The afferent fibers essential for the reflex movements of the bladder are contained in the pelvic nerves, those for the movements of the urethra in the pudendals. The hypogastric nerves contain no afferents for any of the important reflex mechanisms. The sensations set up by distension of the bladder are conveyed in both the pelvic and hypogastric nerves. The sensation of pain travels chiefly in the hypogastrics, but also in the pelvic nerves. Excision of the presacral nerve is practised for the relief of vesical pain. Tactile and thermal sensations and the sensation of pressure or filling of the bladder are conveyed mainly in the pelvic nerves (Learmonth).

THE NERVE CENTERS GOVERNING MICTURITION

Centers for micturition are situated in the mid brain, hind brain and spinal cord. The observations cited in the section on the voluntary control of the detrusor muscle also indicate the existence of a center at the cortical level, and electrical excitation of the premotor area causes a rise in vesicle pressure followed by micturition. Increase in the tone of the bladder wall follows electrical stimulation of the anterior hypothalamic nuclei, stimulation of the posterior nuclei causes inhibition (Beatty and Kerr).

Barrington, experimenting with cats, found that destruction of a small area of the hind brain (lying ventral to the internal edge of the superior cerebellar peduncle and extending forward from the level of the motor nucleus of the fifth nerve to the anterior end of the hind brain) temporarily abolished the animal's ability to empty its bladder voluntarily. Destruction of an area in the mid brain extending from the ventral part of the posterior end of the cerebral aqueduct to just beyond the mesencephalic root of the fifth nerve, was followed by permanent loss of voluntary micturition.

The reflex performance of the act was not however, impaired. A more extensive lesion in the region of the mesencephalic root caused, in addition, frequency of micturition. Levin and Longworth observed that, in cats injury to the tegmentum of the mid brain was followed immediately by hyperactivity of the detrusor muscle to stretch. The capacity of the bladder becomes reduced as a consequence, and rhythmic waves of contraction appear. After a time, this increased activity diminishes and the bladder enlarges again.

The spinal centers lie in the second, third and fourth sacral segments. Only the third, fourth, fifth and sixth reflexes described in the section on reflex mechanisms are carried out through the spinal centers.

The descending and ascending paths conveying impulses to and from the spinal centers of micturition are situated in the dorsal half of the lateral column of the cord near its periphery, i.e., in close proximity to the pyramidal tract. The fibers of these paths show extensive crossing in the sacral segments (Barrington).

THE EFFECTS OF NERVE SECTION AND OF CORD INJURIES ON MICTURITION

Section of the hypogastric (presacral) nerves does not interfere with micturition, these nerves contain neither efferent nor afferent fibers essential for the performance of the act. Incontinence which might be expected to result (since motor fibers are conveyed by this nerve to the internal sphincter) does not occur. Indeed incontinence does not follow a prostatectomy operation involving destruction of the internal sphincter, for the external sphincter is capable alone of preventing the escape of urine. Frequency of micturition was found by Barrington to follow section of the hypogastrics in the cat, it also occurs as a temporary effect of resection of the presacral nerve in the human subject. The phenomenon is due apparently, to the loss of the inhibitory sympathetic upon the tone of the detrusor.

impairment of the ability of the bladder to adapt its capacity to as large a volume of urine as usual.

Section of the pudendal nerves in the human subject is also according to Learmonth, without any notable effect upon micturition, though of course paralysis of the external sphincter results.

Section of the pelvis causes paralysis of the bladder wall. The detrusor is atonic, the tone of the internal sphincter is raised. Retention of urine with overdistension of the bladder and overflow—dribbling—occurs. Barrington found that the tone of the sphincter diminished after a few days and the animal, apparently experiencing the sensation of fullness of the bladder, assumed the usual position for micturition and performed the act by a contraction of its abdominal muscles.

Severance of the posterior sacral nerve roots is followed immediately by the loss of all the important reflexes of micturition since the afferent paths (through the pelvis and pudendals) are interrupted, the bladder wall is flaccid and the resistance at the internal sphincter is increased. However, after a period of overdistension with overflow incontinence, the bladder may empty automatically at intervals. The sensations, except pain of overdistension (afferent fibers of hypogastrics intact) are retained.

Destruction of the sacral nerves (as in lesions of the cauda equina) or of the spinal centers will interrupt not only motor impulses to the bladder, but also the afferent impulses travelling by the pelvis and pudendals. The bladder is then completely isolated from central nervous control, but, after a period of retention of urine with overflow it may partially expel its contents automatically. The detrusor and internal sphincter act coordinately. Such an action suggests a neural mechanism of some sort. It occurs in animals even after the hypogastrics have been sectioned as well and time allowed for degeneration to occur, it cannot therefore be due to preganglionic axon reflexes. Probably, in such and other instances in which motor impulses from the central nervous system have been interrupted, local reflex arcs through ganglion cells in the vesical plexus or bladder wall are responsible for the automatic action. The latter is only a makeshift for the normal micturition reflex since the bladder is not completely emptied but always retains a part of its contents (residual urine). McLennan draws attention to the fact that the state of the bladder after the afferent limb of the reflex arc is interrupted as in tabes is different from that following destruction of both afferent and efferent limbs. In the former the bladder is lax (hypotonic) and of large capacity, whereas in the latter it is hypertonic and of normal capacity. The reason for such a difference is obscure.

After transection of the cord above the sacral region, normal micturition cannot occur. Nevertheless, after a variable period of retention with

overflow the spinal (sacral) centers assume control and the bladder empties at intervals automatically (see also mass reflex, ch. 65). Owing to the absence of the first and second reflexes of Barrington which, as just mentioned, are governed by higher centers, the bladder does not empty itself completely, but always contains a quantity of residual urine.

Bladder sensibility is completely lost following section of the hypogastrics and pelvic nerves or transection of the cord above the entrance of the afferent fibers of the hypogastrics. Injury or disease (e.g., tabes) of the posterior columns involving these fibers together with those from the sacral roots will have a similar effect.

Bilateral lesions of cortical areas 4 and 6 in man abolish voluntary control of the bladder, urinary incontinence results. Incontinence is seen not uncommonly in the aged, and may occur though no organic lesion is apparent, it is attributed to impairment of voluntary control by the cortical centers.

Nocturnal enuresis, or the passage of urine during sleep, occurs in young children up to an age which varies considerably, and may be attributed to the undeveloped state of the neural mechanism through which the act of micturition is voluntarily inhibited. But enuresis during sleep sometimes persists beyond the usual time and even to adult age. It may then be associated with some definite organic abnormality e.g., in the lumbo-sacral vertebrae, e.g., spina bifida occulta, but nocturnal enuresis in the adult is usually related to some functional neurological disorder, or to psychological factors. Evidence of pelvic autonomic dysfunction or psychiatric conditions in the subject's immediate family are present in a large proportion of such persons. In others there is definite mental deficiency.

SECTION FIVE

Digestion

36

THE SALIVARY GLANDS AND THE SECRETION OF SALIVA

General Description of the Digestive Glands

Of the many secretions that are poured into the alimentary canal, some are formed by the cells of the mucous membrane lining the various hollow organs, others are formed by glands that may be in the submucosa or entirely outside the digestive tube and are connected with it by means of ducts. The products of the glands are referred to as external secretions because the alimentary canal is considered to be an extension of the external surface of the body and its contents to be actually 'outside' the body. The secreting cells are epithelial cells and with the possible exception of some of the salivary gland cells, are derived from the endoderm.

Secreting cells are classified as *apocrine*, *holocrine*, or *merocrine*, according to the manner in which they discharge their secretion. In *apocrine* cells, secretory products become concentrated in the luminal end of the cell and are discharged into the lumen of the alveolus or duct along with the portion of the cell in which they have accumulated. Certain cells of the cat's submaxillary gland are said to secrete in this manner. In the case of *holocrine* cells the entire cell along with its accumulated secretion is discharged into the lumen and forms the secretion of the gland; examples are the secreting cells of the sebaceous glands. A possible example in the gastrointestinal tract is the shedding of the intestinal epithelium described in chapter 40 under the head of *Intestinal Secretion*. A *merocrine* cell remains intact and discharges its secretory products through the cell membrane, examples are the acinous cells of the pancreas and most of the other digestive glands.

The glands themselves are classified according

to their cellular composition as—*homocrine* i.e. having secretory tubules lined with cells of one type only or *heterocrine*, having secretory tubules lined with cells of more than one type. Most of the digestive glands are of the *heterocrine* type. Glands have also been classified as *monotypic* or *polytypic* depending upon whether the secreting cells are arranged in one layer or in more than one layer. The pancreatic acini are *monotypic* and the submaxillary and sublingual glands are *polytypic* according to this classification.

Mechanisms of Secretion

The secretions of the digestive glands consist of water, other inorganic materials and organic substances. The organic matter consists principally of enzymes and mucoprotein. The water obviously comes from the blood by way of the tissue fluid since the total daily volume of the digestive secretions far exceeds the total volume of the glands. Unless the gland is one which secretes hydrochloric acid or sodium bicarbonate the inorganic constituents are those that are common to the body fluids and are usually present in approximately the same proportions in which they occur in these fluids. The osmolar concentration of most of the digestive secretions is considered to be the same as that of the blood plasma with the exception of saliva which is hypotonic. According to some observers gastric juice may be hypertonic when first secreted.

Since mucus is a protein and all the enzymes are protein in nature, secretion of organic matter by the digestive glands involves extensive protein synthesis. We recognize two stages in the production of the organic materials, first, a stage of

synthesis or manufacture of the secretory products within the cell and, second, a stage of secretion in which the secretory products are discharged into the ducts, along with a certain amount of water and inorganic salts. So far as we know at present, the first or synthetic stage goes on continuously although it may be modified by secretory stimuli and is influenced by those environmental conditions which alter the general metabolism of the gland cell. Presumably, protein synthesis is a reversible process and subject to the law of mass action. That is to say, the rate of synthesis will be accelerated by increasing the concentration of the raw materials or reacting substances, amino acids chiefly, and will be retarded by accumulation of the synthesized protein, provided the protein remains in solution. The situation is so complicated, however, that such a simple scheme would probably need extensive alteration before it could be applied in a quantitative manner. Actually, in most instances, the synthesized material appears to be precipitated within the gland in the form of secretory granules.

The formation of secretory granules is a fascinating process which has been studied extensively but is still only imperfectly understood. Apparently the granules begin to form first in the vicinity of the Golgi apparatus, where they remain during the period of growth and maturation and when fully developed are transported toward the apical, or luminal portion of the cell where they tend to accumulate. When allowed to accumulate in sufficiently large numbers they may displace the nucleus of the cell toward the base and even invade the protoplasm between the nucleus and the base of the cell. Secretory granules accumulate in resting cells, that is, cells which have not been stimulated to discharge their secretion into the ducts of the gland. In the digestive glands this occurs in the fasting state or in the interdigestive periods. When the glands are stimulated to secrete as the digestive glands are during digestion, the granular material is discharged into the ducts of the gland usually accompanied by water and inorganic salts. In spite of the existence of secretory granules most of the digestive enzymes appear to be present in the gland in diffusible form at some time in the process of synthesis. At any rate most of them may be found in the blood in measurable amounts, presumably having got there by diffusion from the secretory cells.

In the case of those enzymes which have the capacity to destroy tissue, e.g., the proteolytic

enzymes, the material synthesized in the secreting cells is not the enzyme itself but a precursor called a zymogen, for example, pepsin is synthesized as pepsinogen, a proteolytically inactive protein, and trypsin as trypsinogen, which is inactive. The lipases are synthesized as such but are comparatively inactive except in the presence of surface active agents such as bile which are not normally present in the tissues. Another device by which the glands that secrete proteolytic enzymes are protected from digestion by their own secretory products is by the elaboration of antienzymes, for example, the pancreas contains an antitrypsin which inactivates trypsin and undoubtedly serves to protect the gland from digestion by the small amounts of active trypsin that may accidentally be formed in the acinous cells. An antitrypsin is also secreted into the pancreatic juice and probably serves to prevent activation of the trypsinogen within the ducts.

Since the digestive glands secrete water and salts as well as enzymes the secretion of these two classes of products may be stimulated separately, at least in some of the digestive glands. One of the early physiologists to recognize this fact was R. Heidenhain (1878), who undertook to differentiate between the nerve fibers which, when stimulated, cause secretion of organic matter and those which cause secretion of water and salts. The former he designated as *trophic* fibers and the latter as *secretory* fibers. The terms are confusing particularly since the word *trophic* more properly pertains to synthesis than to discharge from the cell of the organic matter in the secretion. Furthermore, the word *secretory* has become firmly fixed in the language as pertaining to the whole process of secretion (and will be used in that sense throughout this discussion). Babkin has suggested that the adjective *hydrotic* be used in place of *secretory* and *ecboic* in place of *trophic*. Babkin's terms, although more nearly correct, are not euphonious and perhaps for that reason have not come into general use.

Salivary Glands

GENERAL FORM AND MINUTE STRUCTURE

The first secretion encountered by the food is saliva. This fluid is secreted by three pairs of glands known as the parotid, submaxillary and sublingual glands, and by numerous smaller glands scattered throughout the mucous membrane of the mouth and pharynx. The parotid gland, the largest of the salivary glands, is situated at the side of the face below and in front of

the ear and the mastoid process, and in front of the sternomastoid muscle. A process of the gland known as the retromandibular process, passes medially behind the ramus of the mandible. The parotid glands are swollen and therefore conspicuous in a person having mumps. The duct of the parotid gland, known as the parotid duct, also called Stensen's duct, after reaching the anterior border of the gland runs forward, external to the masseter muscle and crossing it, turns around the anterior border of this muscle and runs medially through the fat of the cheek, at right angles to the first part of its course, to the buccinator muscle which it pierces to reach the mucous membrane of the cheek. After running for some distance under the mucous membrane, it forms a small papilla through which it communicates with the oral cavity. The opening is opposite the crown of the second upper molar tooth.

The submaxillary glands are next in size to the parotid, they are placed in the submaxillary triangle medial to the mandible. The posterior end of the gland lies very close to the sternomastoid muscle. The submaxillary duct, also known as Wharton's duct, runs from the deep surface of the gland along the mylohyoid muscle beneath the floor of the mouth on the medial side of the sublingual gland, to open on the floor of the mouth at the side of the frenulum linguae, on the summit of the soft papilla known as the caruncula sublingualis. The sublingual glands lie immediately below the mucous membrane of the floor of the mouth. These glands pour their secretion into the mouth, under the tongue, through a large number of ducts which arise near the upper borders of the glands and, after a short course, open upon a series of papillae along the summits of the plicae sublingualis.

—Two types of cells, mucous and serous, can be recognized in microscopic sections of the salivary glands. The mucous cells have large translucent granules which readily transmit light so that in thin sections they appear transparent. The serous cells have small granules that are more opaque and appear darker in sections than the mucous cells. The serous cells secrete a thin, watery fluid containing the starch-splitting enzyme, ptyalin. The mucous cells secrete mucus mainly.

In the salivary glands the cells of the glandular tissue are aggregated into a great number of small groups, with the individual cells arranged in a single layer around a small central cavity or alveolus. The cells are more or less wedge-shaped with their apices converging toward the central

cavity and their bases directed outwards. They discharge their secretion into the alveolus which is drained by a fine duct. Ducts from neighboring alveoli join to form ducts of larger caliber which unite again to form still larger trunks, until finally through a succession of junctions and the formation of channels of ever increasing size, the secretion flows into the mouth by a single large duct, in the case of the submaxillary and parotid glands, or by several of medium size in the case of the sublingual. The general arrangement of the ducts reminds one of the stem branchings of a bunch of grapes—the rounded alveoli at the ends of the finest channels corresponding to the grapes. Glands showing such a pattern are, therefore termed *racemose*. The ducts are named, in accordance with their location, *intralobular* or *interlobular*. The former drain a single alveolus or a group of alveoli. The latter lie between the lobules each being formed by the union of a number of intralobular ducts. The narrowed part of the intralobular duct lying nearer to the alveolus is known as the *isthmus*, or more usually the *intercalary duct*.

In addition to the two types of secreting epithelium, salivary glands have three different types of cells in their ducts. In the intercalary ducts that lead directly away from the alveoli, the epithelium is cuboidal in character. In the intralobular ducts it is columnar and presents a peculiar rod-shaped appearance resembling in this respect some of the cells of the renal tubules. In the interlobular and sublobular ducts the epithelium is cylindrical. The fact that the cells differ in structure suggests that their functions may be different. The rod-shaped epithelium of the intralobular ducts is particularly suggestive of a secretory or reabsorptive function. Evidence presented later, under the head of *electrophysiology*, indicates that these cells reabsorb sodium from the saliva as it passes through the ducts.

Stimulation of the sympathetic nerves to the salivary glands sometimes causes a sudden gush of saliva from the gland. This suggests that some previously secreted saliva is being pressed out of the gland or its ducts as though by contraction of these structures, yet neither the secreting cells nor the duct cells have the structure of contractile tissue and there is no smooth muscle in the glands other than that of the blood vessels. The contractile elements are probably to be sought in what are known as "myoepithelial" cells or "basket" cells which have been described in detail by Zimmerman (1927). These are flat or star-shaped cells which lie between the basal membrane and the

FIG 361 Human submaxillary gland showing both mucous and serous groups of cells. Inserts are views with oil immersion. zymogen granules are clearly shown. (After Stormont from Cowdry's *Special Cytology*.)

secretory cells. They are modified epithelial cells and they may have a contractile function although there is no clear evidence of such. They are distributed around the alveoli and the striated ducts, the latter are often somewhat dilated as though serving a reservoir function.

The alveoli of the parotid gland consist entirely of serous cells, parotid secretion, when collected separately from that of the other glands, has the characteristic watery character of serous secretion. The submaxillary gland contains some alveoli made up of mucous cells and others made up of serous cells, the two types may be seen side by side and in about equal numbers. In addition, many of the mucous alveoli have clusters of serous cells applied to their deep surface which appear to form caps, these, in section, are crescentic in shape and they have, therefore, been given the name of demilune cells. The secretion of these cells is believed to reach the lumen of the alveolus by means of small canaliculi between the mucous cells lining the alveolus. The sublingual glands have a similar structure, except that the serous elements are less prominent.]

The cytoplasm of both the serous and mucous

cells shows a granular structure. The fine granules of the serous cells are believed to furnish the enzyme of the secretion and are called zymogen granules. The mucinogen granules of the mucous cells provide the mucin that gives to the secretion of these cells its slimy character. When the glands are in the resting state the granules accumulate and the fine zymogen granules may load the cytoplasm to such an extent that the nucleus is almost obscured. When the glands enter upon secretory activity, the granules, whether zymogen or mucinogen, become less numerous as a result of their extrusion into the alveolar cavity. After a prolonged period of secretion, only a few remain, these are in the region of the cell bordering the cavity of the alveolus, the rest having been discharged along with the water and other constituents of the secretion. After a period of rest they accumulate again and gradually fill the cell.

REGULATION OF SALIVARY SECRETION

Enough saliva is secreted continuously to keep the mucous membrane of the mouth and pharynx moist but during mastication and swallowing of food the amount of secretion is increased. Also it appears that the character of the secretion is adapted in some degree to the type of food undergoing mastication. As we shall learn later on, there are at least two ways of regulating the secretion of the digestive glands: one is through the nervous system and the other by means of hormones. In the case of the salivary glands it is believed that the regulation is exclusively through the nervous system. At any rate all efforts to date to find a salivatory hormone have failed.

Innervation of Salivary Glands

The glands are supplied with secretory nerves from two sources—the bulbar and the thoracolumbar divisions of the autonomic nervous system (ch 71). The bulbar centers consist of a group of nerve cells which run forward from the anterior end of the glossopharyngeal nucleus to the sensory nucleus of the facial nerve. The anterior (rostral) part is termed the *superior salivatory nucleus*, and governs secretion by the submaxillary gland, the posterior (caudal) part, called the *inferior salivatory nucleus*, controls secretion by the parotid gland.

The submaxillary and sublingual glands receive secretory impulses through the *chorda tympani nerve*. These fibers have the following course: (Arising from the *superior salivatory nucleus* they leave the brain in the *nervus intermedius* of II *Risberg* (ch 65). They pass without interruption

through the genicular ganglion of the facial nerve and descend with the facial to the point where its *chorda tympani* branch is given off. They enter this nerve which upon approaching the cavity of the mouth joins the lingual nerve. In the floor of the mouth the secretory fibers leave the lingual again to make connections with the nerve cells of small ganglia. From these, postganglionic fibers arise which terminate by fine arborizations around the secretory cells (fig. 36.2). The ganglia furnish fibers to the submaxillary gland are small and numerous, and are situated in the hilum of the gland. The sublingual gland contains no ganglion cells, it receives its postganglionic fibers from a small ganglion—the *submaxillary ganglion*—situated in the course of the chorda fibers just beyond their point of separation from the lingual and before they enter the gland (see diagram fig. 36.3).

The *sympathetic supply* (postganglionic fibers) is derived from the superior cervical ganglion. The fibers reach the gland via the plexuses of the external carotid artery and its branches. The pre-ganglionic fibers arise from the upper one or two thoracic segments of the cord. Fine filaments end in the secretory cells.

The *chorda tympani* also carries *dilator fibers* to the blood vessels of the gland, *vasoconstrictor fibers* are derived from the sympathetic.

The bulbar fibers to the *parotid* pursue the first part of their course in the glossopharyngeal but they follow a devious path before finally terminating around the gland cells. They arise in the medulla from the *inferior salivatory nucleus*. At the jugular foramen they separate from the glossopharyngeal (petrous ganglion) in its *tympanic branch* (Jacobson's N), and after passing into the trunk of the *small superficial petrosal nerve* are conveyed to the *otic ganglion*. There they com-

municate with ganglion cells from which postganglionic fibers arise. The latter are transmitted by the *auriculo-temporal* branch of the fifth nerve to the gland cells. The parotid also receives sympathetic secretory fibers. The cell stations of the latter as in the case of the submaxillary and sublingual lie in the superior cervical ganglion. The *dilator fibers* to the blood vessels travel with the bulbar fibers. The vasoconstrictor fibers are furnished by the sympathetic, and follow the blood vessels into the gland.

Stimulation of the Secretory Nerves— Electrophysiology

Electrical stimulation of the nerves to the salivary glands produces different results in different species of animals. Stimulation of the parasympathetic nerves usually produces an abundant flow of quite watery saliva regardless of the gland or species studied, but stimulation of the sympathetic secretory fibers to the submaxillary or sublingual glands, although causing an abundant secretion in the cat, causes only a scanty and very viscid secretion in the dog. Even in the cat in which the secretion is fairly abundant, the composition of sympathetic saliva is different from that obtained on stimulation of the parasympathetic nerves. There is no clear proof that the

sympathetic trunks contain secretory fibers for the parotid gland (Bablin, 1950). Stromblad (1955) obtained only a scanty secretion from the parotid gland of cats on administration of adrenalin or on stimulation of the sympathetic trunk in the neck. This is the more remarkable since the other salivary glands of the cat respond well to sympathetic stimulation. Stromblad suggests that the secretion observed on sympathetic stimulation may have been produced by stimulation of contractile elements in the glands, causing expression of saliva rather than a true secretion.

Stimulation of the autonomic nerves to the salivary glands causes characteristic changes in the electrical potentials that may be observed by placing electrodes in various positions on or within the gland and connecting them to a suitable recording device. With one electrode on the hilum and another on the outer surface of the submaxillary gland stimulation of either the sympathetic or parasympathetic nerves causes the hilum of the gland to become electropositive to the outer surface, after a comparatively long latent period. The latent period is 0.2 to 0.3 seconds with the parasympathetic and somewhat longer when the sympathetic is stimulated. Following parasympathetic stimulation the hilum positivity rapidly declines and may change to a negative potential, there is another sharp rise in hilum positivity when the current is turned off. The potential caused by sympathetic stimulation is more consistently hilum positive.

Since the submaxillary gland is composed of several different types of cell, each of which may have its own electrical characteristics, it is doubtful what significance should be ascribed to the external secretory potential. More precise information may be obtained from the use of microelectrodes with the tip placed in the interior of a single cell. With these, Lundberg (1957), has obtained three types of response representing presumably three types of cells: alveolar cells, demilune cells, and duct cells. In all cases the interior of the cell was electronegative to the external medium. In the case of the alveolar cells, stimulation of either the parasympathetic or sympathetic caused a sustained increase in internal negativity or "hyperpolarization" of the cell membrane. This followed a time course roughly parallel to that already described for the external secretory potential. When the microelectrode was in what was believed to be a demilune cell the parasympathetic caused hyperpolarization but the sympathetic caused a decrease in the internal

negativity of the cell (apparent depolarization). With the electrode in what was thought to be a cell of the striated ducts both sympathetic and parasympathetic nerves caused apparent depolarization.

In the sublingual gland microelectrodes picked up currents corresponding to those obtained from alveolar cells of the submaxillary but the external secretory potential was of a polarity opposite to that of the submaxillary gland, that is, the hilus became electronegative. This difference was believed to be due to differences in the cellular composition of the two glands and not to any difference in the electrical response of corresponding individual cells.

These electrical phenomena are remarkable in several respects. Evidently they are not analogous to the familiar action potentials of nerve and muscle. They appear not to be concerned with the excitatory process (which must be quite different in gland cells and in muscle cells) but are concerned with the functional work of the cell. Lundberg has presented good evidence that the hyperpolarization, associated with secretory activity, is caused by an active transport of chloride ions through the outer cell membrane which is triggered by the release of a neurohormone at the autonomic nerve endings. The apparent depolarization, when it occurs, is not a self-propagating disturbance of the cell membrane of the sort we are accustomed to associate with depolarization, but is probably due to the sustained activity of an ion transport mechanism in the duct cells opposite to that causing hyperpolarization in the alveolar cells.

As a corollary to these observations Lundberg (1958) has suggested that secretion of water and salt by the alveolar cells is accomplished through the activity of an active chloride ion transport mechanism in the outer cell membrane which "pumps" chloride ions into the cell from the surrounding interstitial fluid. Electrical forces cause sodium to accompany chloride and osmotic forces take in water. As a result of the increased hydrostatic pressure within the cell the salt and water escape through the inner membrane (where there may also be an ion pump) into the lumen of the alveolus. He has suggested further that the rodlike epithelial cells of the ducts actively absorb sodium from the secretion. Sodium absorption at this point would account for the apparent depolarization of these cells (decreased internal negativity) and also for the fact that saliva may be hypotonic with respect to the blood.

*Distribution of the Autonomic Nerves
within the Glands*

The fact that stimulating different nerves caused secretion of different types of saliva caused R. Heidenhain to elaborate his previously mentioned theory of the differing functions of the autonomic nerves for the digestive glands. Since the chorda tympani nerve to the submaxillary gland usually causes an abundant, watery secretion, Heidenhain believed that it contained chiefly secretory fibers. The organic matter present in the saliva was, he believed, due to an admixture of "trophic" fibers. The fact that, in the dog, stimulation of the sympathetic causes only a very small amount of highly viscid secretion (containing a high concentration of organic matter) suggested that the sympathetic nerves consist mainly of "trophic" fibers, particularly in the dog, but with a greater admixture of "secretory" fibers in the cat. As a corollary to this hypothesis, it was assumed that one and the same secreting cell received two kinds of nerve fibers, "secretory" and "trophic."

Heidenhain's theory was challenged by Langley and Fletcher (1890), and later by Carlson and his coworkers (1907, 1908), who demonstrated the importance of the blood supply to a gland in determining the composition of its secretion. Langley came to the conclusion that there is only one kind of secretory nerve for the salivary glands and that the changes in composition seen on stimulating different nerves depends upon the effect which these nerves have on the blood vessels of the salivary glands. If stimulation of a particular nerve, for example, the sympathetic, caused not only secretion but constriction of the blood vessels so as to limit the blood supply of the gland, the gland then would put out the usual amount of solids but a smaller amount of water, resulting in a highly viscid secretion. If, on the other hand, in addition to secretory fibers the nerve contained vasodilator fibers so that an abundance of water was available for the secretion, the gland would put out a more watery fluid. This was in accordance with the fact that the parasympathetic nerves convey secretory and vasodilator fibers, whereas the sympathetics convey secretory and vasoconstrictor fibers to the salivary glands.

The combined physiological and histological studies of Stormont (1932), and more recently of Rawlinson (1933, 1935) in Bahkin's laboratory have supported the concept that the individual cells of the salivary glands do not receive a double innervation but that each type of cell is innervated

by one or the other division of the autonomic nervous system but not by both. Rawlinson found, for example, that prolonged stimulation of the chorda tympani nerve, with the cervical sympathetic trunk cut, caused the mucous alveolar cells to decrease in size and to become irregular in shape and many of them to lose their ability to take the mucicarmine stain, whereas the alveolar lumen increased in size. The changes were greater the longer the stimulation of the chorda tympani and the more profuse the secretion. There were no definite or constant changes in the demilune cells which, it will be recalled, are serous cells. On the other hand, stimulation of the cervical sympathetic trunk caused no changes in the mucous alveolar cells but after prolonged stimulation the demilune cells were diminished in size and clear vacuoles appeared in their cytoplasm. If the ducts were blocked the vacuolation of the demilune cells became more pronounced, indicating that it was due to the accumulation of secretion. Furthermore, injection of massive doses of adrenaline caused marked changes in the demilune (serous) cells but had practically no effect on the mucous cells. These experiments strongly suggest that the chorda tympani, which is the parasympathetic nerve for the submaxillary gland in the cat, is distributed exclusively to the mucous cells in this species, whereas the sympathetic nerve innervates the demilune cells.

On the basis of these and other experiments performed in his laboratory, Bahkin (1950, p. 869) proposed the following functions for the autonomic nerves to the cat's submaxillary gland:

Parasympathetic nerves

- 1 Hydrelatic effect (secretion of water and salts) on the mucous cells
- 2 Echolic effect (production of enzymes) on the same cells
- 3 Vasodilator effect

Sympathetic nerves

- 1 Hydrelatic effect on the demilune cells
- 2 Motor effect on the myoepithelial cells
- 3 Vasoconstrictor effect

However, recent studies of the electrophysiology of the salivary glands by Swedish investigators cast serious doubt on these conclusions. Lundberg (1957, 1958) found, for example, that characteristic electrical changes could be produced in a single cell of the cat's submaxillary gland by stimulation of either the sympathetic or parasympathetic nerve. Although it might be possible to explain this fact as due to

neurohormones from adjacent cells, the straightforward and probably correct explanation is that both nerves innervate one and the same cell. It has also been found (Emmeln 1955) that once the gland is responding maximally to parasympathetic stimulation, stimulation of the sympathetic does not augment the secretion as it would do if it activated glandular elements not innervated by the parasympathetic.

It is not possible with our present knowledge to resolve these apparent contradictions but it should be kept in mind that Rawlinson was dealing with what Babkin called *ecohic nerves* that is nerves that caused discharge of organic matter from the cells, purely hydrelatic (secretory) stimuli do not cause extensive histological changes in secreting cells. Lundberg on the other hand was dealing mainly with hydrelatic phenomena. There may be a difference in the way in which the two types of nerves, *ecohic* and hydrelatic are distributed. At present we do not know how the individual cells of the cat's submaxillary gland are innervated.

Limitations of electrical stimulation. It is now possible to clarify the apparent species difference between dogs and cats with respect to the response of the salivary glands to stimulation of the sympathetic nerve. In both animals the sympathetic contains secretory fibers for the submaxillary and sublingual glands and it also contains vasoconstrictor fibers for the blood vessels supplying these glands. The difference lies in the relative effectiveness of the vasoconstrictor elements. In the cat although vasoconstriction occurs, it lasts for only a short time even though the nerve may be continuously stimulated. Consequently the glands have an adequate blood supply throughout the major part of the period of stimulation. In the dog on the other hand the vasoconstriction persists throughout the period of stimulation so that although the secretory fibers to the serous cells are activated there is an inadequate supply of fluid to form the secretion. The result is a small amount of highly concentrated saliva.

It should be remembered that electrical stimulation of a nerve trunk is highly artificial. All the fibers in the nerve are stimulated even though they may be wholly unrelated in function. This is a situation that never occurs under conditions of normal reflex stimulation. It may be assumed that when the secretory fibers are stimulated reflexly, whether these are sympathetic or parasympathetic, the blood supply to the gland is adjusted to the needs at the moment, whatever they may

be. Another point that should be clarified is the watery character of the secretion obtained on parasympathetic stimulation, in spite of the fact that these nerves are believed to cause secretion of mucus. Undoubtedly mucus is secreted even on artificial stimulation but secretion of water and mucus in the proper proportions to produce an ideal lubricant for the food must depend on normal reflex stimulation.

Paralytic salivary secretion. Claude Bernard observed in 1861 that if he cut the chorda tympani nerve in a dog or a cat in about twenty-four hours the submaxillary gland began to produce a scanty secretion of thin turbid saliva. The turbidity was due to the presence of leucocytes. The secretion increased until the seventh or eighth day at which time it reached a plateau and began to diminish about the third week. It stopped some six weeks after the nerve was cut. During this time the gland increased in size and no secretion could be obtained on stimulation of the mouth. Stimulation of the sympathetic however produced a flow of saliva. Division of the sympathetic nerve or extirpation of the cervical ganglion did not evoke a paralytic secretion. Rawlinson repeated these observations in Babkin's laboratory and found on examination of the gland that there was evidence of secretory activity during the paralytic secretion not as one might suppose in the mucous cells innervated by the chorda tympani but in the demilune cells. Moreover these cells were more excitable than normal on stimulation by adrenaline or electrical stimulation of the sympathetic nerves. Evidently cutting the chorda tympani causes some alteration in the gland alveoli which greatly increases the excitability of the sympathetic nerve endings on the serous or demilune cells. This may be due to continuous activity of the postganglionic neurons of the chorda tympani when it is disconnected from its preganglionic fibers thus causing a continuous release in small amounts of acetylcholine in the gland. The heightened irritability of the sympathetic innervation is thought to be due to this minute amount of neurohormone. Evidence of this relationship is seen in another phenomenon studied extensively also in Babkin's laboratory known as augmented salivary secretion.

Augmented salivary secretion. It has long been known that if one stimulates a secretory nerve to one of the salivary glands a subsequent stimulus of the same strength to the same nerve will evoke more saliva than the first stimulus provided the second stimulus is applied within a few minutes after the first has ceased. Likewise if one stimulates a parasympathetic nerve and then follows that by stimulation of the sympathetic the sympathetic stimulation will produce more saliva than a sympathetic stimulus of the same strength.

not preceded by parasympathetic stimulation. Similarly, stimulation of the sympathetic augments the response to parasympathetic stimulation. In the case of the submaxillary gland augmented secretion has been observed in the following situations by different investigators: chorda after chorda, chorda after sympathetic, sympathetic after chorda, and sympathetic after sympathetic. In short, augmented secretion is observed after any two successive stimulations of the same or of different secretory nerves of the salivary glands provided the second stimulus is not too long delayed.

The augmented secretion was studied extensively by Langley (1889) and more recently by Babkin (1950) and his coworkers. The explanation of this phenomenon is perhaps to be found in the interaction of the neurohormones of the parasympathetic and sympathetic nerves: acetylcholine and noradrenaline or adrenaline. Although these substances are considered generally to act antagonistically, it is nevertheless true that minute amounts of acetylcholine increase the excitability of sympathetically innervated structures to epinephrine or norepinephrine, likewise, minute amounts of epinephrine or norepinephrine increase the excitability of parasympathetically innervated structures to acetylcholine. In the salivary glands in particular, where there is reason to believe that many cells are activated by both adrenergic (sympathetic) and cholinergic (parasympathetic) nerves, adrenaline or noradrenaline and acetylcholine would appear to act synergistically. The augmented secretion observed on chorda after chorda or on sympathetic after sympathetic stimulation, would appear to be a simple case of summation. We may assume that whether the sympathetic or the chorda has been stimulated some neurohormone persists for a time after the stimulus has ceased, and this, added to the neurohormones released by subsequent stimulation, augments the total amount of neurohormone present.

The Reflex Secretion of Saliva (Artificial Stimulation)

The salivary glands can be readily excited by the artificial stimulation of afferent nerves supplying structures in the mouth. The reflexes are brought about through the salivary centers. The efferent limbs of the reflex arcs—the secretory fibers of the chorda tympani and the tympanic branch of the glossopharyngeal respectively—have been considered above. The afferent pathways are long fibers contained in the trunks of the chorda tympani and glossopharyngeal nerves, in the lingual, buccinator and palatine branches of the fifth nerve and in the pharyngeal branch of

the vagus. The fibers of the chorda tympani subserving the sensation of taste are distributed to the anterior two-thirds of the tongue. They arise from cells in the genicular ganglion, the central processes of the ganglion cells enter the pons in the *nervus intermedius* of Wrisberg to make connections with cells in the tractus solitarius from which impulses are relayed to the superior salivatory nucleus. The afferent fibers of the glossopharyngeal nerve concerned in the salivary reflex, carry sensations of taste from the posterior third of the tongue. They arise from cells in the petrous ganglion. The central processes of these cells enter the medulla to make connections through the tractus solitarius with the inferior salivatory nucleus (see also p. 1300). The lingual fibers (cells of origin in Gasserian ganglion) furnish the general buccal mucosa with common sensation—touch, pain, etc. Secretion of saliva may be induced by stimulation of the central end of any one of these three groups of afferent fibers. It can also be brought about by stimulating sensory nerves in other situations. For example, experimental stimulation of the central end of the vagus, sciatic or indeed of practically any sensory nerve of the body may cause salivation. According to some, stimulation of afferent nerves of the gastric mucosa is particularly likely to initiate a reflex secretion into the mouth. In disease stimuli arising in the esophagus may cause profuse salivation (esophago-salivary reflex). Stimulation of trigeminal terminals in the nasal mucosa will also evoke a secretion of saliva (Babkin).

The Secretion of Saliva under Natural Conditions

In the normal life of the animal the secretion of saliva is brought about reflexly in two ways, either through (a) the stimulation of the nerves of the mouth by the presence therein of food or other substances, or (b) by the stimulation of some organ of special sense other than that of taste. The former type of reflex is termed *unconditioned* or *inherent*, the latter, *conditioned* or *acquired*. A reflex of one type does not, of course, exclude the other, and as a matter of fact both are called into play together under ordinary circumstances.

The unconditioned salivary reflex. Materials placed in the mouth call forth, after a short latent period (two or three seconds), a secretion of saliva which varies in *quantity* and *quality* with the physical and chemical nature of the substance introduced. The effects which sensations of taste produce upon the secretion of saliva are well known. Among edible substances, those, generally

speaking, which are the most palatable or arouse the sensation of taste with the greatest intensity, are the most potent salivary stimulants. Materials that are entirely inedible will, if unpleasant to the taste—acids especially—cause profuse salivation. In these instances the secretion depends mainly upon the stimulation of the taste fibers, and the stimulus is chemical in nature. But we have seen that stimulation, not only of the taste fibers (chorda tympani and glossopharyngeal) but of the fibers endowing the mucosa of the mouth with common sensibility (lingual nerve) as well, will produce a salivary flow. So, materials such as dry sand, inedible powders, whether soluble or insoluble, or any other material which is capable of stimulating these endings in a purely physical way will evoke a secretion. The mere movements of the jaws and of the tongue over the mucosa of the mouth will have such an effect, although there is no material present in the mouth. A secretion occurs when any substance is chewed, whether or not it is edible or possesses taste. The chewing of india rubber (or gum) for instance, the manipulations of the dentist, the contact of his instruments with the oral mucosa or the grinding of a tooth are familiar and potent causes of salivation.

The remarkable adaptability or purposeful character of the salivary reflex has been remarked upon by Pavlov. The physical and chemical qualities of the juice as well as its quantity, are adapted to the physical or chemical characters possessed by the particular substance initiating the reflex. For instance if clean pebbles be placed in a dog's mouth, they are expelled—merely allowed to drop out of their own weight. No secretion or very little occurs since none is required, but if the stones are crushed and given as a powder, a profuse watery salivation follows to rid and cleanse the mouth of the useless material. The juice in this instance is poor in organic material and resembles that obtained upon electrical stimulation of the chorda tympani nerve or of the parasympathetic fibers to the parotid. Strong acid produces an abundant saliva which according to Pavlov is relatively rich in protein, thus exerts a buffer action which reduces or annuls the injurious effect of the acid. The salivary response to the various foods is also adapted to their peculiar qualities. A chunk of meat if given to a dog, is very quickly swallowed. Under the circumstances what is most required of saliva is a lubricant action. Accordingly, a highly viscous juice rich in mucin, is produced. If the meat is first dried and powdered, or if dry biscuit is fed to the animal the secretion is characteristic of parotid or chorda saliva—e.g., watery and abundant, but poor in mucin. Milk

evokes the secretion of a saliva rich in mucin, and foods, in general, produce a saliva rich in organic material—mucin and ferments—whereas inedible substances tend to call forth a more watery juice. These adaptations are much less pronounced in man.

Professor Babkin (1930, p. 697) in whose laboratory at McGill University these observations were confirmed and extended, interpreted the results as follows: 'It was evident from the facts observed that a salivary gland does not secrete as a unit, but that the different sets of epithelia of which the glands are composed contribute different components to the secretion and furthermore that local productivity depends on the intensity of the excitation received from the salivary center. The salivary center may be regarded as a compound structure consisting of several parts. Each peripheral stimulus, transmitted through the appropriate taste and other sensory nerves of the mouth cavity, acts on different parts of the salivary center and these in their turn excite reflexly and selectively the various epithelial groups in the salivary glands. Moreover it must not be forgotten that the brain possesses not one but two salivary centers—parasympathetic and sympathetic. The parts of these centers innervating different epithelial groups may be stimulated reflexly in various combinations and this will be reflected in the composition of the saliva secreted.'

THE CONDITIONED OR ACQUIRED REFLEX. The secretion which flows into the empty mouth when 'the mouth waters' is the result of a conditioned reflex. The stimulus which initiates such a reflex is not applied to the nerves of the mouth but is received by one or other of the organs of special sense particularly those of sight and smell. A conditioned reflex may also be elicited through the sense of hearing or through sensory impressions arising from stimuli applied to the skin. In brief, a conditioned reflex is one in which the cerebral centers play an essential part, and in which training and experience are the basis for the development of the reflex process. Conditioned reflexes are taken up in detail in chapter 68.

THE REACTION, QUANTITY AND COMPOSITION OF SALIVA

Human mixed saliva according to the investigation of Starr, is slightly acid in reaction. In 86 per cent of a large series of normal persons the pH was found to vary between 6.35 and 6.85. The lowest pH found was 5.75 and the highest 7.05. Salivary reaction is dependent mainly upon the

relative concentrations of free and combined CO_2 , that is, upon the ratio $[\text{H}_2\text{CO}_3]/[\text{NaHCO}_3]$. So, in order that the true pH value be obtained the juice must be collected without loss of CO_2 . The older figures in the literature are too high (7.50 to 8.00) since this precaution was not taken. (The hydrogen ion concentration of the saliva was found to vary directly with the CO_2 content of the blood. This means that when the CO_2 tension in the blood is high, more CO_2 finds its way into the salivary secretion to lower its pH, and vice versa. Forced breathing causes a lessened amount of CO_2 in the saliva, and consequently a rise in its pH. On the other hand, conditions associated with a retention of CO_2 in the blood increase the loss of the gas in the saliva. Ingestion of NaHCO_3 , although it reduces the acidity of the urine, increases that of the saliva, since a rise in the CO_2 tension in the blood results.)

In man the amount of saliva secreted in 24 hours amounts to from 1000 cc to 1500 cc, but the output of the resting gland is only about 0.25 cc per minute. The cow secretes some 60 liters daily. (Ordinary mixed saliva contains about 99.5 per cent of water and 0.5 per cent total solids. It has a specific gravity between 1.002 and 1.012. Its main constituents are as follows:

I Salts (approximately 0.2 per cent)

Sodium and potassium chloride

Sodium bicarbonate

Acid and alkaline sodium phosphates

Calcium carbonate and calcium phosphate

Potassium sulphocyanate

II Gases

Carbon dioxide, oxygen and nitrogen

III Organic substances

Ptyalin (salivary amylase), maltase and *lysozyme*

Serum albumin and globulin

Urea, uric acid, creatine and amino acids

Mucin, mainly in the submaxillary and sublingual secretions

Glucose is absent, normally, and even in diabetes, none or only small amounts are found in the saliva.

[The bicarbonates and to some extent the phosphates act as "buffers." The buffering action of saliva is such that its pH remains constant under all ordinary conditions, and even though relatively strong solutions of acids or alkalis are introduced into the mouth, the reaction, except for a short period, is not altered. The "acid mouth," so glibly spoken of in dentifrice advertisements as an abnormal condition, and the possibility of altering the reaction of the oral secretions are figments of the imagination. Attempts to change the pH of the saliva experimentally by flooding the mouth with acid or alkaline solutions are followed by contrary effects upon the salivary reaction. Acid solutions cause a rise in pH, alkaline solutions a

fall. The changes last for about 10 minutes, the reaction then returns to normal.

The chlorides are necessary for the activation of the amylase. The calcium salts which are soluble in acid but insoluble in alkaline media tend to be thrown out of solution when the pH rises. (The carbonate and phosphate of calcium may be deposited in the form of concretions (*salivary calculi*) within the ducts or, in combination with organic material, may be laid down upon the teeth as "tartar.") A high salivary pH and a juice rich in mucin are believed to be conducive to tartar deposition and the development of calculi. The potassium sulphocyanate (KSCN) is an excretory product and is probably formed within the body from CN radicals derived from the metabolism of protein. Its production and excretion are thought to represent a detoxicating mechanism. It is said to be in excess in the saliva of habitual smokers, and has been shown by Sullivan and Dawson to be noticeably reduced during the course of pellagra, but returns to normal value during convalescence from this disease.

The bacteriocidal enzyme known as *lysozyme* has a destructive action upon staphylococci, streptococci, meningococci and other microorganisms. It is also present in the lacrimal secretion and is widely distributed in animal tissues and in egg white in which it is closely associated with the protein avidin (p. 928). It has a mucolytic action resembling that of hyaluronidase (Ch. 28) and probably owes its antibacterial activity to its ability to dissolve the polysaccharide in the capsule of the microorganisms.

THE FUNCTIONS OF SALIVA

1 *Preparation of food for swallowing* This is one of the most important functions of saliva. The food is moistened, thus enabling it to be rolled into a plastic mass, and given a lubricating coating of mucus. Claude Bernard showed that a horse with a parotid fistula had the utmost difficulty in swallowing dry hay or oats.

2 *Starch digestion* [The starch molecule is acted upon by salivary amylase and ultimately split into molecules of the disaccharide maltose.] The rapid passage of food through the mouth precludes the possibility that it is acted upon there to any great extent by the saliva. Whether the starchy food, after its thorough impregnation with saliva, undergoes any significant degree of digestion in the stomach, has been debated. (The salivary amylase requires for its activity an alkaline, neutral, or but faintly acid medium, therefore, it was thought that the highly acid gastric juice would prevent, or soon terminate salivary digestion. It has been shown, however, that the latter part of the meal, which usually

consists of carbohydrate, may remain in the fundus of the stomach, protected for some time from the acidifying action of the gastric juice, by a layer of food ingested previously. For example, Walter Cannon (1911), noted that in cat stomachs that were carefully removed and frozen at various times after a meal, the inner layers of food in the cardiac end remained neutral or weakly alkaline for hours and only the outer layers were slightly acidified. For this reason it is likely that under favorable circumstances considerable digestion of starch is accomplished during this period. Bergheim found that 76 per cent of the starch of mashed potatoes was transformed into maltose in the human stomach.

When boiled starch is placed in a test tube in mixed human saliva and kept at body temperature, a slow conversion of the starch into maltose takes place. The chemical changes occur in a series of stages which may be distinguished by the manner in which the product of each reacts with iodine. Iodine gives a characteristic blue color with boiled starch. A short time after the saliva has commenced to act a physical change may be seen to have occurred in the starch, it loses its opalescent appearance and becomes soluble but it still gives a blue color with iodine. Presently, however, the starch begins to break down and is partially converted into a dextrin which now gives a red color with iodine and on this account is known as erythro-dextrin. Small amounts of maltose may also be detected. Still later no color reaction occurs upon the addition of iodine, a colorless achroodextrin has been formed. In the body, starch is entirely converted into maltose and isomaltose which are later digested by maltase in the intestine and yield glucose. In the first stages, traces of glucose may also appear due to the presence in the saliva of maltase in low concentration. [The following scheme illustrates these changes]

(Salivary amylase has no action upon cellulose and for this reason starch for human consumption must be cooked in order that the cellulose envelopes surrounding the starch grains may be broken. Boiling also causes hydration of the starch molecule and renders it more easily digested by amylase.)

3 Solent action Taste is a chemical sense, consequently, all swallowed substances, if they are to stimulate the taste buds, must be dissolved in saliva or other fluid.

4 Cleansing action The constant flow of saliva exerts a very necessary cleansing effect on the mouth and teeth which are rinsed and kept comparatively free from food residues, shed epithelial cells, foreign particles, etc. In this way saliva inhibits the growth of bacteria by removing material which may serve as culture media. One has but to consider the foul condition of the mouth in certain fevers when the salivary secretion is suppressed, in order to realize how important are its cleansing and bactericidal properties. Under these conditions decomposing organic material, swarming with bacteria (sordes), collects upon the teeth and lips and must be removed by artificial means.

5 Moistening and lubricating action The saliva, by moistening and lubricating the soft parts of the mouth, pharynx, and esophagus, keeps them pliable and resilient. This action on the mouth and lips aids in articulation. Frequent sips of water are almost essential for some public speakers in whom, as a result of evaporation from the mouth, during speech, the supply of saliva is insufficient.

6 Excretory function Many substances, both organic and inorganic, are excreted in the saliva. Drugs such as mercury, potassium iodide, lead, etc. when introduced into the body, are excreted in part in the saliva. Severe inflammation of the oral mucous membrane (stomatitis) may be caused by the excretion of excessive amounts of mercury by this route. The blue line on the gum margins in lead poisoning is due to the metal having been excreted in the saliva and deposited as sulfide, sulfur is provided by organic materials contained in the tartar formed on the bases of the teeth, for this reason discoloration of the gums does not occur where teeth are absent. In chronic nephritis saliva contains a high percentage of urea, sugar sometimes appears in the saliva in severe diabetes. In parathyroid overdosage the calcium concentration of saliva is elevated. Several types of microorganisms, some intensely

virulent, for instance the viruses of hydrophobia and anterior poliomyelitis, are excreted in the saliva. The latter disease has been reproduced in monkeys by injecting the saliva of an infected person. To this connection, it may be added that mumps, which is usually looked upon as a specific inflammation of the parotid gland, is more likely a general disease since other organs, for example, the ovary, testicle, cerebral meninges, etc., unconnected with the salivary glands, are often seriously affected. The parotid inflammation may be incidental and result from the passage of the infectious agent through the gland into the saliva.

It should not be inferred that merely because the salivary glands are able to excrete certain substances when these are present in the blood that they provide an essential or important avenue of excretion. Doubtless all the excretory functions of the body could be carried on effectively in the absence of the excretory function of salivary glands.

7 *The role played by the salivary glands in the regulation of the water balance of the body.* When the water content of the body is adequate the saliva is secreted continuously. When, however, large quantities of fluid are lost from the body, either through sweat, the bowels, the kidneys, evaporation from the lungs, loss of blood, or when the water intake is curtailed, the salivary glands in common with the other tissues are subjected to the dehydrating effect. Injection into the veins or ingestion of strong salt solution has a similar effect. Salivary secretion is suppressed, drying of the oral mucous membranes and the contact stimulation of afferent nerves in the mouth and pharynx arouse the sensation of thirst (ch. 43). Thirst may be looked upon as an essential part of a protective mechanism against the depletion of body fluid. It serves to warn the individual that the body's water supplies require to be replenished.

THE ACTIONS OF DRUGS AND CHEMICALS UPON SALIVARY SECRETION

Serous secretion is stimulated by adrenaline and ephedrine, acetylcholine, muscarine, pilocarpine, physostigmine (eserine), and histamine increase the mucus secretion. Atropine which antagonizes acetylcholine and ergotamine which paralyzes sympathetic effects inhibit secretion. Quinine paralyzes the effects of both nerves.

DISTURBANCES OF SALIVARY SECRETION

Permanent suppression of the salivary secretion—*xerostomia* or *aptyalism* as it is termed—is

an unusual condition, little is known regarding the mode of its production. Temporary suppression of salivary secretion is more common and occurs in emotional states and in fevers, or as already mentioned, when the water content of the tissues is lowered. Excessive salivation or *ptyalism* is not unusual and is often particularly troublesome in pregnancy, its cause in the latter state is unknown, it is possibly of reflex origin, or due to some metabolic product acting in a druglike manner upon the gland cells or the secretory nerves.

As a result of irritation of the gastric mucosa, in duodenal ulcer, or in lesions of the esophagus, such as carcinoma or spasm of the cardiac sphincter, salivation occurs as a reflex phenomenon, and may be pronounced (*esophago-salivary reflex*). The latter reflex is usually readily elicited in a normal person by the passage of a stomach tube or an esophageal sound. Since the glands respond to mechanical stimuli, painful or otherwise, the salivation associated with abnormal conditions in the mouth, e.g., a carious tooth, carcinoma of the tongue etc. is not surprising.

When the reflex secretion is the result of stimuli arising in the stomach, esophagus or duodenum, and is excessive, the saliva may without the individual's knowledge pass down the esophagus and collect above the cardiac sphincter. The secretion occurs as a rule shortly after a meal and a short time later a large quantity of fluid may have accumulated, it may then be brought into the mouth in one or two gushes without any vomiting effort or even nausea. The condition is spoken of as *water-brash*.

GASTRIC DIGESTION

Secretion of Gastric Juice

STRUCTURE OF THE MUCOSA

The stomach is lined with mucous membrane which is separated from the outer gastric wall by the muscularis mucosae and a supporting stroma of connective tissue. When the stomach is empty the mucous membrane is thrown into numerous longitudinal folds called rugae, these tend to disappear when the stomach is distended. The surface of the mucous membrane is marked by slight linear depressions, into small polygonal areas called *areae gastricae*, giving the surface a mammilated appearance, the areas measure from 1 to 6 mm in diameter. The surface layer of the mucous membrane is made up of tall columnar cells which secrete mucus. The surface is constantly covered by a thick layer of tough tenacious mucus secreted by these cells. The layer of mucus varies in thickness from $\frac{1}{2}$ mm to $2\frac{1}{2}$ mm. Beneath the surface layer are various types of tubular glands which differ in structure and in the composition of their secretion in different parts of the stomach. When the mucus is removed the gastric crypts may be seen. These depressions in the mucous membrane are just too small to be seen readily with the naked eye but are readily seen on moderate magnification. The mouths of the gastric glands open into the bottoms of the crypts.

The gastric mucosa can be divided into several areas, each of which contains a particular type of gland. In the narrow zone surrounding the cardiac orifice, known as the cardiac area, the glands are made up mostly of mucous cells, although a few pepsinogen cells are also present. Similar glands minus the pepsinogen cells are found in the esophagus. Between this area and the pyloric area is the zone of the fundus and corpus which contains the gastric glands proper, so called because they secrete the major constituents of the gastric juice. The lower limit of this area is marked by the incisura angularis on the lesser curvature, and a corresponding notch on the greater curvature. Between this limit and the

pylorus are the pyloric glands which resemble the cardiac glands and secrete mucus, although a small amount of pepsin is constantly present in their secretions.

The Gastric Glands Proper

The gastric glands are made up of three types of cells, mucous cells, pepsinogen or chief cells and parietal cells, the mucous cells may be further divided into isthmus cells and neck cells. The gland as a whole consists of three parts: an isthmus, a neck, and the body of the gland (fig. 37-1). The isthmus connects the gland with the gastric crypt, the neck joins the isthmus to the body, the body, which reaches nearly to the muscularis mucosae, ends blindly and is club shaped or branched. The total number of glands has been estimated at 35,000,000.

Although the isthmus cells are of the mucous type they probably secrete very little mucus inasmuch as they contain little of the granular material commonly considered to be converted into mucus. The cells of the neck are true mucus secreting cells but they secrete a different type of mucus from that of the surface epithelial cells. The mucus of the neck cells is soluble and constitutes a part of the soluble mucus of gastric juice. An important characteristic of the isthmus and neck cells is their frequent mitoses. It is believed that after birth these cells may develop into pepsinogen cells and thus replace chief cells that may have died or been destroyed. No mitoses are seen in the chief cells. In the neck region also are a great many parietal cells. These cells do not form part of the gland wall but appear to lie outside, giving the gland a nodular appearance (fig. 37-1). They can be distinguished from their neighbors not only by their location but by their staining reactions.

Most observers believe that the parietal cells secrete the hydrochloric acid and most of the water of the gastric juice and on this account they are also known as the "oxyntic" or acid secreting cells. Among the several observations which point to this conclusion is the direct corre-

FIG 371 A, gland from the fundus of the stomach 1 crypt or foveola on the mucous surface connected to the neck (2) by the isthmus, 2 neck of gland containing mucin secreting cells 3 chief cells, 4, parietal cells B enlarged drawing showing intercellular and intracellular canaliculi

lation between the number of the parietal cells and the titratable acidity and total chloride content of different regions of the gastric mucosa during secretion. Although separated from the lumen of the tubules by the chief or pepsinogen cells, the parietal cells transmit their secretion into the lumen through delicate canaliculi lying between the chief cells. These canaliculi are extensions of a system of exquisitely fine canals which lie within the protoplasm of the parietal

cells and possess definite walls. Coarse, transparent granules are seen in the protoplasm of the cells during rest. Depletion of this granular material occurs during activity.

The body of the gland, which makes up the remainder of the tubule, is composed principally of pepsinogen cells, called *chief cells*. Parietal cells are also present but in diminishing numbers as the fundus of the tubule is approached. In addition to pepsinogen the chief cells probably produce rennin which coagulates milk and is believed to be produced only in young animals, and a special gelatin splitting enzyme known as gelatinase, which liquifies gelatin at a rate 450 times that of pepsin. It is not known whether each of these enzymes is produced by a different type of chief cell or whether they are produced by one and the same cell. Since the chief cells appear to be morphologically identical there is no anatomical evidence for assuming that they differ from one another in their secretory products.

ORIGIN AND COMPOSITION OF GASTRIC JUICE

The major constituents of gastric juice are water, hydrochloric acid, enzymes and various types of mucus. In addition to the enzymes previously mentioned, the gastric juice contains a small amount of lipase. Additional inorganic constituents are the cations sodium, potassium, and calcium, and the anions phosphate and sulfate.

Hydrochloric Acid and Neutral Chloride

The concentration of hydrochloric acid in pure gastric juice varies from 0 to 150 m eq or more per liter. Other things being equal, the concentration of acid increases with increasing rates of secretion, up to a maximum of about 150 m eq per liter. A small part of the chloride of gastric juice is balanced against metallic ions, principally sodium. This constitutes the so-called neutral chloride. Since the concentration of other negative ions in the juice is negligible, its osmotic activity is primarily due to the acid, plus the neutral chloride. Since gastric juice is practically isotonic with blood, the ionic concentration of total chloride in the gastric juice differs but little from that of the total base of the blood, for example, in some experiments of Gilman and Cowgill (1933) the gastric chloride was 168 m eq per liter and the total base of the blood 160 m eq per liter.

In highly acid gastric juice the neutral chloride is present only in small amounts but in a less

acid secretion it may constitute a major portion of the total chloride. When it is present in such large quantities its source becomes a matter of considerable interest. The source of the neutral chloride has been a matter of widespread discussion and controversy, but current thinking tends to the view that it is secreted by the nonparietal cells, (mucous cells of the surface epithelium and chief cells of the gastric glands), along with the organic materials secreted by these cells, and that a certain amount, perhaps a smaller amount, enters the gastric contents by diffusion from the interstitial fluid. In impure gastric juice a large part of the neutral chloride represents swallowed saliva and regurgitated duodenal contents, or perhaps even salt taken with the food.

THE MECHANISM OF SECRETION OF HYDROCHLORIC ACID BY THE GASTRIC GLANDS. The precise manner in which the gastric mucosa secretes hydrochloric acid is still unknown, however, the following facts have been established which, taken together, point in a general way to the processes which must be involved in the secretion.

First, it is generally, although not universally, agreed that the acid is formed by the parietal cells of the gastric glands (Davies, 1951, for a dissenting opinion see Rehm and Dennis, 1957). It is not believed to be produced in the protoplasm of these cells but to appear first in the secretory canaliculi which communicate with the lumen of the gland. This conclusion is based on the observation that the parietal cell shows an alkaline reaction while secreting acid.

Second, the acid as secreted by the parietal cell, has a uniform concentration of approximately 0.17 molar. The theory of the constancy of the concentration of hydrochloric acid as secreted by the parietal cells was first put forward by Pavlov and has since been supported by many investigators, including Hollander and Cowgill (1931). This theory is mainly based on the observation that the nearer one approaches to a pure parietal secretion, the nearer the concentration of hydrochloric acid approaches 0.17 molar. The acidity when plotted against the neutral chloride gives a straight line expressing the inverse relationship between them. When extrapolated this line comes to a point representing a zero value for neutral chloride and an acidity of around 170 m eq per liter. Since neutral chloride and acid chloride are inversely related, the total chloride tends to remain relatively constant. However, since some of the nonparietal secretion contains relatively little chloride, the total chloride increases somewhat with increasing rate of parietal secretion

and therefore with increasing total acidity (figs 37.2, 37.3 and 37.4).

A somewhat different opinion was expressed by Fisher and Hunt (1950) who made a study of the extensive data of Ihre (1938) on gastric secretion in human subjects. They tested mathematically various assumptions regarding the composition of parietal secretion in the gastric juice and concluded that the most probable concentration of hydrochloric acid in human parietal secretion

FIG. 37.2 Showing neutral chloride as a function of acidity (After Hollander)

FIG. 37.3 Total chloride as a function of acidity (After Hollander)

FIG. 37.4 Total chloride as a function of time (After Hollander, redrawn)

is 160 m eq per liter and that the secretion contains, in addition, 10 m eq per liter of neutral chloride. This does not necessarily mean that human parietal secretion differs from that of experimental animals but merely that different methods of estimation give different results. The precise values are, of course, not known.

Third, the secretion of hydrochloric acid involves expenditure of energy, that is to say, no simple chemical reaction which could proceed spontaneously can explain the formation of hydrochloric acid by the gastric glands. One estimate is that the secretion of one gram molecular equivalent of hydrochloric acid requires expenditure of 10,000 gram-calories of energy.

Fourth, the energy is derived from oxidation, probably of glucose, and requires the activity of the enzymes ordinarily active in such oxidation.

Fifth, for every hydrogen ion produced, a bicarbonate ion is released into the interstitial fluid and ultimately into the blood. This requires a continuous supply of carbon dioxide. The carbon dioxide may be derived from the metabolism of the parietal cell itself if the secretory rate is low but at higher rates of secretion the metabolic carbon dioxide has to be supplemented with carbon dioxide derived from the circulating blood. The need for carbon dioxide arises from the fact that, whatever the reacting system may be, removal of hydrogen ions results in accumulation of an excess of hydroxyl ions, if these were not neutralized the resulting alkalinity would soon destroy the secreting cells. The fact that secretion of hydrochloric acid into the gastric juice results in secretion of an equivalent amount of bicarbonate into the blood explains the alkaline tide, so-called, seen in the urine during digestion (Bence-Jones, 1849).

Sixth, carbonic anhydrase (ch. 13 and 29) is present in high concentration in the parietal cells (Davenport, 1939) and participates in the overall process, though probably not directly in secretion of hydrogen ions. Its function apparently is to aid in the hydration of carbon dioxide to produce the carbonic acid that is utilized in neutralizing the hydroxyl ions produced during secretion. Secretion of hydrochloric acid is greatly depressed and in some subjects totally inhibited by the administration of large doses of Diamox, which is an inhibitor of carbonic anhydrase (Janowitz *et al.*, 1957). Although excised frog gastric mucosa will secrete in the absence of carbon dioxide, the tissue is destroyed by the alkalinity resulting from the loss of hydrogen ions (Davies and Longmuir, 1948). In the living animal, at least

in mammals, some mechanism apparently exists to prevent secretion under these circumstances and thus protects the secreting tissue from self destruction.

Seventh, the over-all reaction can be summarized in the following equation:

This equation is not intended to describe the chemical reactions in detail but merely to indicate the beginning and end products and their quantitative relationships. It indicates that the ultimate source of the hydrogen ion is water, and the ultimate source of the chloride ions is the salt of the blood. Also that for each mole of hydrochloric acid produced a mole of sodium bicarbonate has to be formed. The intermediate steps, the source or sources of the energy, and the enzymes and substrates concerned in the intermediate reactions, all of which constitute the real problem of the secretion of hydrochloric acid, are not even suggested. The well known fact that the reactions of this equation would ordinarily progress to the left is a simple qualitative proof of the fact that energy is required for the secretion of hydrochloric acid.

Rehm (1950) and his coworkers have shown that there is a natural, maintained potential difference across the gastric mucosa, the secretory surface being negative in an external circuit to the nutrient surface. When the two sides of the mucosa are connected electrically a continuous current can be maintained representing about 10 per cent of the metabolic energy. The natural potential decreases with the onset of acid secretion. The rate of acid secretion can be increased or decreased by passing an electric current from a battery through the mucosa so as to increase or decrease respectively the potential difference across the tissue. Experiments with metabolic inhibitors show that most of the pathways of aerobic metabolism and the related phosphorylations are required to maintain the potential difference and the acid secretion. The facts prompted Rehm (1949, 1950) to propose a theory of acid secretion in which it is assumed that electrical energy is utilized in the separation of hydrogen ions during the secretion of hydrochloric acid. It seems more likely that here, as elsewhere, the potential difference is the result of—rather than the cause of—the activity

As to the intermediate steps between carbon dioxide and water at one end of the reaction, and hydrogen ions and bicarbonate at the other end (Davies (1951), after reviewing the history of re-

search in this field from Claude Bernard's time until 1951, had thus to say "The available evidence shows that two related mechanisms of acid secretion are possible. In mechanism 1, the metabolic hydrogen atoms from glucose and water, which are transported by the dehydrogenases, become oxidized to hydrogen ions at the cytochrome level, and the electrons react with oxygen and water to form, first hydroxyl ions, and then bicarbonate ions by further reactions with carbon dioxide. This process uses the oxidation-reduction energy from the level of atmospheric oxygen to that of the cytochromes. In mechanism 2, phosphate bond energy, generated by reactions at lower oxidation-reduction levels is utilized to concentrate hydrogen ions, formed by ionization from water, in an electron cycle mechanism in which hydrogen ions are reduced to covalent hydrogen atoms, transported by a carrier system and oxidized to hydrogen ions at high concentration as a result of coupled phosphorylation. Kinetic and thermodynamic considerations show that the hydrogen carrier and electron transport systems could be oxalosuccinate-malate and cytochrome *b*, or perhaps fumarate-succinate and cytochrome *c*. Both mechanisms require a spatial array of enzymes in the paracanalicular zone of the oxyntic cells, and in both cases chloride ions move in the opposite direction to, and as a result of, the movements of the electrons carried by the cytochromes."

Davenport (1957), writing six years later, had this to say "In agreement with Conway" (1953) "and many others, I suspect that the secretory process itself is a cyclic oxidation and reduction. A carrier molecule within the cell combines with high energy phosphate. The product is oxidized and the energy contained within it is dissipated in transporting the newly released proton" (hydrogen ion) "against a concentration gradient into the gastric juice. Then the carrier is reduced by substrate and is ready to reenter the cycle. Two minor problems remain. For each proton secreted an electron must be taken up by oxygen, and the pH of the cell must be kept down by intracellular neutralization using the carbon dioxide mechanism." "Carbonic anhydrase which occupies a peripheral position is involved, an enzyme behaving like succinoxidase is there, and it is likely that some sulphhydryl compound is essential." Davenport, like Davies, recognizes the need for assuming appropriate orientation of the various components involved in the reaction (Dr Davenport's concept is illustrated in figure 37.5).

Davies (1951) considers that, the rate of transport of water by the oxyntic cells is so enormous that it could not be handled molecule by molecule by any known enzyme systems. The water must be moved in bulk, and probably flows osmotically as a result of the secretion of the hydrogen and chloride ions by the oxyntic cells."

Fig. 37.5 Schema of a possible mechanism of gastric acid secretion showing the four essential parts a) generation of high energy phosphate bounds from substrate and oxygen, b) cyclic oxidation and reduction generating hydrogen ions, c) removal of electrons to oxygen, and d) intracellular neutralization by carbon dioxide. From Davenport, 1957 (Courtesy of University of Wisconsin Press)

REGULATION OF GASTRIC SECRETION

Methods of Study

Studies of the regulation of gastric secretion offer some difficulty because of the fact that gastric juice is secreted in only small amounts in the fasting stomach and that secreted during digestion is always contaminated with food. This difficulty was overcome by Pavlov (1910) who devised a method for collecting pure gastric juice from the fed animal. This is accomplished by making an incompletely separated pouch of part of the stomach, now known as a Pavlov pouch. The stomach is divided by an incomplete incision into a larger and smaller portion. The mucous membrane is completely divided but an isthmus of the muscular wall is retained to connect the two parts and serve as a pathway for the vagus nerve fibers that supply the gastric glands. The cut edges of each part are then stitched together so as to restore the continuity of the main stomach wall and to make a closed cavity out of the smaller portion, or pouch, except for a small outlet that is brought out through the abdominal wall to provide drainage for the pouch secretions (fig 37.6). The pouch usually consists of a part of the

FIG 37.6 The Pavlov pouch. Upper drawing shows line of incision to form a flap C cardiac part of stomach. Lower drawing shows the completed operation. S, pouch, the mucous membrane has been reflected to form a partition between the main cavity of the stomach and the miniature stomach. A, A, abdominal wall (after Pavlov)

body and fundus of the stomach. Numerous modifications of the Pavlov pouch have been devised, most of them designed to retain a greater portion of the nerve supply to the pouch than did the original operation devised by Pavlov. A Pavlov pouch, or any one of its modifications, responds to all the nervous and humoral stimuli that affect the main stomach and makes possible the collection of pure gastric juice which can then be analyzed to determine the influence of various stimuli upon the volume and composition of the juice. Although a gastric pouch gives information regarding the secretory activity of only that particular portion of the stomach from which it is excised, pouches may be prepared from any region of the stomach, consequently the method makes possible investigation of the function of any part of the gastric mucous membrane.

If a pouch is completely separated from the main stomach by dividing the isthmus between the two, leaving only the blood supply intact, it is known as a Heidenhain pouch. The Heidenhain pouch is useful for investigating the secretion of a vagally denervated portion of the stomach, it continues to receive a sympathetic nerve supply through the periaarterial nerve plexuses. If an attempt is made to cut the sympathetic fibers as well by stripping the arteries, the pouch is known as a Bickel pouch (Bickel and Katsch, 1912).

Farrell and Ivy (1926) prepared a completely denervated pouch of the stomach by transplanting a portion of the stomach of a dog into the subcutaneous tissue of the animal's abdominal wall. After the pouch had established a new blood supply, they severed its connections with the original nerve and blood supply of the stomach. Such a preparation responds only to humoral stimulation and has been of fundamental importance in demonstrating the chemical nature of many of the stimuli which affect the stomach. "Pouches" have also been made of the entire stomach (the Fremont pouch, Pavlov, 1910), by cutting the stomach off from the esophagus and duodenum and connecting these two organs by means of an end to end anastomosis. The cut ends of the stomach are closed with sutures and a fistulous opening made from some part of the stomach through the abdominal wall.

In the human gastric juice can be collected through a stomach tube, the secretion may be stimulated by means of a test meal or by use of one of the gastric secretagogues such as histamine. Similar methods can be used in unoperated animals but it is simpler and just as satisfactory for most purposes to prepare the animal with a

gastric fistula and in this way avoid the use of a stomach tube

Another of Pavlov's devices for the study of gastric secretion is esophagostomy. In this operation the esophagus is divided by a transverse incision and the cut ends brought to the outside through a wound in the neck (fig 377). After healing, all the food which the animal eats escapes from the lower end of the upper segment of the esophagus and the animal can be fed by placing food in the lower segment through its exposed upper end. The maneuver of feeding such an animal with the consequent loss of food is known as sham feeding. The animal is able to experience all the sensations of eating without getting any food into its stomach.

THE INNERVATION OF THE GASTRIC GLANDS
Stimulation of the vagus nerve causes the secretion of juice high in peptic power and strongly acid. This action is mediated through acetylcholine. According to Alley and Babkin the glands of the lesser curvature respond more readily to vagal stimulation than do those of the greater curvature, and secrete a stronger juice. This fact may be of significance in the development of gastric ulcer (p. 621). Baxter has shown that stimulation of the sympathetic causes the secretion, mainly from the pyloric glands, of an alkaline mucoid juice which is very low in peptic power, this secretion is unaffected by atropine but is annulled by ergotamine (which paralyzes motor and secretory sympathetic fibers). Vineberg's results indicate that the vagus controls the secretion of mucus by the mucous neck cells and the surface epithelium of the gastric mucosa. The influence exerted by the sympathetic upon the peptic and oxyntic cells of the gastric body is not definitely known. According to some observers its effect upon these elements is inhibitory.

THE QUESTION OF THE CONTINUOUS OR INTERDIGESTIVE SECRETION OF GASTRIC JUICE Pavlov found that the secretion of gastric juice in dogs was intermittent, beyond the secretion of some alkaline mucus the gastric glands in the absence of food or psychic influences (see below) remained at rest. This conclusion has been confirmed by the recent experiments of Babkin. But in man, juice is secreted continuously in fairly large amounts, though this fact does not necessarily indicate a fundamental difference between the activities of the glands of the human and canine stomachs. The shorter intervals between meals, and psychic influences which are impossible to eliminate in the case of the human subject, are probably responsible for the continuous and apparently spontaneous

FIG. 377. A two stage operation for making an esophageal fistula. 1 First stage, showing esophagus exteriorized. 2 Second stage, performed four or five days later, showing excision of elliptical segment of anterior esophageal wall. 3 Completed operation, lateral view. (After Dragstedt and associates.)

taneous secretion. This secretion is increased during sleep.

THE PHASES OF GASTRIC SECRETION

Cephalic or Initial Reflex Phase

The fact that there can be an abundant secretion of gastric juice even though there is no food in the stomach is readily demonstrated by means of sham feeding. When an animal provided with an esophagostomy is sham fed secretion of gastric juice begins within 5 minutes and may continue for as long as $1\frac{1}{2}$ hours. If the vagus nerves have been previously cut, sham feeding has no effect on the gastric secretion, proving that secretion in this instance is the result of reflexes for which the vagus serves as the efferent pathway. By collecting the juice from an innervated pouch, Pavlov was able to show that it contains a very high concentration of both hydrochloric acid and pepsin. A similar type of gastric juice is secreted by the empty stomach on electrical stimulation of the vagus nerves. The phase of gastric secretion which results from the sight, smell or taste of food or from the act of eating and which is prevented by section of the vagus nerves is known as the *cephalic, or initial reflex phase*. If the secretion results from the sight or smell of food without the food making actual contact with the mouth it is referred to as psychic secretion. Pavlov referred

to the secretion produced during the initial reflex phase as "appetite juice"

THE PSYCHIC SECRETION IN MAN In man, the cephalic phase causes the secretion of from 50 to 150 cc within 20 minutes (Ivy). Richet (1878) observed long ago that in a subject who had suffered esophageal stricture and into whose stomach an artificial opening (fistula) had been made for feeding purposes, the secretion of gastric juice occurred when food was taken into the mouth. Within more recent years Carlson has carried out extended observations upon a subject who had had a similar operation performed on account of an obstructed esophagus resulting from the ingestion of a corrosive in childhood. This subject therefore was already prepared, like Pavlov's dogs, for sham feeding, the only difference being that there was no opening in the neck, it being necessary to spit out the food after chewing it. All the findings of Pavlov were, in the main, confirmed in the case of this subject. The influence of appetite or the desire for the food was particularly well brought out. The subject especially enjoyed the dessert, and the curve of gastric secretion showed the most pronounced rise when sweets or fruit, such as oranges, were chewed. The secretion, however, did not last for as long as in Pavlov's experiments, but commenced to decline as soon as the stimulation of the taste buds had ceased (fig 378). Nor did the mere sight or smell of food (conditioned stimulus) evoke a response except when in one instance the subject was sent from the laboratory to select his meal from a nearby cafeteria. In this instance there was a very definite response to the sight and smell of the food. Several other observers have reported the existence of definite conditioned reflexes for gastric secretion in man.

The psychic effect upon gastric secretion has been demonstrated also by Bennett and Venables

FIG 378 Typical curve of secretion of gastric juice collected at 5 minute intervals during the mastication of palatable food for 20 minutes. The rise in secretion during the last 5 minutes of mastication is due to chewing the dessert (fruit) for which the person had an especial fondness (After Carlson)

(1920) upon subjects during hypnosis. A suggestion made to the subject that he was eating a savory food called for a secretion of juice. The mere suggestion of nauseating substances inhibited secretion (see below). In experiments upon medical students Hawk and his associates (1920) showed that a meal which had a disgusting appearance and a foul smell (indol was scattered over a dirty table-cloth) retarded digestion.

The application of these experimental results to dietetics is obvious. Foods agreeably flavored and attractive in appearance, impressions received from a meal prepared in a pleasing way, and, probably also, sensations aroused by the surroundings but not directly concerned with the food itself, have all an effect upon gastric secretion. The impulse which guides the gourmet is sounder physiologically than that which impels the glutton. The question of calories and the relative digestibilities of the various foodstuffs should not be allowed to obscure the psychic element entirely in these matters, for the "delights of the table" have true digestive value. These facts are expressed in the words of Pavlov "appetite spells gastric juice" or in the hospitable words of Macbeth. Now good digestion wait on appetite and health on both. Good gastronomical custom seems guided by this truth, for it has decreed that the meal shall begin and end with the more strongly flavored and appetizing dishes.

The Chemical Phases of Gastric Secretion

THE GASTRIC PHASE Pavlov also observed that if food were placed in the stomach without allowing the animal to smell or taste it, there was also a secretion of gastric juice beginning about 15 minutes after the food had been introduced. Usually this required that the animal be fed through a gastric fistula while asleep. Thus, Pavlov considered to be the gastric phase of gastric secretion. It has more recently been described by Babkin (1930) as part of the second, or chemical, phase of secretion. The mechanism of stimulation in the second phase was at first thought to involve local reflexes within the gastric wall, since it occurred in the absence of extrinsic innervation, but after Byliss and Starling discovered secretin Edkins (1906) suggested that a similar excitant for gastric secretion might be produced by contact of food with the gastric mucosa. Extracts of the pyloric mucous membrane prepared by Edkins did indeed stimulate secretion of gastric juice. He proposed that the stimulating substance be known as *gastrin*.

Gastrin was long believed to be a nonspecific tissue extract and to owe its activity to histamine (Sacks *et al.*, 1932), a common constituent of such extracts, but recent work has made it seem highly probable that it is a true hormone, somewhat similar in composition to secretin. It is elaborated by the pyloric mucous membrane of the stomach, and is absorbed and carried in the blood to the gastric glands, stimulating them to secrete (Komarov, 1942). The evidence on this point consists of the fact that extracts have been prepared in a number of laboratories both in America and in Europe which stimulate gastric secretion but do not depress blood pressure as histamine does. Furthermore, the activity of such preparations is not destroyed by histaminase, an enzyme which inactivates histamine. Active material is obtained only from the pyloric portion of the stomach, and, in lesser amounts, from the duodenum. None is obtained from the fundus or the body of the stomach, or from other tissues.

The controversy over the nature of gastrin is reminiscent of the efforts of Popileski during the early part of the century to prove that secretin is a nonspecific tissue extract. He did, in fact, come to the conclusion that secretin is identical with histamine. Although mistaken in his opinion, his efforts were not fruitless for they resulted in discovery of the gastric secretagogue action of histamine, a fact which has been of great service to physiology and medicine (Popileski, 1920).

Secretion formed by pure gastrin stimulation, excluding the nerves, contains less pepsin than that secreted during the initial reflex phase and resembles the secretion produced in response to histamine. Indeed the action on the gastric glands of the most highly purified preparations of gastrin so closely resembles the action of histamine as to suggest a close relationship between the two substances. Bahkin (1938, 1950) has suggested that histamine is liberated in the vicinity of the parietal cells by vagus stimulation. Linde (1950) has gone even farther and concluded on the basis of his experiments with an antihistamine, that gastrin as well as vagal stimulation acts by liberating histamine. According to this concept, both acetylcholine and gastrin possess the capacity to liberate histamine in the vicinity of the parietal cell; the histamine then acting as a stimulus to secretion of water and acid. Whether or not this is the correct explanation, the recent work of Ivy and his coworkers leaves little doubt that histamine or something very similar to it is involved in some way in the secretion of hydro-

chloric acid by the stomach (Ivy and Schayer, 1957; Schayer and Ivy, 1957, 1958).

The effective stimulus for the normal gastric phase of gastric secretion is the presence of food in the antrum. In addition to the chemical substances in the food, such as meat extractives, products of protein digestion and soaps, which excite gastric secretion when present in the antrum, mechanical stimulation of the pyloric portion is a highly effective stimulus. Simple distension with a balloon causes release of gastrin as does the presence of solid objects such as bone chips, or even brass or steel shavings. It is probable that the harmful effect of a coarse diet in peptic ulcer disease is caused more by the mechanical stimulation of the antrum by indigestible food particles than it is by irritation of the ulcer surface itself.

Considerable evidence has accumulated in recent years indicating that the gastric phase of gastric secretion is not a pure chemical phase but that its full functioning is dependent in some way upon the nervous system. Also Uvnäs (1942) and Linde (1950) in Sweden, have brought forward evidence suggesting that efficient functioning of the reflex phase is dependent to some extent on the presence of gastrin. Different investigators have suggested that (1) gastrin is released by stimulation of the vagus nerves, (2) that gastrin is necessary for the secretory effect of the vagus nerves on the gastric glands, (3) that a certain amount of vagal activity is necessary for the secretory effect of gastrin on the gastric glands, (4) that gastrin is released by a local reflex mechanism involving the presence of cholinergic nerve endings in the antral mucosa. Only the last is supported by enough experimental evidence to be considered a fact (Robertson *et al.*, 1950; Gregory and Ivy, 1941; Zelony and Savich, 1911). Thomas (1952) after reviewing the experimental evidence came to the following conclusions:

1. Gastrin is released from the pyloric mucosa by local mechanical and chemical stimuli acting through a cholinergic nervous mechanism that probably comprises Meissner's plexus and its local and central connections.

2. Stimulation of the vagi facilitates the nervous mechanism involved in the release of gastrin and may cause the release of some gastrin in the absence of specific local stimuli.

3. Neither gastrin alone, nor vagus stimulation alone, can cause maximal stimulation of the gastric glands to secrete hydrochloric acid. Abundant

secretion is obtainable only when nervous and hormonal stimuli act simultaneously.

The importance of these considerations lies in the light they shed on the effects of the operations of vagotomy, on the one hand, and of subtotal gastric resection on the other. If the nervous and hormonal mechanisms of stimulation were independent of each other, we should expect that cutting the vagus nerves would influence only the initial reflex phase of gastric secretion and leave the gastric phase in full effect. This is not the result observed, all phases of gastric secretion are profoundly depressed by vagotomy and in a certain percentage of patients permanent achlorhydria results. Likewise, resection of the antrum, or subtotal gastric resection should affect only the gastric phase. Experience proves, however, that the cephalic phase is also profoundly influenced.

A fact first noted by Pavlov and since confirmed by many investigators (Wilhelmj *et al.*, 1936, Dragstedt *et al.*, 1951, Oberhelman *et al.*, 1952) is that the pyloric mucosa not only has the capacity to stimulate gastric secretion but also to inhibit it. Pavlov described the phenomenon as follows: "with the same dogs we also discovered a new form of autoregulation on the part of the stomach, which concerns the secretion of hydrochloric acid. It appears that acid prevents the further secretion of gastric juice when it has accumulated in any considerable quantity within the cavity of the organ." Dragstedt showed that hydrochloric acid in the stomach has to be in contact with the pyloric mucosa in order to produce inhibition. Whether it releases an inhibitory hormone or merely stops the production of gastrin by the pyloric mucosa is still unknown. Acid in the duodenum also inhibits gastric secretion (Wilhelmj *et al.*, 1934, Uvnäs *et al.*, 1956) provided the pH of the duodenal contents is lowered to 2.5 or below (Pincus *et al.*, 1942).

THE INTESTINAL PHASE The inhibitory effect of fat. Pavlov observed also that the presence of certain food substances in the small intestine stimulated gastric secretion. This so-called intestinal phase has been extensively investigated by Babkin (1928, 1950) and his coworkers and others. The following substances have been found capable of exciting gastric secretion when placed in the small intestine: water, extractive substances of meat, products of protein digestion, (for example, peptone and amino acids), milk, alcohol, histamine, saponin, adrenaline, 1:10 normal hydrochloric acid, 10 per cent glycerine solution and magnesium sulfate. The intestinal phase

is regarded as being quantitatively unimportant and is somewhat temperamental, being present only under certain conditions. For example, in the experiments of Beamer *et al.* (1944), introduction of a peptone solution into the intestine caused no gastric secretion unless bile was present. In the presence of bile it caused a flow of gastric juice after a latent period of about 2 hours. The long latent period is also characteristic of the intestinal phase described by Webster and Armour (1932).

Most experiments on the intestinal phase of gastric secretion have been done, for obvious reasons, on animals in the fasting state with the stomach empty. The results may be quite different when the intestinal phase occurs in its proper sequence following a cephalic and a gastric phase. The known tendency of stimuli of different sorts to act synergistically in the gastrointestinal tract suggests, but does not prove, that the stimuli normally causing an intestinal phase may be much more effective in the presence of the residual stimuli of the cephalic and gastric phases.

The cause of the intestinal phase is unknown, except that it is due to chemical stimuli. The evidence on this point is due to the ingenious experiments of Gregory and Ivy (1941) who used a denervated pouch of the type described by Farrell and Ivy. This completely denervated gastric pouch secreted when food was placed in the intestine, proving that it was secreting in response to some chemical substance circulating in the blood. The stimulus may be a hormone or it may be secretagogues absorbed with the food from the intestine, as suggested by Babkin (1950).

Perhaps one reason for the somewhat erratic behavior of the intestinal phase of gastric secretion is the ease with which inhibition of secretion may be induced by placing certain substances in the intestine. The inhibitory effect of acid has already been mentioned. Although acid in certain concentrations may stimulate gastric secretion, if the intestinal pH is lowered to 2.5 or below it acts as an inhibitor. The most potent inhibitor of gastric secretion is fat in the intestine. Fat in the stomach is without inhibitory effects but as soon as it passes the pylorus gastric secretion begins to diminish and, if the quantity of fat is large, may cease all together. The inhibition lasts as long as the fat remains in the intestine but after the fat is absorbed the inhibition is followed by a pronounced increase in gastric secretion, the so-called rebound phase of fat inhibition. The inhibition and subsequent stimulation of secretion

by fat is known as the *biphasic* effect of fat. The stage of increased secretion which follows the inhibition is believed to be due to release of gastrin by the soaps which have regurgitated into the stomach from the intestine during digestion of the fat. Were it not for the rebound phase, fat would be a most useful substance for controlling gastric secretion, even so, it can be used successfully if given in small amounts at frequent intervals over a long period of time. The use of cream in this way is the basis of one form of treatment of peptic ulcer.

Enterogastrone The mechanism of inhibition of gastric secretion by fat was elucidated by Lam (1933, see also Kosaka and Lam, 1930), who showed that if the intestinal mucous membrane was exposed to fat, and then extracted, the extract caused inhibition of gastric secretion when given intravenously. Kosaka and Lam suggested that the inhibitory substance be called "enterogastrone." The substance has since been studied extensively by Ivy and his students in Chicago and it is to their work that we owe most of our knowledge of its chemical and physiological properties, as well as the first demonstration of the humoral nature of the inhibitory effect of fat on gastric motility (Farrell and Ivy, 1926, see also Ivy and Gray, 1937). Enterogastrone has never been obtained in pure form, hence, its chemical composition is unknown. Since it inhibits motility as well as secretion and the relative effect on the two functions differs in different preparations, it is probable that more than one substance is involved. Enterogastrone or some similar substance is excreted in the urine and is given the name "urogastrone."

Regulation of Gastric Acidity

As we have seen, the hydrochloric acid of the gastric juice is probably secreted at a constant concentration of approximately 170 meq per liter. Ordinary gastric juice, however, is considerably less acid than this and after a meal the gastric contents are still less acid. In dogs after a meal of raw meat, which is a powerful stimulus to gastric secretion in these animals, the contents of the body and fundus of the stomach usually have a pH between 1 and 2 and the contents of the pyloric portion between 2 and 3. The decrease in acidity is undoubtedly due to a combination of factors which may be classified for convenient discussion as intragastric and extragastric. Perhaps the first intragastric factor to become effective is exchange of hydrogen ions for sodium ions by diffusion through the gastric mucosa. This

factor has been emphasized particularly by Teorell (1947). There is no doubt that such diffusion takes place but its relative importance in regulating gastric acidity has never been determined. Another intragastric factor is the non-parietal secretion of the gastric glands, including the fundic and pyloric glands and the surface epithelium of the stomach. All the cells, other than the parietal cells, secrete a fluid which is either neutral or alkaline. The neutral secretions dilute the acid, and the alkaline secretions particularly those containing mucin, tend to neutralize some of it. In both cases the effect is to lower the acidity. Even though the non-parietal elements of the gastric glands, particularly the chief cells, may secrete very little water they do secrete protein which is an excellent buffering agent.

Among extragastric factors we recognize swallowed saliva and regurgitated duodenal contents as tending to reduce the acidity of the gastric contents. Very considerable quantities of saliva are swallowed with the food and although it may not be alkaline in reaction it does contain considerable quantities of mucin and other protein substances and so will tend not only to dilute but to buffer the gastric contents. Regurgitation of duodenal contents into the stomach occurs regularly after a fat meal and in the presence of high gastric acidity. It occurs at irregular and unpredictable intervals under other circumstances. The mechanism of duodenal regurgitation will be discussed in connection with gastric emptying in chapter 41. Since the regurgitated intestinal contents contain alkaline secretions from the pancreas and the intestinal mucosa they can exert a considerable influence on gastric acidity.

Undoubtedly the most important factor in lowering the acidity of the gastric contents after a meal is the food itself. Native protein, being an amphoteric substance, is an excellent buffer and as digestion progresses the number of amino groups available for neutralizing acid increases enormously. As the food becomes liquid and mixes with the gastric juice it also has a diluting effect so that during digestion of a normal meal the gastric mucosa is well protected from excess acidity. It may also be mentioned in this connection that the tough layer of mucus which adheres to the surface epithelial cells serves to protect these cells from the action of hydrochloric acid as well as from the mechanical trauma to which they might be subjected by coarse food or other swallowed substances.

FIG. 37.9 Reconstructed curves to show the approximate distribution between the several phases of the gastric secretion in a dog after a meal of 300 grams of meat. I Cephalic or initial reflex phase, II Gastric or pyloric phase, III Intestinal phase. Thomas and Friedman 1951 (Courtesy of W B Saunders Co Philadelphia)

The Normal Course of Gastric Secretion

With the above facts in mind we may consider the sequence of events affecting the secretion of gastric juice following a normal meal. First, there is the sight and smell, and the taste of food which, if agreeable and if the individual has an appetite, will initiate the psychic or cephalic phase of gastric secretion. This phase is augmented when the food is actually chewed and swallowed. The first juice secreted has powerful digestive action, particularly upon the protein constituents of the food, and releases from the food chemical excitants for the second or chemical phase of secretion. These, along with the mechanical action of such food particles as enter the pyloric antrum, cause the release of gastrin which augments and prolongs the secretion due to the cephalic phase and initiates the gastric phase. The gastric phase of secretion continues as long as food remains in the stomach. As soon as the stomach is empty and the buffering substances present during digestion are no longer available the pH of the antrum or duodenum falls to a point at which the inhibitory effect of acid becomes evident and that period of gastric secretion is brought to an end. If there is some defect in the mechanism that regulates the flow of hydrochloric acid so that it continues after the stomach is empty, a condition of hypersecre-

tion or continuous secretion is said to be present, and this may lead to ulceration of the gastric or duodenal mucous membrane.

The relative importance of the several phases of gastric secretion is indicated in figure 37.9.

GASTRIC DIGESTION—Continued

Applied Physiology

GASTRIC ANALYSIS

Study of gastric secretion in the human subject requires use of a gastric tube unless one is fortunate enough to have access to a patient with a gastric fistula, such as Alexis St. Martin, who was studied by Beaumont. St. Martin was injured by the accidental discharge of a shotgun, the shot tore a hole in his side and carried away a part of his stomach. On recovering from this wound he was left with a permanent gastric fistula and much of our elementary knowledge of gastric function we owe to the careful observations that William Beaumont, who was at the time a military surgeon in the United States Army, made on his patient. Other studies on gastric fistula patients have since been made in physiological laboratories. A. J. Carlson (1923) had three such subjects available in his laboratory at the University of Chicago. More recently, Wolf and Wolff (1943) have reported their observations on the now famous Tom Little.

A great variety of stomach tubes have been used from time to time, the tendency in recent years being toward tubes of smaller size, number 12 French gage is a common size. Very recently plastic tubes have come into use, they have the advantage over rubber tubes that the wall can be thinner and the size of the lumen greater for a given outside diameter. Since they are cheap they need not be re-used and hence are thrown away and not re-sterilized. If the patient is unconscious or, for any other reason unable to swallow the tube, it may be passed through the nose. Passage of the tube through the nose has certain advantages particularly if the tube has to remain in place for a long period of time. A tube in the nose will cause less discomfort over a period of time than one in the mouth and is less likely to be bitten or otherwise damaged by the patient.

The tube is usually passed when the stomach is empty, the patient being fasted for this purpose. The volume and acidity of the fasting gastric contents vary a great deal in normal in-

dividuals, but it is rare in the human to find the stomach completely empty or entirely devoid of hydrochloric acid. From 20 to 40 cc of gastric juice are commonly found in the fasting human stomach and the acidity of the fasting secretion will ordinarily range from 0 to 20 or 30 clinical units (m eq per liter) of so-called free hydrochloric acid. After the stomach has been emptied it is customary to give the patient a small meal called a test meal of which a great variety are in use. Typical test meals are 300 ml of oatmeal gruel, a piece of dry toast and a cup of tea, a shredded wheat biscuit or a piece of toast with 350 to 400 ml of water, two slices of bread with out the crusts, arrowroot biscuits with tea or water, (Machella, 1951).

Fractional Gastric Analysis

Fractional gastric analysis was introduced by Rehfuess (1914) and his associates and is now in common use wherever gastric analysis is done. Beginning about 30 minutes after the test meal has been eaten, samples (usually 10 ml) of gastric contents are removed from the stomach through the tube by suction at intervals which may be 15 or 30 minutes. Each sample is placed in a small flask and set aside for subsequent analysis. Taking of samples is continued for 2½ hours at the end of which time the stomach is completely emptied through the tube. The samples are then analyzed for free and total acidity and for peptic activity. Other tests may be done as indicated.

The words *free acid*, *total acid* and *combined acid* were coined at a time when we had little understanding of the nature of acidity and little knowledge of ionization and the nature of buffers. They were based on the concept that a certain fraction of the hydrochloric acid exists free in solution, a certain other fraction exists in combination with protein or other acid absorbing substances and that these fractions could be distinguished by the use of indicators. We realize now that the indicators merely tell us when the solution has reached a certain pH.

It is customary to titrate the gastric contents first to pH 3.5 using dimethylamino-azobenzene as an indicator. This indicator changes from red to yellow somewhere between pH 3 and 3.5. The amount of acid indicated by titration to this level is spoken of as free hydrochloric acid. Free acid may be defined as the acid equivalent of the amount of standard alkali necessary to bring the pH of the solution to 3.5. It is expressed in clinical units (which is the number of milliliters of 0.1 normal base needed to titrate 100 ml of gastric contents to the desired pH). Another sample is titrated with phenolphthalein as the indicator. This indicator changes to a pink color between pH 8 and 9. The amount of standard alkali needed to titrate to this pH is a measure of the total acidity also expressed in clinical units. The difference between free and total acidity is the combined acid. The combined acid is, of course, a measure of the buffering capacity of the gastric contents and will be influenced by the type of food and the amount of mucus and other buffers that happen to be present. Sometimes the acidity of the gastric contents is expressed in pH units, this is a useful notation when the acidity is low, but gives less information than the conventional notation when free acid (so-called) is present (James, 1957).

If no free acid appears in the gastric contents after a test meal it does not necessarily prove that the subject is achlorhydric, that is, one who secretes no hydrochloric acid. To detect true achlorhydria it is necessary to use a more powerful secretory stimulant such as histamine or one of its analogs.

THE HISTAMINE TEST

As a test of gastric secretion the parenteral administration of histamine has certain very definite advantages over the ordinary test meal: (a) Histamine evokes a maximum secretory response and is often able to evoke a response when the test meal fails to do so (see below). It is thus of value in distinguishing false from true anacidity. (b) The response is not affected by conditions such as appetite and other psychic factors which influence the response to the test meal. (c) The test meal and salivary secretion (the latter cannot be measured) add to the volume of the contents, it is therefore impossible to determine accurately the quantity of juice secreted. (d) Swallowed saliva and the test meal itself partly neutralize the acid. (e) In the histamine test the glands respond promptly, maximal acidity being reached within 20 or 30 minutes; therefore, almost pure juice is obtained for analysis and neutralization factors and gastric evacuation exert a minimum influence. The test is usually performed the first thing in the morning with the subject fasting. In a subject of average weight about 0.25 mg is injected.

THE ISO-SECRETORY OR NORMAL CURVES OF GASTRIC ACIDITY

If in a normal person the free and total acidities of the gastric contents are determined every 15 minutes for a period of from 2 to 3 hours after the ingestion of a test meal, the results plotted against time along the base line with HCl percentages or clinical units in the vertical axis, a curve is obtained as shown in figure 38.1. The

FIG. 38.1 Normal curves of gastric acidity following a test meal (Redrawn from Maclean.)

curve for total acidity commences to rise a short time after the meal, and about 1 hour later reaches a maximum which varies from 35 to 70 in different persons. The curve maintains its maximal height for half an hour or less and then commences to decline reaching the resting level again in from 2½ to 3 hours after the ingestion of the test meal. The curve of free acidity runs parallel to, but at a lower level than that for the total acidity, the values ranging in different normal persons between 20 and 40 (0.07 to 0.15 per cent). Values are much higher after foods, such as meats, which stimulate gastric secretion more powerfully, averaging from 80 to 120 for total and from 60 to 100 for free acidity.

The figures given above represent the range of the great bulk of normal persons, but the gastric acidities show very wide individual variations in health, being influenced markedly by age and sex. The average free and total acidities (after a test meal) in young healthy males are about 40 and 65, respectively (see figs. 38.2 and 38.3). They are somewhat lower in females. They are also lower in children, the adult level being reached at about the age of 20 years. In men after 30 years and in women after 50 years a progressive decline in acidities (total and free) occurs and the incidence of anacidity and of subacidity increases sharply. A high normal value for gastric acidity is regarded by some as an index of physical fitness, the level tending to be low, it is said, in persons of sedentary habits and poor muscular development.

HYPOCHLORHYDRIA (SUBACIDITY) AND ACHLORHYDRIA (ANACIDITY)

When the stomach contents give values persistently below 20 'clinical units' (0.05 per cent) for free HCl after test meals the condition is spoken of as *hypochlorhydria* or *subacidity*. The complete absence of free HCl is referred to as *achlorhydria* or *anacidity*. Bennett and Ryle in a study of 100 healthy male subjects (medical students) found achlorhydria present in 4.0 per cent. In the general run of hospital cases without gastric disease or pernicious anemia 14 to 20 per cent show anacidity. It has already been pointed out that the absence of free hydrochloric acid from the stomach contents may be simply the result of excessive neutralization and not of the suppression of acid secretion. Again, there may be no secretion of acid after a test meal yet the glands respond to the more powerful stimulus of histamine, anacidity of this character is called *false* or *apparent anacidity*. The failure of acid to appear after the injection of histamine is referred to as

FIG. 38.2 Normal standards. The shaded areas represent the limits within which lay 80 per cent of the data for free and total acid at the different ages. The heavy lines represent modes. (After Vanzant, Alvarez and associates.)

FIG. 38.3 Percentage decline of mean gastric acidity with advancing years (males). (After Poland.)

true anacidity. The figures given above as reported by Bennett and Ryle for anacidity in healthy subjects as well as those given for hospital cases do not permit a distinction to be drawn between the two types of the condition since test meals were used in the investigations. It is therefore impossible to say in what proportion of the cases true anacidity existed. The incidence of true anacidity appears however, to be less than 1 per cent in young healthy male subjects and not more than 1 or 2 per cent in the case of young healthy females.

In cases of anacidity the peptic concentration of the gastric juice though usually low is in some cases not far below the normal value—further evidence that the secretion of acid and of pepsin are governed by independent mechanisms. Complete

absence of both acid and pepsin from the gastric contents is called *achylia gastrica*.

The incidence of anacidity, both apparent and true, shows a definite increase with advancing years up to the sixth decade. Vanzant Alvarez, and associates, in an investigation of a large series of patients without gastric disease, found it present in from 25 to 35 per cent between the ages of 60 and 70 years. Females showed a higher incidence than males. After the sixth decade some reduction in the frequency of the condition was observed (see figs 38.2 and 38.4).

Anacidity in the majority of instances gives rise to no gastric symptoms and is compatible with perfect health. In some cases it is associated with flatulent dyspepsia and occasionally a persistent diarrhea (gastrogenous diarrhea) which is relieved by the administration of acid.

The following are the chief pathological conditions associated with anacidity.

(a) *Pernicious anemia*. Achlorhydria is a constant phenomenon. Pepsin is also usually absent. Histamine is ineffective.

(b) *Carcinoma of the stomach*. There is anacidity in over 60 per cent of cases. It is due to the chronic gastritis and atrophy of glandular tissue. This, it is believed, precedes by a variable period the development of the growth. The anacidity may be either false or true.

(c) *Chronic gastritis* causes a gradual depression of the secretory function and may lead finally to its complete suppression.

(d) Hypochlorhydria or achlorhydria may also occur during acute fevers, in malnutrition, gall-

bladder disease, Addison's disease, sprue, acne rosacea and chronic arthritis.

HYPERCHLORHYDRIA AND HYPERSECRETION

"There is no disease known capable of inducing true gastric hyperacidity" (A. J. Carlson, 1923). "The concept of hyperacidity unquestionably lacks actual foundation" (B. Ihre, 1938). Nevertheless "hyperacidity" is a clinical entity and should be defined. In clinical hyperacidity the free acid has a value of from 60 to 90 after a standard test meal, and may, instead of declining in the second hour, remain high or continue to rise. The high acidity of the gastric contents does not mean that the juice as secreted by the gastric glands is excessively acid. So far as is known the normal maximum of from 0.5 to 0.6 per cent of hydrochloric acid in the gastric secretion is never exceeded. The high acidity of the gastric contents is due either to the secretion of an abnormally large quantity of juice (hypersecretion) or to impairment of the factors regulating gastric acidity (p. 609), e.g., failure of the secretion rate to become reduced during the second hour, or delayed gastric evacuation.

Acute episodes of hyperacidity may be caused by dietary errors or alcohol. The worst offenders among the foods are the fats, since the secondary hypersecretion which they cause is apt to occur after most of the buffering agents have left the stomach. Dilute alcohol introduced into the gastrointestinal tract by any route of administration stimulates secretion of highly acid gastric juice (Beazell and Ivy, 1940). Strong solutions are said to stimulate mainly secretion of mucus (Babkin, 1950). Since alcohol has no capacity to buffer acid, it is very likely to cause some degree of hyperacidity unless taken with food or other buffering agents. Excessive use of coffee may also cause hyperacidity, since caffeine has been shown to stimulate secretion of gastric juice (Roth and Ivy, 1944).

A much more serious problem is the chronic hypersecretion frequently associated with duodenal ulcer disease which is particularly evident when the gastric secretion is collected during the night (Kursner *et al.*, 1959). The cause of continuous gastric secretion in the absence of food is one of the great unsolved problems of medicine. In general there are two main points of view, each with numerous variations. One is that hypersecretion is the result of duodenal irritation, either by a chronic ulcer or by some condition that may ultimately lead to ulcer (Ivy and Bachrach, 1940; Grossman, 1951). It has been suggested

FIG. 38.4. Curves showing the relation between the incidence of achlorhydria and age (After Vanzant, Alvarez, and associates.)

that duodenal irritation may cause release of histamine which, when carried by the blood to the stomach excites the parietal cells as does exogenous histamine. Opposed to this view is the evidence that in many ulcer patients hypersecretion is evident even when the ulcer is "inactive," that is, not causing symptoms.

A much more widely held theory is that the hypersecretion is primary and the duodenal irritation or ulceration, if it occurs, is secondary to the chronic hyperacidity (Dragstedt, 1944). In support of this view is the well known fact that duodenal ulcers heal only after the hyperacidity has been corrected. The argument is weakened somewhat by the fact that gastric ulcers are usually associated with hypoauidity and could not, therefore, be due to primary hyperacidity although they are, like duodenal ulcers, favorably influenced by antacid treatment (Atkinson and Henley, 1955).

Among the possible causes of primary gastric hypersecretion, excessive use of tobacco, coffee or alcohol have been suggested (Ivy *et al.*, 1955). Proof of a significant association of these agents with chronic hypersecretion is lacking. Excessive use of coffee, tobacco or alcohol is often indicative of a state of nervous tension or anxiety which, of itself, may cause hypersecretion. Since they undoubtedly aggravate the disease in susceptible persons, limitation of their use is generally considered necessary in the treatment of diseases associated with so called hyperacidity.

Although the causes of primary hypersecretion are unknown, thinking in recent years has tended to crystallize on the concept that it represents a continuation of the cephalic or reflex phase of secretion into the interdigestive period (Dragstedt, 1942). This concept focuses attention on the central nervous system and its relations to the autonomic nerves. From this we derive the psychosomatic theory of gastric hypersecretion and ulcer disease, discussed in a later section.

The neutralization test. This test is of value in investigating the acid regulating mechanism in duodenal ulcer, especially in determining the success or failure of an operation performed for its cure. Instead of stimulating gastric secretion by a test meal or histamine injection, 300 cc of 0.5 per cent hydrochloric acid solution are introduced through a rubber tube into the fasting stomach after its contents have been removed by aspiration. Samples of the acid solution are withdrawn from time to time as in the ordinary method of fractional gastric analysis and the total acidities determined. The results are plotted and the

curve compared with a normal standard curve. In the normal subject the total acidity falls from a value of 130 at the beginning of the test to around 40 within an hour or so. In cases of duodenal ulcer the total acidity falls more slowly and may be 70 or more after the lapse of 3 or 4 hours.

ESTIMATION OF PEPTIC POWER

The earliest method of determining the peptic activity of a sample of gastric juice was introduced by Vett in 1889. Egg white is drawn into a glass tube of 1 mm bore and a few inches long. The albumin is coagulated by placing the tubes in water at a temperature of 85°C and leaving them until the water has cooled. The tubes are then broken into sections about an inch long and immersed in the gastric juice diluted 1 to 15 with N/20 HCl and incubated at a temperature of 37°C for 24 hours. After this time the length of the column of digested albumin at each end of the tubes is measured in millimeters under the low power of the microscope and the average of a number of measurements taken. The peptic power of the sample is expressed in accordance with Schutz's law which states that the amount of proteolytic enzyme present is proportional to the square of the number of millimeters of digested albumin. Therefore if the average length of the digested column is 2.5 mm, the peptic power of the undiluted juice will be $2.5^2 \times 16 = 100.0$. This is the average normal value.

Anson and Mirsky's method utilizes hemoglobin as the substrate. After the juice has acted upon the hemoglobin for 10 minutes the undigested protein is precipitated with trichloroacetic acid and removed by filtration. The quantity of protein split products, which is a measure of peptic activity, is estimated colorimetrically after the addition of phenol reagent.

THE EFFECTS OF VARIOUS CHEMICALS AND DRUGS UPON GASTRIC SECRETION

Alkalis in general have been held to exert a depressing effect upon the secretion of gastric juice. Sodium bicarbonate, for instance, a favorite ingredient of digestive mixtures was investigated by Pavlov in dogs and found to be definitely inhibitory. This observation has been confirmed by Farrell, though others find that the inhibitory effect does not occur unless the dose is excessive, and that in small repeated doses it augments the secretion (Boyd). This seems to be true also of other alkalis, large doses depress but small doses, especially if repeated, may augment the flow of juice. Nor does the inhibitory effect of large doses persist after their discontinuance; on the contrary, hypersecretion not uncommonly follows ("acid rebound"). The value of alkalis in gastric disor-

ders depends chiefly, however, upon their antacid properties, i.e., upon their ability to neutralize or buffer the acidity of the gastric contents rather than to depress secretion. For this purpose the unabsorbable alkalis, such as aluminum hydroxide and magnesium silicate are preferable to such substances as sodium bicarbonate and calcium carbonate which can be absorbed from the intestine. In the doses necessary to exert an appreciable effect on gastric acidity the soluble alkalis can cause profound changes in the acid base balance of the body and have been known to produce severe alkalosis. The insoluble antacids do not affect the acid base balance of the body, and because of their slower and more prolonged action they are less likely to cause an acid rebound in the stomach. Incidentally, the acid rebound effect is now believed to be due to the temporary absence of the inhibitory effect of acid in the antrum following neutralization of the gastric contents by the alkali.

The various preparations of *buffers* are without any appreciable effect upon secretion unless they contain alcohol. *Acids* depress gastric secretion which is completely inhibited by the introduction into the stomach of a 1 per cent solution of hydrochloric acid (p. 609). Acid also exerts an inhibitory effect from the intestine upon gastric secretion. When introduced into the dog's intestine gastric secretion from a Pavlov pouch is inhibited. *Condiments* have little direct effect, but act indirectly in adding flavor to the food, stimulating the taste buds and thus encouraging the psychic secretion. *Histamine* is one of the most powerful stimulants of gastric secretion. Histamine liberated within the body, e.g., in dermatophism or even by the immersion of the hand in cold water at a temperature of 18°C. causes a detectable secretory response within 15 minutes. Gastric secretion is not inhibited by such antihistamine drugs as *neointerger* and *benadryl*, and most other agents of the same class, of the few which are antisecretory the dose required must be inordinately large. *Caffeine* and *alcohol* are strong secretory stimulants. The latter has a pronounced secretagogue action, causing the secretion of a juice of high acidity and rich in mucus. It is possible that alcohol exerts its secretory action through the liberation of histamine, for it has been shown that the histamine output of the perfused lung of the guinea pig is increased by the addition of alcohol (2 to 6 per cent) to the perfusion fluid. *Liver extract*, *meat*, and *vegetable extracts* generally are powerful excitants of the gastric glands, an action which they owe to the

presence of secretagogues. *Insulin* (through its hypoglycemic effect on the vagus center), *acetylcholine* (usually), *mecholyl* (*acetyl-β methylcholine chloride*), *pilocarpine* and *nicotine* are secretory stimulants, whereas *belladonna* or its alkaloids *atropine* and *hyoscyne*, and *hyoscyamus* or its alkaloid *hyoscyamine* are secretory depressants. *Atropine* or *vagus* section depresses or abolishes the cephalic secretion, the drug reduces somewhat, but does not suppress, secretion due to histamine, alcohol, or caffeine.

Atropine, although it depresses gastric secretion, is not a practical drug to use for control of gastric acidity because, in the doses required to have an appreciable effect on the secretion of gastric juice, it has intolerable side actions such as acceleration of the heart, dilation of the pupil, paralysis of accommodation etc. Recently a number of synthetic drugs with actions on the stomach similar to those of atropine have become available commercially. Many of these possess a greater action on gastric secretion and motility and have less effect on other peripheral structures than atropine so that their use for regulation of gastric secretion becomes feasible. These drugs are known generally as parasympatholytic drugs.

There is a widespread clinical impression that smoking tobacco increases gastric secretion and gastric acidity but the experimental evidence is not convincing. Conflicting results have been reported by equally competent investigators but the available evidence suggests that smoking one or two cigarettes increases gastric acidity in a majority of persons whereas smoking several cigarettes or smoking for a long time depresses gastric secretion. Such a result would be in accord with the known fact that nicotine in small doses stimulates *voluntary* gagging whereas larger doses cause depression. The immediate effect of morphine is to depress gastric secretion but it causes gastric retention and hence tends to prolong the gastric phase and thus to increase the total secretion. Adrenergic blocking agents do not affect gastric secretion.

INFLUENCE OF VITAMINS AND HORMONES ON GASTRIC SECRETION

Vitamins

Little is known of the effect of vitamins, or vitamin deficiency, on gastric secretion. *Achlorhydria* has been observed in severe thiamine deficiency (*ber-ber*) and the claim has been made that *achlorhydria* can be cured by administration of vitamin A (Foldes and Vajda, 1941; Schödt,

1934, 1935) However, Dyer and Roe (1941) found that acute or chronic vitamin A deficiency had no effect on the ability of rats to secrete hydrochloric acid or mucin in their gastric juice when the amount of secretion was expressed in terms of body weight Babkin and his associates (1940) found that vitamin D in excessive doses depressed gastric secretion but this was apparently due to the considerable increase in blood calcium concentration which resulted from administration of the vitamin. In their experiments only the reflex phase of secretion was effected by the hypercalcemia Other studies on the effects of the blood calcium level on gastric secretion indicate that the normal blood calcium level of 10 mg per cent is optimum for secretion of gastric juice, any considerable change in this level whether in the direction of increase or a decrease depresses gastric secretion

Hormones

The effect of changes in blood calcium on gastric secretion has already been mentioned, these changes can be induced by administration of Parathormone as well as by administration of vitamin D and with the same results Hypophysectomy causes characteristic changes in the chief cells of the gastric glands consisting of a decrease in the size of the nucleus, and loss of most of the pepsinogen granules Adrenalectomy also causes involution of the zymogen cells and diminishes the output of pepsin in the gastric secretion (Baker and Abrams, 1954) Gastric acidity is diminished following adrenalectomy, indeed in human subjects adrenalectomy results in a very low level of gastric secretion (Gray, 1958) Secretion of hydrochloric acid is also reduced by hypophysectomy in rats (Jones and Harkins, 1958)

Great interest is attached to the possible effects of adrenocorticotrophic hormone (ACTH) and the adrenal steroids and the various synthetics that simulate the action of the steroids, on gastric secretion Since these agents have come into general use and some instances of exacerbation of duodenal ulcers have been reported following their use, it is assumed that the ulcers are aggravated by an increase in the volume, acidity, or peptic activity or of all three in the gastric juice The stimulating effect of these agents on gastric secretion has been emphasized by Gray and his associates (1955) They have noted particularly an increase in the output of uropepsin in circumstances in which it may be assumed that adrenal cortical activity is increased either through natural stimuli such as are involved in stress or

through the administration of ACTH or of the steroids themselves, or of their synthetic counterparts Gray and others have also reported an increase in gastric acid secretion under similar circumstances but negative results have also been reported Although the evidence is conflicting it appears that, when given in sufficiently large doses over a considerable period of time, these agents can, and do increase the hydrochloric acid and pepsin secretion by the gastric glands and that in some cases at least this has been a factor in the aggravation of duodenal ulcer disease

Serotonin is a substance, possibly a hormone, secreted by certain enterochromaffin cells found principally in the intestinal mucosa which greatly augments intestinal motility when given intravenously Among its numerous physiological actions it appears to exert an inhibitory effect on gastric secretion, particularly that produced by reflex stimulation or through the action of drugs that resemble acetylcholine The effect of serotonin is of interest in connection with the action of reserpine which has been used as a tranquilizer and in the treatment of high blood pressure Although therapeutic doses of reserpine are said not to influence gastric secretion large doses given for a considerable time do increase the acid output of the gastric glands and it has been suggested that this might be due to serotonin the production of which is increased by reserpine, evidently however, since serotonin inhibits gastric secretion, some other factor is operative in the reserpinized subject (Haverback *et al*, 1957)

Insulin may be considered with the hormones although its effect on gastric secretion is not strictly a hormonal influence on the stomach Insulin, in a dosage sufficient to lower the blood sugar to about 50 mg per cent, has an effect on the gastric glands similar to that of stimulation of the vagus nerves, that is the output of acid and pepsin is increased The effect is due to the rapid decrease in blood sugar concentration which, through some mechanism not understood at present, has a stimulating action on autonomic centers of the brain stem The effect on the stomach is due to stimulation of the vagus centers but sympathetic as well as parasympathetic centers are stimulated by the change in blood sugar The well known insulin convulsions are merely a further manifestation of this general excitatory effect of rapidly induced hypoglycemia

Since the effect of insulin on gastric secretion is dependent upon the integrity of the vagus nerves, the 'insulin test' has been used as a means of determining the completeness of thera-

peptic vagotomy in human subjects (Hollander, 1946) A positive insulin test is proof of the presence of intact vagus fibers but a negative result is less conclusive since some subjects with intact vagi fail to secrete in response to insulin The test has, nevertheless, been of great value in the surgical control of duodenal ulcer

The inhibitory effect of enterogastrone on gastric secretion has already been referred to It may be mentioned here that commercial preparations of enterogastrone have not been successful in the control of gastric hypersecretion in peptic ulcer disease This may be due to the lack of a suitable commercial preparation or it may be that the hypersecretion of ulcer disease is a sign of the failure of the gastric glands to respond to normal inhibitory mechanisms of which enterogastrone is one Enterogastrone is effective mainly against the chemical phases of gastric secretion It has little influence on the initial reflex phase, as we shall see later on it is precisely the initial reflex phase which is believed to be prolonged and augmented in duodenal ulcer disease

LOSS OF GASTRIC JUICE FROM THE BODY

When abnormally large quantities of gastric juice are lost from the body as in pyloric obstruction with persistent vomiting or in intestinal obstruction a profound effect upon the acid base balance of the body is produced There is a fall in blood chloride leading to a state of compensated or uncompensated alkalosis Because calcium salts are less soluble in alkaline body fluids, tetany due to calcium deficiency may occur in uncompensated alkalosis (ch 13) Dragstedt and Ellis (1930) have shown that, in animals, drainage of the gastric juice to the exterior, through a fistula results in a reduction of blood chloride and alkalosis, marked dehydration and a rise in nonprotein nitrogen in the blood, leading to severe depression and death

EFFECT OF EMOTIONAL STATES ON GASTRIC SECRETION

The effect of emotional experience on visceral function was discussed in popular vein by Walter B Cannon in his book on "Bodily Changes in Pain, Hunger, Fear and Rage," (1915) He focused his attention on the inhibitory effects of acute emotions such as sudden fear and anger and for a long time this was considered to be the main effect of emotional states on gastric function The fact that certain types of emotional disturbances could stimulate gastric function, specifically could increase secretion of hydrochloric acid, was

first demonstrated by Wolf and Wolff (1943) in their studies on their modern Alexis St Martin, known as Tom Tom had a gastric fistula which made it possible to observe changes in the gastric mucosa and to note increases and decreases in the secretion of hydrochloric acid When exposed to sudden fear or pain, Tom's stomach became pale and ceased to secrete hydrochloric acid, in accordance with the concept popularized by Cannon, however, when a situation developed which caused prolonged resentment or deep seated chronic anger the opposite effects were observed, the gastric mucosa became congested and the secretion of hydrochloric acid was increased Subsequently, similar results have been observed by a number of investigators on human subjects and on animals Although there are individual variations, the weight of evidence indicates that chronic anxiety, anger, resentment and fear, if sufficiently prolonged, tend to produce effects on gastric function characteristic of increased activity of the parasympathetic division of the autonomic system including increased secretion of hydrochloric acid by the stomach

The central mechanism for these effects is doubtless situated partly in the hypothalamus This portion of the brain has been shown repeatedly to be a center for the coordination of impulses involved in emotional expression (Bard, 1923, 1929, Fulton, 1929) Clark (1932) refers to the hypothalamus as a visceral correlation center and Hess (1947) considers that "in the diencephalon the functions of the various autonomic organs are synthesized into cooperative action" MacDonald (1951), citing the work of Hess, concludes that the hypothalamus is "the head ganglion of the autonomic system"

It has long been known that stimulation of the posterior portion of the hypothalamus brings about visceral responses characteristic of the activity of the sympathetic division of the autonomic nervous system Evidence that the vagi or other parasympathetic nerves could be activated from the hypothalamus has not been so abundant but it is becoming increasingly apparent that parasympathetic effects can be obtained from various regions of the hypothalamus by appropriate stimulating techniques (Strom and Uvnas, 1950) Thus we see that mechanisms exist for the alteration of visceral function, presumably including gastric secretion, as a part of the general phenomena associated with emotional expression

Emotional feeling, as distinguished from emotional expression, involves the cortex Widespread connections between various parts of the cerebral

cortex and the hypothalamus are also known. Connections with the rhinencephalon are particularly abundant and are, no doubt, more deeply involved in our visceral responses to conscious experiences than are most of the other parts of the brain (MacLean, 1949). Since these areas are believed to be primarily concerned with emotional experience they may be of fundamental importance in visceral responses to emotional stimuli. The tracts that connect the hypothalamus directly or by way of the thalamus with the neopallium have been analyzed in detail by Murphy and Gellhorn (1945) who studied the distribution of action potentials resulting from the local application of strychnine to various points in the cortex, thalamus and hypothalamus. In discussing their results they state that certain of the conducting paths that they demonstrated may be said to be tracts of preferential discharge of low resistance. These were paths from the hypothalamus to the cortex and from the cortex to the hypothalamus, both by way of the thalamus, also included were two-way paths between the hypothalamus and the thalamus. The authors suggest that these two-way conduction paths between cortex and hypothalamus may constitute, under some circumstances, "reverberating circuits" by which they mean closed chains of neurons over which impulses may continue to circulate long after the exciting stimulus has subsided.

CHRONIC GASTRIC AND DUODENAL ULCER (PEPTIC ULCER)

Epigastric pain coming on usually in from a half to one and a half hours after a meal and vomiting are the chief clinical features of gastric ulcer. In a certain proportion (about 20 per cent) of cases blood appears in the vomitus (hematemesis).

In duodenal ulcer, pain occurs usually within from 2 to 3 hours after a meal, that is, when the stomach is nearly empty. The onset of the pain is therefore earlier after a light than after a heavy meal. The pain is relieved by taking food.

Pathogenesis

It is generally agreed that the dominant factor in the development of gastric and of duodenal ulcer is the action of the pepsin by hydrochloric acid of the gastric juice. The term peptic ulcer is therefore well chosen. The importance of this factor is evidenced by the following facts:

(1) Apart from the ulcerations caused by some specific disease, e.g., tuberculosis, syphilis, car-

cinoma, etc., ulcer of the gastrointestinal tract is confined to those regions which are exposed to the action of acid. (a) *Gastric ulcers* in the great majority of cases involve the pyloric part of the stomach, they are most frequently situated on the lesser curvature near the incisura angularis or on the anterior or posterior wall in close proximity to this limited area. They are never seen in the dome of the fundus and rarely on the upper part of the greater curvature, these regions it will be noted, are not in contact with acid for any length of time. (b) The lower part of the esophagus into which highly acid juice frequently regurgitates, and the adjacent part of the stomach wall, i.e., the cardia, are sometimes the site of ulceration. (c) *Duodenal ulcer* occurs practically exclusively within the first inch or less of the duodenal cap (p. 692), and nearly always upon its anterior or posterior wall, that is, where the chyme before it has been neutralized by the alkaline juices of the duodenum comes into contact with the mucosa. (d) After gastrojejunostomy the so-called stomal ulcer may occur in the jejunal mucosa in the region of the anastomosis, i.e., where the gastric juice first impinges. (e) In a Meckel's diverticulum which contains ectopic gastric glands an ulcer occasionally forms. The ulcer's site is either in that part of the mucosa of the diverticulum, which does not itself contain acid-secreting glands or in the ileum at the point where the diverticulum opens into it. Matthews and Dragstedt (1932), experimenting with dogs produced an "artificial Meckel's diverticulum" by transplanting a pouch of the gastric wall into the ileum, an ulcer developed in the ileum just beyond the transplant in every experiment. These observations emphasize a curious fact that the commonest situations of ulcer are not in the mucosa which secretes the acid, but in neighboring parts which normally secrete a neutral or alkaline fluid—the pyloric region, duodenal cap, cardiac region, esophagus, jejunum or ileum. The pyloric type of gland extends farther up the lesser curvature than up the greater curvature (fig. 38.5). It has even been suggested that the occurrence of ulcers in the body of the stomach, i.e., in the acid-secreting part of the mucosa, is actually dependent upon the presence of patches of aberrant pyloric glands. (f) Mann and Williamson, employing dogs, excised the duodenum and transplanted it into the ileum thus diverting its alkaline juices away from the region of the pylorus. The cut end of the jejunum was anastomosed to the pylorus. Fourteen out of sixteen animals upon which this operation was performed developed chronic ulcers.

FIG 38.5 Diagram showing the distribution of the parietal (acid secreting) cells in the human stomach. In the black area the proportion of parietal cells was maximal and was taken as 100 per cent, in the cross hatched area on lesser curvature the percentage of parietal cells was 75 per cent, in the shaded area at the fundus 50 per cent and in the white area 0 to 1 per cent. (After Berger, *Amer J Anat*, 1934 54, 87)

in the jejunum just beyond the pylorus. However, Lawley and Ivy found that this operation, if combined with excision of the fundus, or if the alkaline secretions are drained into the stomach, does not cause a jejunal ulcer.

Ulcers have also been produced by inducing continuous secretion of hydrochloric acid by implanting histamine in beeswax under the skin. This results in the continuous absorption of histamine and consequent continuous stimulation of the acid secreting cells of the stomach. Ulcers also occur in the duodenum. True peptic ulcer does not develop in the absence of hydrochloric acid. Although a small acute or subacute ulcer may sometimes develop in the absence of acid, a large chronic ulcer of the duodenum is almost never seen with anacidity, as for example, in pernicious anemia.

(2) There is a definite tendency toward hypersecretion in most duodenal ulcer patients, though not in patients with gastric ulcer. The evidence on this point has been nicely summarized by Grossman (1951) as follows: 'Patients with gastric ulcer show a distinct difference from those with duodenal ulcer in this regard. In gastric ulcer patients there is little or no tendency to secrete excessive amounts of acid, whereas this tendency is distinctly present in duodenal ulcer patients. Thus, both experimentally and clinically, the ulcer associated with hypersecretion of acid is duodenal in location. This hypersecretion of duodenal ulcer patients manifests itself in all types of gastric secretory studies, whether these studies are on the interdigestive secretion during the day or night, or on the secretion in response either to a meal or to drugs such as histamine, insulin or

caffeine. The difference between normal persons and duodenal ulcer patients is greatest in studies on the basal or interdigestive secretion and in the response to caffeine. The response of the ulcer patient to caffeine deserves special mention because it is characterized by being abnormally prolonged as well as elevated.

"There is no sharp dividing line between the secretory level of duodenal ulcer patients and normal persons. Some duodenal ulcer patients secrete no more acid than the average normal person, some normal persons secrete as much acid as the average duodenal ulcer patient. Only a small percentage of duodenal ulcer patients secrete acid at rates higher than the highest level encountered in normal subjects. The difference between the acid secretory rates in normal persons and patients with duodenal ulcers is a statistical phenomenon, the average secretory rate of normal persons is distinctly below the average for patients with duodenal ulcer. The difference is statistically highly significant, that is the probability of its having occurred by chance or random sampling error is low."

In duodenal ulcer the typical findings upon gastric analysis are a fasting juice of greater volume than normal and of high acidity, and a curve of gastric acidity after a test meal which rises well above (20 units or more) the normal maximum. In some cases the stomach empties more rapidly than usual as a result of exaggerated gastric motility, and the curve of acidity after reaching its maximum value falls steeply again. In other instances the stomach empties in the usual time but the curve of acidity is maintained at its maximum as a result of continued gastric secretion—the *plateau type of curve*. In still other instances the emptying of the stomach is delayed as a result of pylorospasm or achalasia (see below), and the curve of gastric acidity instead of falling at the usual time continues to rise—the so-called *climbing curve* (fig 38.6). High gastric acidity is less commonly associated with gastric ulcer, according to Vanzant the acidity is actually a little below the normal average. True anacidity, however, is rarely, if ever, found.

Atkinson and Henley (1955) also found the acidity in gastric ulcer patients to be below the average of normal subjects but Ibre (1938) found it to be essentially normal. The relatively low gastric acidities found in gastric ulcer are probably the result of an associated gastritis and do not necessarily indicate that hyperchlorhydria did not precede the development of the ulcer.

(3) Stimulation of gastric secretion, as by the

FIG 38-6 Chart showing "climbing" type of curve of gastric acidity (After Ryle)

continued administration of histamine or of caffeine (p 618), is one of the most effective experimental means of producing gastric ulcer. Although gastric ulcers are produced experimentally by means of a constant drip over the gastric mucosa of a solution of hydrochloric acid, some pepsin must be furnished by the stomach itself. Irrigation of a loop of jejunum with acid alone will not cause ulceration but this is readily produced by the addition of pepsin to the perfusion fluid.

(4) Measures directed toward the prevention of excessive gastric secretion and toward the neutralization of the acidity of the gastric contents are of outstanding value in encouraging the healing of the ulcer.

Though the importance of acid in the production of ulcer cannot be denied this factor cannot be solely concerned. For one thing, many persons who show hyperchlorhydria do not develop ulcer. "Why in these instances is the gastric mucosa immune to the action of the pepsin hydrochloric acid?" Indeed, the question has often been asked, "Why does not the pepsin hydrochloric acid of even normal gastric juice digest the gastric or duodenal mucosa?" It is also an extraordinary fact, firmly established by several workers, that the tissue of other parts of the intestinal tract or of other organs, though susceptible to the action of acid in their normal situations, are not digested when transplanted into the wall of the normal stomach. Dragstedt and Vaughn, for example, removed areas from the gastric wall of dogs and then sutured portions of the duodenum, ileum, jejunum, colon, spleen or kidney into the gaps.

In no case was the transplanted tissue digested. In the case of the kidney and spleen their gastric surfaces became covered with a layer of gastric epithelium. Sections of transplanted intestinal mucosa were found to be perfectly normal after a period of nine months.

On the other hand, as shown years ago by Claude Bernard (1859), the intact leg of a living frog is digested when introduced through a fistula into the stomach of a dog. Pavy (1923) showed the same thing for the rabbit's ear and Dragstedt and Vaughn have demonstrated that the intact limb of a live frog placed in an extract of frog's gastric mucosa is digested.

Until comparatively recently there has been no convincing or even very plausible answer to the question of why the stomach does not digest its own wall. One explanation offered was that the greater alkalinity of the blood coursing through the vessels of the gastric tubules as a result of the loss of H ions served to neutralize the effect of the acid juice. Others suggested that the immunity of the gastric mucosa to autodigestion is due to its containing an antipepsin. A possible explanation is the presence of ammonia in the gastric wall produced by the action of urease on urea.

UREA UREASE-AMMONIA MECHANISM The presence of ammonia in the gastric contents was observed many years ago (1852) by Bidder and Schmidt, but little significance was attached to the finding until Luck and Seth demonstrated its production in gastric tissue by the action of urease upon urea ($\text{urea} + \text{urease} \rightarrow \text{NH}_3 + \text{CO}_2$), and pointed out the possible role of this mechanism

in neutralizing gastric acid. A rise in blood urea as in renal insufficiency, or after the oral administration of urea is followed by a corresponding increase in the urea + ammonia in the gastric wall, and a rise in the ammonia concentration of the gastric juice. In the gastric mucosa the concentration of urease is higher than in any other tissue, it is found in greatest amounts in the cells of the surface epithelium. FitzGerald and his associates have made an extended study of this mechanism. Hastings and his colleagues found that the total urea content of the body (as determined by urea tagged with C^{14} and an analysis of the expired air for $C^{14}O_2$) was 10 per cent per hour, this was reduced after gastrectomy.

Another factor which may be even more important is the presence of the protective layer of mucus which normally covers the entire gastric mucosa. Hollander (1951) has pointed out that the mucus "adheres to the underlying tissue with great tenacity, is capable of maintaining a considerable thickness instead of flowing off rapidly as the acid secretion does, is generally impermeable to destructive chemical agents because of its cohesiveness and is impermeable to pepsin because of its absorptive properties." Hollander also calls attention to the remarkable capacity of the surface layers of the gastric mucosa to regenerate and to secrete a fresh layer of mucus, should the mucous barrier be broken down at any point.

A CONSIDERATION OF OTHER FACTORS CONCERNED IN THE PRODUCTION OF ULCER. *Bacterial infection*, and interference with the blood supply to the mucosa, either as a result of emboli or thromboses have been thought by some to be responsible for ulcer production. Except perhaps in rare instances, these are no longer believed to play a role. *Tobacco smoking* has been thought in some instances at any rate, to encourage ulcer formation or to interfere with the healing of an ulcer already formed, however, if smoking is conducive to gastric or duodenal ulceration the manner in which it acts is not clear. *Trauma*, although not essential to the production of ulcer is probably often a contributory factor. It is not difficult to believe that in the presence of other causative factors, rubbing of food against the gastric mucosa or the passage of coarse indigestible material into the duodenal cap, will encourage the production of ulcer, or retard the healing of an existing one. Mann and Bollman point out that the site of duodenal ulcer corresponds to the area of mucosa upon which the gastric contents impinge, and, when the gastric movements are energetic, this may occur with considerable force. They found

that the experimental production of ulcer was considerably delayed if the propulsive force of the stomach was reduced by making an hour-glass constriction in the prepyloric region. Ivy and his associates have also shown that in the rabbit coarse food retards the healing of an area of the stomach wall from which the mucosa has been denuded.

The possible effect of trauma upon the blood supply of the gastric mucosa is referred to elsewhere.

The role of stress in the etiology of peptic ulcer—Psychosomeric disease. As our knowledge of the control of visceral function has increased it has become more and more evident that experiences with a high emotional content can adversely affect visceral function to the extent of causing organic disease. Whether or not this takes place depends as much upon the individual and his reaction to his experiences as upon the experiences themselves, but in any case the emotional factor is predominant. Disease traceable to the individual's reactions to his environment, particularly his emotional reactions, are known as psychosomatic diseases. They might better be called psychovisceral diseases (Thomas, 1955) because they generally affect some part of the viscera rather than the external body structures.

The fact that emotional states have an influence on gastric secretion has already been mentioned. The possibility is suggested that various forms of stress can, through this mechanism, cause gastric hypersecretion and thus promote the development of gastric or duodenal ulcers. In this connection some observations of Harvey Cushing (1932) are significant. He reported three cases of acute perforated ulcers with death following removal of cerebellar tumors which possibly had caused injury to the hypothalamus. He concluded that there was a parasympathetic center in the diencephalon, apparently situated near the tuber cinereum from which fibers passed backward to the medulla for relay to the vagus and other autonomic centers. He noted that experimental lesions anywhere in the intracranial course of these fibers were prone to cause gastric erosions, perforation, or ulcers. Similar observations have been reported by Keller (1933-1934) and his associates. It may also be recalled that the stimulation of the hypothalamus in the region of the tuber cinereum is followed by increased movements of the stomach and that hypersecretion and gastric hypertonus are frequently features of duodenal ulcers. That emotional stress is frequently associated with duodenal ulcer is well

known Dragstedt says "for a number of years many investigators have commented on the high incidence of ulcers in those persons whose occupations involve unusual anxiety, stress and strain and on the tendency for healed ulcers to recur during periods of great emotional tension" "On the basis of available experimental evidence on the genesis of ulcers—it seems most probable that the central nervous system plays an undoubted role in causing the disease through increasing the volume of gastric juice"

Reference should be made also to the probable role of the pituitary and adrenal hormones in the response of the viscera to environmental stimuli. These glands are surely involved in reactions of the body as a whole to stress. Specific effects on the gastrointestinal organs of the hormones that are probably released in these reactions are little known or understood, but it is known that acute gastrointestinal ulceration and mucosal hemorrhages are common occurrences in severe non-specific types of stress. Although these have generally been interpreted as being due to activation of autonomic nerves, the work of Gray and his associates (1955) indicates that the adrenal hormones secreted in response to corticotrophin (ch 58) may cause increased gastric secretion and thus play a part in causing duodenal ulceration.

The role of emotional factors (particularly emotionally induced hypersecretion) in gastric ulcer is not so evident although Dragstedt and associates (1954) believe that *gastric stasis*, which tends to cause a prolonged gastric phase of secretion, may be a factor in the production of gastric ulcers. There is no assurance that the etiology of gastric ulcer is the same as that of duodenal ulcer. Indeed there is reason to believe that the two may have quite different causations since gastric ulcer is about as common in women as in men whereas duodenal ulcer occurs with a much higher frequency (about 85%) in males.

The Cause of Pain in Duodenal Ulcer

As mentioned previously duodenal ulcer is characterized by pain which appears several hours after a meal, most commonly at night or in the early morning. The pain is of a burning character and is usually felt somewhere in the epigastrium. Although it is evident that the pain appears at a time when the ulcerated surface is exposed to unneutralized acid from the stomach and, indeed, can be induced experimentally by introducing acid into the stomach or duodenum, the mechanism of its production is obscure. The viscera

are not supplied with pain fibers which can be demonstrated in the healthy subject by any of the ordinary methods of producing pain. The intestines can be cut, burned, or pinched without causing any other sensation than that due to contraction of the smooth muscle in the wall of the gut. Muscle spasm or stretching of the wall causes a characteristic type of pain which is different from that of ulcer pain.

One suggestion as to the cause of ulcer pain is that contact of acid with the ulcerated surface stimulates local reflex mechanisms which initiate muscle spasm in the smooth muscle in the vicinity of the ulcer. The difference in the quality of ulcer pain from ordinary muscle cramp may be due to the greater excitability of the sensory nerves induced by the inflammatory process. Another explanation utilizes this increased excitability and presumes that the threshold has been lowered sufficiently so that direct chemical trauma is capable of causing the sensation of pain, the pain in this instance being attributed to the action of acid on the exposed nerve endings or nerve fibers in the ulcer. One argument in favor of the direct acid irritation theory is that the pain is continuous and not intermittent as is the pain of muscle spasm, for example, intestinal or biliary colic. There is little to be urged against the direct acid irritation theory except the seeming impossibility of the mechanism.

The pain is relieved by the administration of alkali and by such drugs as diminish the secretion or motility of the stomach, these are the belladonna alkaloids and the numerous synthetic parasympatholytic drugs. The pain is also relieved by sympathectomy or vagotomy. The former operation is effective because the visceral afferent fibers including the pain fibers, from the abdominal organs accompany the sympathetic nerves. The latter has an effect like the parasympatholytic drugs, it diminishes gastric secretion and motility. It is interesting that pain can be induced in a vagotomized subject by introducing a large volume of acid into the stomach. Presumably the acid overflows into the duodenum and imitates the usual mechanism of ulcer pain. The success of this experiment is a strong argument in favor of the direct acid irritation theory, but it does not absolutely rule out spasm of the duodenal muscle as a cause of pain, since the vagi do not have a profound influence on the smooth muscle of the small intestine which may still respond by contraction to local irritation.

A point in favor of the muscle spasm theory is the fact that the parasympatholytic drugs relieve

the pain of ulcer even when they fail to suppress greatly the secretion of acid. However this effect as well as the immediate effect of vagotomy may be due to the delayed emptying of the stomach which both induce, thus causing the acid to remain in the stomach where it does not make contact with the ulcer.

Physiological Principles in Treatment of Peptic Ulcer

The treatment of peptic ulcer is directed toward the relief of pain, reduction of the acidity in the gastric and duodenal contents, protection of the ulcerated surface from mechanical trauma, and so far as possible elimination of environmental stress. Unless severe hemorrhage is a presenting symptom it is customary at present to use medical treatment first. Surgery is resorted to if the ulcer bleeds or if complications such as obstruction or perforation develop, it is also used in intractable cases that do not yield to medical treatment. Relief of pain and reduction of acidity are accomplished by administration of alkalis or other antacids such as ion-exchange resins. The parasympatholytic drugs are also effective. The judicious use of food can accomplish the same result. All protein containing foods act as antacids and the fat in milk inhibits gastric secretion. One difficulty is that any effective antacid is likely to be followed by an acid rebound, that is to say, when the effect of the antacid has passed off the gastric acidity tends to rise above its former level. For this reason, food, especially milk is given in small amounts at frequent intervals. The same principle applies to the use of antacids, indeed these are sometimes given by continuous intragastric drip (Winkelstein, 1951).

The diet for these patients is selected with the idea of reducing so far as possible stimulation of gastric secretion and mechanical irritation of the ulcer. Stimulation of the cephalic phase of secretion is avoided by eliminating highly spiced foods and foods which make a strong appeal to the appetite such as broiled steaks, stimulation of the gastric phase as well as mechanical irritation of the ulcer is avoided by eliminating coarse and indigestible food such as raw vegetables and fruit. The use of tobacco and alcohol in moderation is permitted by some physicians and forbidden by others. On physiological principles they should both be eliminated. Rest and a placid way of life are desirable but cannot always be achieved.

Two different surgical approaches to the reduction of gastric acidity are in current use. The older method, known as subtotal gastric resection

in which the pyloric portion and a large part of the body and fundus of the stomach are removed, is aimed primarily at the gastric phase of gastric secretion. Since experience has shown that removal of the antrum alone does not effect an adequate reduction in gastric acidity it is the custom now to take out a large part of the body and fundus of the stomach as well. More recently the operation of double vagotomy or vagotomy has come into use (Dragstedt, 1944, 1945, 1946). In this operation an attempt is made to sever completely the vagus nerves immediately above or below the diaphragm and to remove enough of the vagus trunks to prevent regeneration. The objective is to eliminate the cephalic phase of secretion which Dragstedt believes to be responsible for the hypersecretion in duodenal ulcer patients. The operation is not recommended for gastric ulcers.

Double vagotomy results in profound depression of gastric motility as well as secretion and the resulting gastric stasis proved to be a double hazard to the patient, there was danger of over distention and atony of the stomach and the retained food, acting in the antrum as a stimulus to the release of gastrin increased the gastric phase of secretion. These problems have been met by performing, at the same time as the vagotomy, a gastric drainage operation. Usually a gastroenterostomy is done in which an opening is made between the stomach and jejunum. This facilitates gastric emptying and encourages regurgitation of intestinal contents into the stomach thus tending further to lower gastric acidity. Although the two surgical approaches to the problem of peptic ulcer are based on quite different philosophies they are about equally effective, probably this is because of the interdependence of the gastric and cephalic phases of secretion mentioned in chapter 37.

PANCREAS, LIVER AND BILIARY SYSTEM

Secretion of Pancreatic Juice

STRUCTURE OF THE PANCREAS

The pancreas is an elongated gland which extends from the duodenum obliquely upward behind the stomach, across the posterior abdominal wall to the spleen at the level of the first and second lumbar vertebrae. It develops from two outgrowths of the primitive gut, one arising from the ventral and the other from the dorsal gut wall immediately below the primitive stomach. As a result of the rotation of the gut and its mesenteries and the growth of the rudiments themselves the two portions of the pancreas come into contact at the left of the duodenum and eventually fuse. The duct of the ventral pancreas joins the duct of the dorsal portion somewhere along the course of the latter, usually near its origin, and the two subsequently form a continuous channel which constitutes the major pancreatic duct (ductus pancreatus or duct of Wirsung). In keeping with the fact that the proximal portion of this duct was developed in conjunction with the liver bud, the duct of Wirsung in the adult enters the duodenum in close association with the common bile duct. That portion of the duct of the dorsal rudiment which lies between the duodenum and the point of anastomosis with the ventral duct is normally retarded in subsequent development and becomes the accessory duct (ductus pancreaticus accessorius or duct of Santorini).

For descriptive purposes the adult pancreas is divided into a head, body and tail. The most massive portion of the gland is the head, it is flattened dorsoventrally and lies within the concavity of the duodenum to which it is attached by numerous blood vessels, the pancreatic duct and loose connective tissue. The uncinate process is a hooklike medial projection from the lower part of the head. The body of the pancreas makes up the major portion of the remainder of the gland, it is somewhat prismatic in shape and presents an anterior, a posterior and an inferior surface. The tail is the pointed, tongue-like left

end of the gland which lies in contact with the spleen.

When studied microscopically, the pancreas is seen to be made up chiefly of groups of cells forming acini which tend to be spherical or ovoid in general contour, in the closely packed tissue of the pancreas they are actually polygonal. Groups of acini form primary lobules also polygonal in contour, which are imperfectly separated from other primary lobules by incomplete connective tissue septa. Numerous adjacent primary lobules form a secondary lobule, the secondary lobules are completely surrounded by connective tissue and can be dissected out as separate structures connected to the rest of the gland by ducts, nerve fibers, lymphatic vessels and blood vessels. The pancreatic tissue proper is composed of acinous cells, islet cells (described in chapter 48) and duct cells. The acinous cells, owing to the spherical shape of the acini, tend to be pyramidal with the truncated apex of the pyramid directed toward the lumen of the acinus, they are large cells with a well developed nucleus and abundant granular cytoplasm. The granules, called *zymogen granules*, vary in number and position in the cells depending on the state of activity of the gland but tend to be more abundant in the apical region of the cell which is adjacent to the lumen of the acinus.

The microscopic appearance of the pancreatic acinous cells changes considerably during functional activity. In the resting gland, i.e., the one that has not been stimulated to secrete for many hours, the cells are filled with granules that are large and closely packed and may displace the nucleus toward the base of the cell. When the pancreas is made to secrete, either by food or by drugs, the following changes can be observed: first, the entire cell is reduced in size, second, the granular, inner or apical zone is diminished in size more than the outer zone, the latter, though smaller, now occupies relatively more of the cell volume, the zymogen granules of the inner zone are smaller in size and fewer in number than in the resting cell, and those that remain are con-

gregated near the apical border of the cell (R. Heidenhain, 1883). The changes in appearance of the acinous cell during secretion have been taken as indicating that the pancreas has been secreting enzymes. Secretion of pancreatic juice containing little or no enzymatic material causes correspondingly little change in the appearance of the acinous cell.

An interesting feature of the duct system of the pancreas is the manner in which the small or terminal intralobular ducts end in relation to the acinus. Cells, corresponding in structure to the cells of the terminal ducts, may be seen in microscopic sections within the acini. These are called centroacinar cells, most investigators have concluded that the terminal ducts extend into the lumen of the acini where they form a sort of lining.

PANCREATIC JUICE

The pancreas secretes a colorless, odorless, alkaline fluid of low viscosity, tasting strongly of sodium bicarbonate. Some specimens have been described as having a faint straw color. Exceptional specimens having a high concentration of enzymes may be viscous and may even jelly at low temperatures. Pure pancreatic juice collected from dogs without loss of carbon dioxide has a pH between 8 and 8.3 and an extreme range of specific gravity of 1.007 to 1.042, the usual values being between 1.010 and 1.018. The osmolar concentration of the juice is the same as that of the blood when the two are collected simultaneously from the same animal. When the osmolar concentration of the blood is altered experimentally the pancreatic juice shows a corresponding change.

The distinguishing chemical characteristic of the juice is its high bicarbonate content. This is in contrast to the strongly acid character of the gastric juice which is secreted at the same time. The fact that the pancreas secretes base while the stomach is secreting acid is a factor in maintaining the acid base balance of the rest of the body. Likewise, the fact that the two secretions are mixed in the intestine helps to maintain the normal pH of the intestinal contents. The fact is now well established that the bicarbonate and chloride concentrations of pancreatic juice vary in a reciprocal manner so that the sum of the two expressed in milliequivalents is approximately constant, and nearly the same as the total base of the blood plasma. Also, that within physiological limits, the bicarbonate concentration increases and the chloride concentration decreases with increasing rates of secretion. This relation-

ship holds over a wide range of secretory rates and is such that a straight line results when the logarithm of the bicarbonate concentration in m eq per liter is plotted against the reciprocal of the rate of secretion expressed as cubic centimeters of secretion per kilogram of body weight per minute, the slope indicates an inverse relation. The rate of increase in bicarbonate concentration with the rate of increase in the rate of secretion varies with different animals so that the rate of secretion cannot be estimated from the bicarbonate concentration of an unknown sample, however, it is possible to say that if the bicarbonate concentration is high the pancreatic juice was secreted at a rapid rate, or a rate that was rapid for that particular animal. The maximum bicarbonate concentration in juice collected from different dogs ranges between 135 and 148 m eq per liter and the maximum rate of secretion is about 0.1 cc per kg per minute, or about 1 cc per minute for a 10-kg dog, higher rates than this are occasionally seen. In addition to chloride and bicarbonate the pancreatic juice contains a small amount of phosphate, but less than that occurring in blood plasma.

The principal bases of pancreatic juice are sodium, potassium, and calcium. The concentrations of sodium and potassium are approximately equivalent to those of the blood plasma but the calcium concentration is only 3 or 4 mg per cent as compared to about 10 mg per cent for blood. The low calcium concentration compared to that of the blood is attributed to the fact that much of the blood calcium is combined with protein and is not in a diffusible state.

The protein content of pancreatic juice varies over a wide range but in an orderly manner with the conditions governing secretion. In 200 samples of dog's pancreatic juice collected under different conditions, the protein content in different samples varied between 0.1 per cent and 10 per cent. Concentrations found in human pancreatic juice collected through accidental or surgical fistulas are nearer the lower extreme, ranging from 0.1 to 0.3 per cent. The protein in the juice consists mainly of enzymes. Using electrophoresis, a method by which the proteins in a mixture can be separated by means of their different mobilities in an electrical field, it has been possible to determine that there are at least ten distinct proteins in pancreatic juice, with the possibility of still others that fail to separate out in the time during which the electrical field is maintained (Grossberg, Komarov, and Shay, 1952). This method of separating the proteins of

pancreatic juice also separates the enzymatic activity, proteolytic activity is found in one component, lipolytic activity in another, and amylolytic activity in another, a fact which confirms the belief that the proteins dealt with in the electrophoretic procedure are the actual enzymes of the juice. It is interesting that when different methods were used to stimulate secretion of the juice the electrophoretic patterns differ, depending upon the method used, for example, a meat meal produces pancreatic juice having a different electrophoretic pattern and therefore a different protein composition from that secreted in response to stimulation by means of urocholone and secretin. This suggests that the relative concentration of the different enzymes in the juice can be made to vary by using different stimuli to cause secretion.

The enzymes of pancreatic juice are capable of digesting all three types of foodstuff, that is, the juice contains proteolytic, amylolytic and lipolytic enzymes. The proteolytic enzymes as they occur in the pancreatic tissue and freshly secreted pancreatic juice possess no proteolytic activity and are referred to in that state as zymogens. In the older literature the proteolytic activity was attributed to trypsin, the corresponding zymogen being trypsinogen. Kunitz and Northrup (1934) have shown that what was called trypsin or trypsinogen consists of at least two components, for one of which they retained the name *trypsin* and for the other they coined the name *chymotrypsin*. The zymogen of chymotrypsin is known as chymotrypsinogen. These several substances have been isolated and obtained in crystalline form and many of their properties determined by Kunitz and Northrup.

Trypsin and trypsinogen have a molecular weight of 34,000. As an enzyme trypsin hydrolyzes native protein, producing proteoses and peptides. It accelerates coagulation of the blood, in which it acts as a thrombokinase, but has only a feeble action in clotting milk. Its optimum pH for digestion of casein lies between pH 8 and 9. When pure, it is reversibly inactivated by heat in acid solution, it slowly decomposes in alkaline solution. Trypsinogen is indistinguishable on chemical analysis from trypsin, but has different solubilities and a different crystalline form, it exhibits no proteolytic activity. In solution it changes spontaneously to active trypsin but the change is accelerated by acid or by exposure to concentrated magnesium sulfate, calcium chloride, active trypsin or to certain activating enzymes called *kinases*. The effectiveness of trypsin

in the activation of trypsinogen is of great importance because such autocatalytic reactions progress with great rapidity once they are started and require only minute amounts of activating agents to set them going. Spontaneous activation of trypsinogen is suppressed in crude extracts, and doubtless also in living pancreas, by the presence of an inhibitor which inactivates small amounts of trypsin. The trypsinogen as secreted in the living animal is activated on contact with the intestinal mucosa by means of an enzyme in the mucosa called enterokinase. Enterokinase does not appear in the intestinal secretion in the absence of pancreatic juice but is present in intestinal mucosal extracts. A similar substance is present in pancreatic extracts. Kunitz has observed that certain common molds (*penicillium*) produce an enzyme capable of activating trypsinogen.

Chymotrypsinogen has a molecular weight of 25,000, it is converted to chymotrypsin by active trypsin only but indirect activation can be accomplished by enterokinase if trypsinogen is also present. If chymotrypsinogen is activated rapidly by fairly large amounts of trypsin, π -chymotrypsin is formed which then changes spontaneously to δ -chymotrypsin, as a result of the π -chymotrypsin acting upon itself. If smaller amounts of trypsin are used the major products are α , β , and γ -chymotrypsin which appear to have essentially the same molecular weight as chymotrypsinogen and π - and δ -chymotrypsin. A sixth type, known as chymotrypsin (and chymotrypsinogen) β , has also been isolated. Alpha chymotrypsin is the active enzyme first crystallized by Kunitz and Northrup. The nature of the structural differences among the various chymotrypsins, other than in their crystal form is unclear. The activity of chymotrypsin is comparable to that of trypsin but it has different specificities, for example, it coagulates milk but not blood. Chymotrypsin digests casein somewhat more rapidly than does trypsin but the digestion is carried much further by a mixture of the two enzymes than by either alone, a fact which indicates that the two enzymes attack different linkages in the protein molecule. Like trypsin, chymotrypsin is reversibly inactivated by boiling in acid solution. Its optimum activity occurs in the same pH range as that of trypsin, i.e., 8 to 9 for casein digestion.

The peptides resulting from protein digestion by trypsin and chymotrypsin are further digested by enzymes known as *peptidases*, most of these come from the intestinal mucosa but one has been

identified and isolated from pancreatic juice, an enzyme known as carboxypeptidase which splits off the end amino acid containing a free carboxyl group from polypeptides. In fresh pancreas it occurs in an inactive form, procarboxypeptidase and, like chymotrypsinogen, it is activated by trypsin.

The ability of pancreatic juice to emulsify and hydrolyze fats is probably due to a single enzyme called *pancreatic lipase*. This enzyme is known principally through its activity and has not been isolated in a pure state or crystallized. Pancreatic lipase hydrolyzes fat only in the presence of bile salts or other substances with similar properties, for example, some of the synthetic detergents. Bile salts in high concentration inhibit the action of lipase as do salts of certain heavy metals, e.g., copper, iron and cobalt, it is also inhibited by the halogens, fluorine, iodine and bromine. The pH at which pancreatic lipase exhibits its optimum activity varies with the substrate, but is always on the alkaline side of neutrality.

The amylolytic activity of pancreatic juice is due to *pancreatic amylase* which may be one or two enzymes. The finding of amylolytic activity in two components of the juice which can be separated electrophoretically (Grossberg *et al.*, 1952) and the fact that different methods of measuring amylase activity give different results in the same sample of pancreatic juice (Waldron, 1951) indicates that there may be more than one enzyme involved in the digestion of carbohydrate by the pancreas and that these two enzymes have somewhat different activity. Pancreatic amylase is secreted in active form but becomes inactive if dialyzed against distilled water owing to the removal of neutral salts which are thus proved to be essential for the activity of the enzyme, the most efficient activating ion is chloride. The optimum pH for activity of pancreatic amylase varies between 6.5 and 7.2 depending upon the kind and concentration of neutral salts present in the solution. The enzyme digests glycogen as well as starch. Under favorable conditions the end product in both instances is maltose. The pancreatic juice is said also to contain maltase and sucrase and under certain conditions, lactase.

Pancreatic juice also contains ribonuclease and desoxyribonuclease which partially hydrolyze the corresponding nucleic acids into mononucleotides. The action of these enzymes has not been clearly characterized. The optimum pH for desoxyribonuclease is in the neighborhood of 7.

The importance of the pancreatic enzymes in digestion is evidenced by that fact that when

pancreatic juice is excluded from the intestine by pancreatectomy or ligation of the ducts there is serious impairment of digestion and absorption of the various foodstuffs. This is most pronounced in the case of fat and protein, unabsorbed fat particularly appearing in large amounts in the stools, this condition is known as *steatorrhea*. The bicarbonate of the juice also serves to neutralize the gastric juice as it enters the intestine and to establish in the intestine a pH more favorable for intestinal digestion than would otherwise be the case.

METHODS OF COLLECTING PANCREATIC JUICE

In order to obtain pancreatic juice for study it is necessary to make some kind of pancreatic fistula that is some sort of preparation through which the pancreatic juice, instead of flowing into the intestine as it does normally, is brought to the outside of the body where it may be collected. The first such fistula was described by Regner de Graaf in 1664. He cannulated the pancreatic duct of a dog with a quill from a wild duck which he selected because that kind of bird hath longer and thinner (quills) than all others. The cannula was brought out through the abdominal wall and the pancreatic juice collected in a small vessel attached to its outer end. Of great historical interest is the permanent fistula devised by Pavlov in 1879 (see Pavlov, 1910). Pavlov cut out a rhomboid portion of the duodenal wall surrounding the opening of the major pancreatic duct and after repairing the duodenum, transplanted the excised papilla, with the duct attached into the skin of the abdominal wall. It is now customary to collect pancreatic juice from animals through a duodenal fistula which is provided with a metal or plastic tube that can be closed when the fistula is not in use (Thomas 1951). The opening of the duct can be seen through the fistulous opening into the duodenum and a glass or metal cannula inserted into the duct. If the accessory duct is tied at the time the fistula is made the total secretion of the pancreas can be collected in this manner over a period of hours.

PANCREATIC FISTULA

The digestive disturbances that follow ligation of the ducts or removal of the pancreas are also observed when the pancreatic juice is diverted from the intestine through a complete fistula. Such fistulas however, give rise to other, more serious complications which tend to obscure the digestive disturbances. Within a few days after

the fistula has been made the secretion becomes continuous and increases in amount, and its composition changes. The concentration of total solids falls to 1 or 2 per cent, chiefly owing to the almost complete absence of protein (Babkin, 1928). These changes are associated with changes in the microscopic appearance of the pancreas (Heidenhain, 1883), the acinous cells decrease in size and lose most of their granules. The animal loses weight rapidly, refuses to eat and dies.

In animals with complete fistulas Johnston and Ball (1930) found a decrease in chloride and an equivalent increase in the bicarbonate concentration of the pancreatic juice as drainage progressed. The increase in bicarbonate is not a constant finding since Heidenhain obtained some specimens of juice which did not effervesce on addition of acid and some samples collected by Johnston and Ball had a pH as low as 7.16. The total base of the juice remains normal or nearly so and because of this and the hypersecretion there is a substantial loss of base (Na, K, Ca) from the body which gives rise to changes in the blood that ultimately prove fatal.

The most important blood changes are lowered plasma volume (dehydration), decrease in chloride, decrease in bicarbonate and a decrease in total base (Elman and McCaughan 1927, Gamble and McIver, 1928, Dragstedt *et al.*, 1930). The pH of the blood may increase or decrease, probably depending on the relative amounts of chloride and bicarbonate lost, excessive vomiting is common and this tends to increase the loss of chloride. Hypersecretion of the stomach has been observed in pancreatic fistula and this would add to the chloride loss when vomiting is present. It may also account for the hypersecretion of the

pancreas when HCl from the stomach enters the intestine. In one group of animals studied by McCaughan (1929) the blood chemistry remained approximately normal, the animals, nevertheless, died within 5 to 8 days (the usual survival time) apparently because of dehydration. Changes in blood chemistry corresponding to those seen in experimental animals, but usually less severe, have been observed in human patients with pancreatic fistula (Miller and Wiper 1944).

Administration of sodium chloride or sodium bicarbonate intravenously or by mouth prolongs the life of experimental animals with pancreatic fistula, sometimes indefinitely, but the ideal treatment is return of the secreted juice to the gastrointestinal tract. For animals with an incomplete fistula of the Pavlov type the administration of sodium bicarbonate and a diet that does not stimulate excessive secretion such as bread and milk may be all that is required.

A summary of the results observed in experimental pancreatic insufficiency is presented in tables 39.1 and 39.2.

REGULATION OF PANCREATIC SECRETION

Claude Bernard believed that the pancreas secretes only when stimulated as, for example, during digestion. Heidenhain noted, however, that the secretion was continuous in herbivorous animals but he agreed with Bernard that in the dog and cat and other carnivora there was no secretion without stimulation. Proof has since been obtained that secretion is continuous in rabbits, white rats, white mice, guinea pigs and frogs. Baxter (1931) found that secretion in the rabbit continued even after removal of the small intestine and after decapitation. The idea that

TABLE 39.1
Functional disturbances in experimental pancreatic insufficiency

Procedure	Functional Changes		
	Absorption deficit	Duodenal ulcer	Fatty liver
Pancreatectomy	100% of animals (severity variable)	Rare	92% (Dragstedt)
Ligation of ducts	100% of animals (severity variable)	33% (Dragstedt)	50% (Dragstedt)
Total fistula	100% of animals (severity variable)	Limited by early death, otherwise probably 100% (Dragstedt)	None
Mann-Whitman operation	Some deficit (no exact data)	90-100%	No data

TABLE 39 2

Blood changes in experimental pancreatic insufficiency

Procedure	Blood Changes			
	Enzymes	Salts and Water	Sugar	Fat
Pancreatectomy	No change	No change	Hyperglycemia	Hypolipemia
Ligation of ducts	Increase in blood amylase ('diastase')	No change	No change—hyperglycemia possible late effect	Hypolipemia in 50 per cent
Total fistula	No change	Decrease in total base, decrease in Cl, decrease in HCO_3 , dehydration, pH variable	No change	No change

the pancreas of the fasting dog does not secrete unless stimulated by means of food or other external agents has had to be modified in the light of subsequent work. Boldyreff (1916) observed pancreatic secretion at intervals in fasting animals, associated with periods of secretory and motor activity in other organs of digestion which we now recognize as hunger periods. This periodic secretion was studied thoroughly by Scott and his coworkers (1940, 1941) and they found that although periodic secretion did occur it was associated with hunger activity of the stomach only about half the time. Continuous secretion is the rule in human patients with pancreatic fistulas and McClure (1937) states that pancreatic enzymes are always found in the intestinal contents collected by intubation of normal subjects.

Whether continuous or intermittent, the amount of secretion is always increased after meals. This occurs in response to specific stimuli associated either with the act of eating or the presence of food in the gastrointestinal tract. Proof that the act of eating serves as a stimulus to the pancreas was obtained in Pavlov's laboratory (later confirmed by Ivy, 1926) by means of sham feeding (ch. 37) that is feeding a dog provided with an esophagostomy so that the food did not reach the stomach. In these circumstances the pancreas begins to secrete within one to one and a half minutes after feeding and continues for 12 to 20 minutes. The volume secreted is small but the concentration of enzymes is increased over the fasting secretion. The short latent period as well as direct experimental evidence has served to prove that the secretion is not due to gastric hydrochloric acid entering the duo-

denum (Tonkish, 1924). The response is abolished by cutting the vagus nerves. Food and food products in the stomach do not, apparently, have any direct stimulating effect on the pancreas, however, they become effective stimuli when the gastric contents enter the intestine.

All the major constituents of the gastric chyme influence the secretory activity of the pancreas in one way or another after they have entered the intestine. These include water, hydrochloric acid, products of protein digestion, fats, fatty acids, soaps and products of starch digestion. Each of these substances has a different effect on the pancreas, producing a characteristic type of pancreatic juice. Hydrochloric acid produces an abundant secretion of dilute alkaline fluid containing a minimum amount of enzymes. Fatty acids and soaps, although producing an abundant secretion, increase the concentration of enzymes, whereas the products of protein digestion when used in the absence of other stimuli produce only a small amount of secretion which is highly concentrated in enzymes, fats are said to act in a similar manner.

Secretin and Pancreozymin

The mechanism through which the various stimuli act on the pancreas to promote secretion has been under investigation for more than half a century. The discovery of secretin in 1902 by Bayliss and Starling was an event of great historical significance inasmuch as secretin was the first chemical substance known to be secreted into the blood and act as a stimulus to an organ at a distance from the site of its formation. Recognizing this fact, Bayliss and Starling coined the

word *hormone* to characterize this and similar substances. Before the discovery of secretin it was known that acid in the intestine induced secretion of pancreatic juice in animals in which all the nerves to the pancreas and to the intestine had been severed. While workers in Pavlov's laboratory in St. Petersburg were busily searching for the unknown nervous pathways which, they supposed, conveyed impulses to the pancreas after all the known fibers had been cut, Bayliss and Starling in England did the simple experiment of making an acid extract of the mucous membrane of the intestine and injecting it into an animal. This caused the pancreas of the injected animal to secrete. The excitement in Starling's laboratory can well be imagined. A "chemical reflex" had been discovered, something hitherto unknown in physiology. They called the new substance *secretin*. The response in Pavlov's laboratory was less enthusiastic, the idea that something other than the nervous system could regulate body function was not in keeping with Pavlov's philosophy, nevertheless he ultimately accepted the fact with good grace.

Although it is probably true that the pancreatic response to Bayliss and Starling's extract was as much due to impurities as to the secretin that it contained, subsequent research has shown that such extracts do contain an active principle which, when highly purified, has a powerful secretory effect on the pancreas. The purest secretin available stimulates only the pancreas and liver, in both organs it causes a dilute, watery secretion and has little or no influence on the secretion of organic solids. Secretin is probably a polypeptide with a molecular weight of about 5,000. It has been obtained in a highly purified state by Hammarsten and his coworkers (1923, 1933) and by many others subsequently. Jorpes and Mutt (1956), of the Karolinska Institute in Stockholm have made a preparation of which 0.1 mg. contains 70 "clinical units" or an amount that will cause the human pancreas to secrete at a rapid rate for an hour or more. Since one clinical unit is equal to sixteen cat units, less than 0.0001 mg. of the preparation should cause detectable secretion in a cat. Greengard, Stein and Ivy have shown that secretin is destroyed by an enzyme found in the blood and urine, which they called *secretinase*.

¹ A clinical unit of secretin is equal to 1 dog unit (Ivy et al., 1930) or 16 cat units (Wilander and Agren 1932). A dog unit is the amount that will increase the rate of secretion in a 10 to 12 kg. dog by 10 drops in 10 minutes. A cat unit is the least amount that will cause detectable secretion in a cat.

The crude extract prepared by Bayliss and Starling caused the pancreas to secrete enzymes as well as water and bicarbonates. Since purified secretin seemed to stimulate only the output of water and bicarbonate a search was made by Harper and Raper (1943) for the material in the extracts which stimulated secretion of enzymes. They succeeded in separating a fraction which did not increase the volume of pancreatic juice but did greatly increase the enzyme concentration. This substance they called *pancreozymin*. Their observations were quickly confirmed by Greengard and others (1944).

It has long been known that hydrochloric acid in the intestine liberates secretin into the blood thus causing the pancreas to secrete. It was not known whether other pancreatic stimuli liberated secretin or pancreozymin or depended on some other mechanism for their effect. In 1951, Wang and Grossman succeeded in preparing a functioning, nerve-free transplant of the canine pancreas. They imbedded a portion of the pancreas in the tissue of the mammary gland leaving its nerve and blood supply intact for the time being. After it had established a new blood supply in its new location the original nerves and blood vessels were cut, leaving a piece of pancreas whose activity could be influenced only through chemical substances reaching it by way of the blood stream. It was found that the flow of pancreatic juice from this transplant was increased by all the common pancreatic stimuli including distilled water, hydrochloric acid, soaps, and peptones. The enzyme concentration was also increased by these same stimuli, thus proving that both secretin and pancreozymin are released by all the ordinary stimuli used to excite pancreatic secretion.

The Secretory Nerves of the Pancreas

The pancreas receives an abundant nerve supply from both the vagi and splanchnic nerves. According to Richins (1945) who made his studies on cats by strictly morphological methods, the entire extrinsic nerve supply to the pancreas passes through the celiac plexus and reaches the gland by way of the nerve plexus surrounding the arteries, chiefly the superior pancreaticoduodenal artery. The vagus fibers end in the intrinsic ganglia of the pancreas, and from these the parasympathetic path is continued through postganglionic unmyelinated fibers to the acinous cells, islet cells and the smooth muscles of the ducts. The efferent splanchnic fibers destined to supply the pancreas, according to this author, all end in the celiac and associated ganglia and from

there the sympathetic path is continued through unmyelinated, postganglionic fibers which are distributed solely to the pancreatic blood vessels. However, the presence of cholinergic secretory fibers in the splanchnic nerves of the cat, which do not synapse in the celiac ganglia, is indicated by the physiological studies of Babkin and others (1939). Myelinated visceral afferent fibers from the pancreas are also present in the splanchnic nerves.

Guillaumie (1934), who used physiological methods on dogs reached conclusions quite different from Richins regarding the course of the vagus fibers. Confirming with few exceptions, the early observations of Popielski (1896), she concluded that a majority (60 per cent) of the vagus fibers to the pancreas course along the lesser curvature of the stomach, cross the pylorus, and after proceeding a certain distance in the duodenal wall enter the pancreas by way of the nerve plexus which surrounds the major pancreatic duct. Incidentally, according to her findings, any method of collecting pancreatic juice in which the ducts are severed or separated from the intestine involves a partial denervation of the pancreas. The remaining 20 per cent of the vagus fibers according to this author, traverse the hepatic plexus and join the pancreas in the region of the pylorus.

It is often incorrectly stated that the pancreas receives the greater part or all of its vagus nerve supply from the right vagus. This error arises from the tendency to overlook the fact that after the vagi merge in the esophageal plexus the right and left nerves can no longer be distinguished. Two or more trunks emerge from the esophageal plexus and the trunk that occupies the more posterior position at the level of the diaphragm, although referred to by some anatomists as the right vagus, contains fibers from both the right and left vagi as they occur in the neck. When stimulated in the neck, the right and left vagi are equally effective in modifying pancreatic function.

The intrinsic ganglia of the pancreas undoubtedly develop in association with the enteric nerve plexuses. It would be interesting to know whether they retain connections with this plexus and whether such connections have anything to do with the effects of intestinal stimuli on pancreatic secretion. In this relation it is interesting that, in addition to the rich plexus of nerve fibers surrounding the pancreatic ducts, there are many nerve fibers in the loose areolar tissue between the pancreas and duodenum.

The first clear demonstration of secretory nerves to the pancreas we owe to Pavlov (1910), who devised a unique method for demonstrating the function of the vagus nerves in unanesthetized animals. He exposed one vagus nerve under anesthesia in a dog with a pancreatic fistula and, after cutting it, brought the peripheral portion into the wound directly under the skin. The wound was closed with sutures and the animal allowed to recover. When the nerve was again exposed 4 to 8 days later, this time without anesthesia, stimulation of the peripheral portion caused an abundant secretion of pancreatic juice. Since stimulation of the freshly cut nerve or of the intact nerve with the animal under anesthesia usually failed to cause secretion, Pavlov concluded that the vagus nerve to the pancreas contained not only secretory but inhibitory fibers (which degenerate earlier than the secretory fibers). It has since been shown that the fibers believed to be inhibitory are those that cause contraction of the large ducts, thus preventing the flow of juice even though secretion occurs. Secretory fibers were demonstrated in the splanchnic nerves in Pavlov's laboratory using a similar method; this observation was subsequently confirmed by Babkin and his associates (1939).

The precise function of the secretory nerve fibers is still unknown. Experiments in which the vagus nerves have been cut have failed to give consistent results in either animal or human subjects; it is therefore not known at the present time whether the denervated pancreas responds to stimuli in the same way as the pancreas with a normal nerve supply. Since the amount of pancreatic juice secreted by the fasting animal, when the individual food products are placed in the intestine, is less than one would expect compared to the volume of pancreatic juice secreted after a normal meal, one is led to suspect that in the fasting state the pancreas does not respond to stimuli to the same extent as the same gland does during digestion. It may be that a combination of stimuli is more effective than the response to individual stimuli would indicate when they are used separately, or it may be that some influence associated with the taking of food operates to increase the irritability of the pancreas to intestinal stimuli. That such may be the case is indicated by experiments of Gay et al. and Guillaumie and of Crider and Thomas (see Thomas, 1950, p. 109) in which it was shown that the action of the secretory nerves and the action of secretin on the pancreas are synergistic, each augmenting the effect of the other. If these observations should be confirmed

by further study they would indicate at least one function of the secretory nerves. The only positively known function is the production of the initial reflex or cephalic phase of pancreatic secretion.

The fact that stimulation of the secretory nerves increases the output of enzymes, as do also various parasympathomimetic drugs such as urocholine, pilocarpine and physostigmine, suggests that they play a part along with pancreozymin in regulating the enzyme output of the pancreas. The parasympatholytic drugs such as atropine and the newer synthetics cause a much more profound depression of pancreatic secretion, including secretion of enzymes, than does section of the secretory nerves. This fact suggests that there are local cholinergic mechanisms involved in the process of stimulation of the pancreas that are not destroyed when the vagi are cut. The location, nature and function of such mechanisms, if they exist, are entirely unknown. The enteric plexuses and the intrinsic ganglia of the pancreas and their connections are possible mechanisms.

Adaptation of Pancreatic Enzyme Secretion to Diet

The fact has already been mentioned that the total enzyme concentration of pancreatic juice is determined to a great extent by the type of stimulus used to provoke secretion. This mode of adaptation is an established fact, and its mechanism is well understood (see above under *secretin* and *pancreozymin*). Another type of adaptation, which involves changes in enzyme composition, is more controversial. Pavlov, as a result of certain errors in enzyme determinations in his laboratory, came to the conclusion that the relative concentration of the different enzymes of pancreatic juice was adapted to the nature of the food undergoing digestion, for example according to his concept, a meal consisting largely of carbohydrate would call forth secretion of pancreatic juice containing a large amount of amylase, whereas a fat meal would call forth secretion of lipase, etc. Babkin, using more precise methods in the same laboratory, found that this was not true, but that the enzymes tended to be secreted in parallel concentration regardless of the nature of the immediate stimulus to secretion. This concept has been challenged recently, especially by Guth, Komarov and their coworkers (1958) who find that there may be considerable variation in the relative concentration of the different enzymes in different samples of pancreatic juice, even when taken on the same day from the same animal. Al-

though the differences they found are statistically significant the fact remains that a large increase in enzyme concentration involves all the enzymes of the juice, although not necessarily all equally.

Efforts to determine whether the composition of the juice can be altered by a prolonged change in the diet have given confusing results. It has been established that a diet low in protein gives rise to considerable alteration in the enzyme composition of the juice (Grossman *et al*, 1943), as does deficiency or excess of certain amino acids (Magee *et al*, 1956, 1957, 1958), however, it is not clear that this represents an adaptation in any accepted sense of the word, rather it suggests that the pancreatic cells which have the task of synthesizing the relatively enormous amounts of protein secreted in the pancreatic juice, are hampered in their work if they are not supplied with adequate and appropriate building material (Hokin, 1952). The pancreatic cells cannot make bricks without straw any more than could the Israehtics of old.

The Mechanism of Pancreatic Secretion

At this point the student should read again the introductory paragraphs of chapter 36.

As in the case of other digestive glands secretion of enzymes by the pancreas involves two distinct processes: (1) synthesis within the cell of the enzymes or their precursors and (2) discharge of enzymes from the secretory cells into the ducts. Synthesis is a continuous process formerly believed to be controlled only by the laws that govern chemical equilibria in general. However, the recent work of Magee and his associates (1955, 1956, 1957, 1958) indicates that the nature of the dietary protein, and in particular its amino acid composition, has a profound effect on the total concentration of enzymes in the pancreas and on the relative concentration of different enzymes. For example, Magee and Anderson (1955) found that in animals fed a high protein diet (casein) the trypsin and lipase content of the resting pancreas was greater than in animals fed a low protein diet. Also daily administration of urocholine (a parasympathomimetic drug) or of DL-valine had an effect similar to casein. Since DL-valine is a powerful stimulant for release of pancreozymin and the parasympathomimetic drugs stimulate enzyme secretion these authors conclude that the stimuli for enzyme secretion (casein, urocholine, DL-valine) also stimulate enzyme synthesis. A similar interpretation could be given the earlier work of Grossman, Greengard and Ivy (1943) who reported changes

in enzyme content of the pancreas with changes in diet

Interesting light has been shed on the synthesis of enzymes, by the recent studies of L. E. Hokin (1951, 1952) and Mabel Hokin (1956) on pigeon and mouse pancreas *in vitro*. It was found that pigeon pancreas slices would synthesize amylase *in vitro* in glucose solutions, in serum, in amino acid solutions and in saline. Synthesis was most rapid in solutions of amino acids and least rapid in normal saline, it proceeded at an intermediate rate in serum. One can see here the effect of an increased concentration of reacting substances (amino acids) on synthesis of protein by the cells of the pancreas. Although pancreozymin and parasympathomimetic drugs caused discharge of amylase from the cells into the surrounding medium (secretion), the rate of synthesis of the enzymes was not materially affected. This is not in accord with the conclusions of Magee and his associates but does not invalidate their conclusions since the experimental conditions were different, particularly with regard to the time during which the stimulus could act. It was found that certain amino acids were essential for synthesis whereas others could be supplied from sources in the medium. The amino acids essential for maximum synthesis were tryptophane, arginine, threonine, valine, tyrosine, lysine, leucine, histidine, isoleucine, and phenylalanine. Similar results were obtained on mouse pancreas except that there was no acceleration of synthesis on addition of amino acids if the animal had been fed before being killed for removal of the pancreas. However, if the animal had been starved for 24 hours, addition of amino acids to the medium increased the rate of synthesis by 25 per cent.

The synthesized material appears within the acinous cells as zymogen granules which accumulate in the resting gland until they come to occupy most of the available space within the cells (Heidenhain, 1883, Hirsch, 1939, 1957, Shuter, 1944). Under the influence of appropriate stimuli the zymogen granules diminish in number and in size, at the same time enzymes appear in the secretion. The exact mechanism is not known but at some point the granules dissolve in the intracellular fluid and are discharged through the cell wall into the ducts. Stimuli such as HCl and secretin which produce a watery secretion with a low enzyme content have little effect on the granules whereas stimuli which call forth secretion rich in enzymes deplete the granules and, if

they act over a long period of time, may leave the cells almost free of zymogen granules. According to the observations of Hokin and Hokin (1956) on pancreatic and salivary gland slices *in vitro*, effective stimuli for secretion of enzymes cause a remarkable increase in the rate of turnover of phosphorus and its incorporation into the ether soluble phospholipids. In the pancreas, secretin has no such effect although it does increase the uptake of oxygen by about 10 per cent. They conclude that "all active transport of proteins out of the cell involves the breakdown and resynthesis of the glycerophosphate bonds in phospholipids." Since the cell membrane is believed to contain a higher concentration of phospholipids than other elements in the cell, one is tempted to speculate on whether or not this observation signifies that the transport of protein out of the cell involves the alternate breakdown and reconstruction of the cell membrane.

It has long been assumed that the inorganic constituents of the juice are secreted by the same cells that produce the enzymes, namely the acinous cells. However, the fact that fluid secretion and enzyme secretion are separately regulated raises a theoretical objection to this view. All current theories of stimulation require that cells shall respond to a stimulus with a characteristic type of functional activity regardless of the nature of the stimulus. In the other digestive glands, about which we have more information, each component of the secretion that is independently regulated is formed by a different type of cell. We must also take account of the clinical observation that in certain types of pancreatic disease enzyme secretion may be depressed or absent whereas secretion of fluid and bicarbonate remains normal (Lagerlof, 1939, Friedman and Snape, 1950). On the other hand, in glands injured by alloxan fluid secretion may be subnormal whereas enzymes are secreted normally. This latter observation, reported by Grossman and Ivy (1946), contains a hint as to a possible solution of the problem. Histological examination of the glands which failed to respond normally to secretin showed no injury to the acinous cells but the cells of the intralobular ducts appeared abnormal, in particular they exhibited vacuolization. The intralobular duct cells are continuous with the centroacinar cells that line the alveoli and are identical with these cells in their cytological structure. It is possible that cells of this type secrete water and bicarbonate whereas the acinous cells secrete only enzymes.

Tissue Damage by Pancreatic Enzymes

Under certain conditions pancreatic enzymes may escape into the tissues surrounding the acini, or into the blood. In explanation of this we may assume that the enzymes, as they are being synthesized, appear first in solution in the cell protoplasm before being precipitated as zymogen granules. Some sort of equilibrium must exist between enzymes in solution and enzymes in the form of the more or less solid granules. We can only speculate on the concentration of dissolved enzymes that may be present at any time, but there is strong indirect evidence that the concentration is considerably increased by such stimuli as cause discharge of enzymes into the ducts. Simple diffusion of dissolved enzymes through the cell membrane of the acinous cells will explain the presence of enzymes in the minute quantities found in the blood in the normal fasting state. The rate of diffusion will vary with (1) the concentration gradient between the cells and the blood, (2) the hydrostatic pressure gradient between the interior and exterior of the cell and (3) the permeability of the cell membrane. The increases in enzyme concentration in the blood which are seen during active secretion in response to food, pancreozymin or parasympathomimetic drugs (Cherry and Crandall, 1932; Zucker *et al.*, 1932) are probably reflections of the increased concentration of enzymes within the cells. If such secretion is accompanied by closure of the ducts, as for example, by inflammatory edema or spasm due to morphine, the increase in hydrostatic pressure within the acini will accelerate the diffusion. Cell damage, from whatever cause, can further augment the diffusion by increasing the permeability of the cell membrane.

As a practical matter we see increases in concentration of pancreatic enzymes in the blood during digestion, after administration of certain drugs, notably morphine (Lagerlof, 1945; Ryan *et al.*, 1949), in acute pancreatitis, in carcinoma of the pancreas, and in many other conditions associated with injury to the cells or obstruction of the ducts, provided only that the damage is not so severe as to destroy the ability of the cells to synthesize enzymes. In order for tissue digestion to occur it is necessary that the inactive proenzymes be activated. The mechanism of activation of extracellular pancreatic enzymes is obscure, probably tissue kinases that may be released from injured cells play a part in activating the proteolytic enzymes. It is commonly believed that reflux of bile (Bernard, 1856; Opie,

1910) into the pancreatic ducts may cause sufficient tissue damage to activate the proteolytic enzymes, whereas the bile itself serves to activate the lipase. In acute pancreatitis from whatever cause there is always the danger of extensive tissue destruction and fat necrosis brought about by activated pancreatic enzymes.

THE SECRETIN TEST FOR PANCREATIC FUNCTION. Since secretin in injectable form has become available for clinical use a test of pancreatic function using this material as a stimulus to promote secretion has been developed. The test was introduced by Ågren, Lagerlof and Berglund (1936) and has since been used in North America by a number of investigators. To perform the test, a double lumen tube is passed through the patient's nose or mouth into the stomach and duodenum, one lumen opening into the stomach for draining gastric juice and the other into the duodenum for collecting the pancreatic and other duodenal secretions. It is necessary to drain the stomach in order to avoid false results caused by contamination of the pancreatic juice with gastric secretions. The gastric and duodenal contents are collected for a period of time to serve as a control and then a dose of 1 clinical unit of secretin per kg of body weight is injected slowly into a vein. Usually the patients are tested for hypersensitivity to the secretin preparation before it is injected. The duodenal contents are then collected in separate 10 or 20 minute samples for a period of time usually 80 minutes. Volume, bicarbonate and enzyme determinations are made on the material collected from the duodenum. Enzyme determinations have not yielded much diagnostic information and the tendency at the present time is to omit them. The test gives useful information in pancreatic diseases associated with diminished secretion such as advanced chronic pancreatitis and cancer of the pancreas.

The secretin test also yields useful information regarding the functional state of the gall bladder. It will be recalled that although secretin increases the output of bile from the liver it does not cause the gall bladder to empty, consequently the bile secreted during a test is normally stored in the gall bladder and does not appear in large amounts in the duodenal contents. If the gall bladder has been removed, or it is so diseased as to be nonfunctional the secreted bile is poured into the duodenum and appears in all the samples collected. Three types of response are recognized: (1) no bile in any sample, this indicates obstruction in the biliary system, or if jaundice is absent, it may be considered normal, (2) some, but not all, samples are free of bile or contain only traces, the normal response, (3) all samples heavily colored with bile, indicates a nonfunctioning gall bladder.

Secretion of Bile by the Liver

The liver forms a secretion which is also an excretion consisting of water, bile salts, bile pigments, inorganic salts and a mixture of lipid materials including fats, cholesterol and lecithin, see table 40 3 The formation of bile is accomplished by two types of cells, the *reticuloendothelial cells*, which help to line the liver sinusoids, and the *liver cells proper* The sinusoids convey blood from the portal vein and hepatic artery to the hepatic vein The reticuloendothelial cells, known in the liver as Kupffer cells, are not confined to the liver but occur also in the spleen and bone marrow where they likewise help to line vascular channels Another name for the Kupffer cells is stellate cells, so called because the cells are frequently star shaped when seen in the endothelial lining of the liver sinusoid Similar cells occur free in the connective tissues, and elsewhere in the body and together comprise what is known as the reticuloendothelial system In general these cells have a phagocytic function, their role in the production of bile will be considered later

The other cells concerned in the secretion of bile, hepatic cells proper, make up the liver lobule and surround the biliary canaliculi The liver cell has an unusually intimate relation to the blood and to the secretion that it forms The lining of the liver sinusoids is said to be deficient in places allowing the blood to come into direct contact with the liver cells On the other hand branching, intracellular canaliculi containing bile have been described as occurring in actively secreting cells The liver cell thus forms a narrow wall between the blood stream on the one hand and the bile stream on the other and it is not surprising that bile sometimes escapes from, or through, the liver cells into the blood

The steady flow of bile from the liver serves as an avenue for the secretion of certain substances important in digestion, and for the excretion of others The most important secretory products of the liver are the bile acids which

appear in the bile as salts of sodium or potassium There are a variety of bile acids to be found in the bile of different species of animals, all of which are formed by conjugation of an amino acid with cholic acid The structural formula of cholic acid contains the tetracyclic carbon group characteristic of the sterols, this is shown below in skeleton form

Cholic acid is therefore related to cholesterol, to the male and female sex hormones (ch. 60) and to corticosterone and other adrenal steroid fractions (ch. 58) It is highly probable that cholesterol is a precursor of cholic acid in normal metabolism Block and his associates have demonstrated the production of cholic acid from cholesterol The latter containing deuterium was fed to dogs, cholic acid containing the isotope was isolated from the urine

THE COMPOSITION OF THE BILE

Table 39 3 gives the composition of human liver bile (parts in 1000), modified from Hammarsten Liver bile has a pH of between 8 0 and 8 6 The reaction of human gall bladder bile is neutral or slightly alkaline, that of the dog (or cat) is definitely acid—pH between 5 0 and 6 0 The chief biliary components are the *bile salts*, *bile pigments*, *cholesterol* and *lecithin* These organic materials make up over 60 per cent of the total biliary solids As a result of the absorption of water and inorganic salts gallbladder bile is several times more concentrated in organic solids than liver bile The biliary constituents may vary independently of one another The acids of human bile are glycocholic and taurocholic acids in which the cholic acid is conjugated with glycocoli, or with taurine Taurine is related to cystine, a sulfur containing amino acid glycine we are familiar with as the simplest amino acid and one which can be synthesized by the body The bile acids therefore all contain nitrogen and taurine contains sulfur in addition The bile acids are presumed to be synthesized in the liver cells, but positive proof of their origin is not available

Little can be said concerning the *site of origin* of the cholic acid, whether it is formed by the hepatic epithelium, or is merely brought preformed to the liver from other body tissues is not

TABLE 39 3

Water	976 22
Solids	23 78
Mucin and pigments	5 00
Bile salts	9 00
Fatty acids from soaps	1 23
Cholesterol	0 63
Lecithin	0 60
Fat	
Inorganic salts	7 32

known That some is formed in the body is indicated by the fact that the bile salts continue to be discharged from a biliary fistula during long periods of starvation That it is derived also from the food appears from the observation that increased excretion follows the ingestion of protein material Though the supplies of glycerol and taurine within the body are apparently plentiful the supply of cholic acid is limited for experiments in which taurine was fed alone caused no increase in the excretion of bile salts whereas cholic acid ingestion alone caused a rise in the excretion of taurocholic acid It is possible to deplete the taurine stores by feeding cholic acid for several days to a dog with a biliary fistula When cystine disulphide cysteine cysteinesulfinic acid or cysteic acid is then fed with cholic acid an increase in the taurocholic acid of the bile follows (Virtue and Doster Virtue) This result suggests that from such or similar compounds taurine is produced in the body That is taurine under these circumstances is evidently supplied from body sources whereas cholic acid must be furnished in the diet The quantity of cholic acid available apparently determines the level of bile acid production (Whipple)

So far as is known the liver is the only situation where the conjugation of taurine or of glycerol with cholic acid and the production of the respective bile acid can take place The following observations suggest that their formation is a specific function of the liver (1) When the function of the liver is depressed by injury or by the establishment of an Eck fistula the output of bile salts may be reduced by 50 per cent or more (Smyth and Whipple 1924) (2) Bile acids appear in the blood of dogs when the common bile duct is ligated On the other hand no accumulation occurs in the blood after removal of the liver

The Circulation of the Bile Salts

After their passage into the intestine the bile salts undergo reabsorption and are carried in the portal blood stream back to the liver for re-excretion This portal biliary circulation of the bile salts is intimately connected with the absorption of fat (p 646) When bile salts are fed to an animal they can be recovered almost quantitatively from a biliary fistula This indicates that in the intact animal the reabsorption of bile salts is almost complete (about 90 per cent) Under ordinary circumstances comparatively small amounts (about 10 per cent) of bile salts are formed afresh i.e., their concentration in the bile is maintained largely as a result of their being circulated over and over again through the portal and biliary systems Nevertheless if the bile is prevented from entering the intestine by

draining it to the exterior through the fistula, its concentration in bile salts does not become materially reduced Experiments by Berman and associates (1941) indicate that a homeostatic mechanism regulates synthesis of bile acids in such a way that the amount synthesized balances the amount lost Thus if an animal is fed an excess of bile acids synthesis is depressed until the excess amount has been eliminated On the other hand if bile acids are drained away by removing bile from the body, synthesis of bile acids is increased

Test for bile salts Pettenkoffer's test Five cubic centimeters of the fluid to be tested are mixed in a test tube with a few drops of a 10 per cent solution of cane sugar One or two cubic centimeters of concentrated sulfuric acid are introduced beneath the surface of the mixture The appearance of a red ring at the junction of the two liquids indicates the presence of bile salts upon agitation the color diffuses through the solution The color is due to the formation of cholalic acid from the bile acids and its combination with the furfural resulting from the decomposition of the cane sugar A few drops of a 1 in 1000 aqueous solution of furfural itself may be employed (Mylus's modification) instead of the sugar solution

Rowntree and associates have developed a method for the quantitative estimation of bile salts in blood based upon the Pettenkoffer reaction The bile salts are extracted from the blood with alcohol and the test performed upon the extract The color is compared in a colorimeter with that produced under similar conditions in a standard solution of pure glycocholic acid The results are expressed in terms of glycocholic acid Normal human blood contains from 2.5 to 6 mg. per cent of bile acids In obstructive jaundice the value is increased sometimes several fold

Hay's test is based upon the property of the bile acids to lower surface tension (p 646)

The Bile Pigments

The biliary pigments are *bilirubin* and *biliverdin* Bilirubin ($C_{42}H_{58}N_4O_6$) is the chief pigment in human bile and in the bile of the carnivora Biliverdin ($C_{42}H_{58}N_4O_6$) is an oxidative derivative of bilirubin and is present only in small amounts in human bile but is the chief pigment of birds bile The pigments constitute from 15 to 20 per cent of the total solids in liver bile

The readiness with which the bile pigments are oxidized and the color changes which they undergo in the process are the basis for Gmelin's test for bile in body fluids If for example a fluid containing bile is passed through filter paper and a drop of fuming nitric acid be then dropped upon the

wet surface of the filter, the pigment is oxidized and a series of concentric rings of different colors appears—yellow, yellowish red, violet and blue green from within outwards. Besides biliverdin other derivatives of bilirubin are found in the body. Urobilinogen (cf. below and ch. 6) is a reduction product of bilirubin, upon oxidation it yields urobilin. Bilicyanin and bilifuscin are formed by the oxidation of biliverdin. The latter two pigments are not found in bile but may be present in gallstones.

Origin of the bile pigments. Bile pigments are derived from the free hemoglobin which results from the destruction of red cells in the body and, in smaller amounts, from other chromoproteins. The red cells have a life span of about 100 to 120 days. Those that perish are disposed of by the

The bilirubin is believed to be taken out of the blood and transferred into the bile through the activity of the liver cells. In the process the pigment is separated from the plasma globulin and, in the liver cells, is conjugated with glycuronic acid forming bilirubin glycuronide (Schmidt, 1956, Billing *et al.*, 1957). Since bilirubin is capable of combining with two molecules of glycuronic acid either the mono- or diglycuronide may be formed. The conjugation may take place also in the kidney but apparently does so only to a slight extent. The iron is stored in the liver, spleen and other tissues and with the globin is eventually utilized for synthesis of new hemoglobin. The chemical relationship between bilirubinglobin and the various bile pigment derivatives is shown schematically below.

reticuloendothelial cells distributed throughout the body. From these cells an average of about 8 grams of hemoglobin is released per day which yields about 280 mg of bile pigments. In order to produce bile pigment from hemoglobin the heme portion must be separated from the protein (globin) portion of the hemoglobin molecule. There is then oxidative scission of the iron-porphyrin. This involves opening of the tetrapyrrole ring at the α position and the "shelling out" of iron. The resulting iron-free pigment is probably biliverdin which is later reduced to bilirubin by the addition of one hydrogen atom. All these reactions are presumed to take place in the reticuloendothelial cells, but the order in which they occur is not known (Drabkin, 1951). In particular it is not known if the splitting of the heme moiety on the protein portion of the molecule must take place before the porphyrin ring is open. In any case the bilirubin is not carried in the blood as such but as a bilirubin protein complex. The bilirubin probably combines with α -globulin of the blood.

It is evident from the distribution of the reticuloendothelial system that bile pigments may be formed, not only in the liver, but also in the spleen and bone marrow and at various other places in the body. This was not generally recognized until the experiments of Whipple and Hooper (1913) and the more conclusive experiments of Mann and his associates (1924, 1925, 1926). The former attempted to isolate the liver from the general circulation whereas the latter removed the liver completely. In either case bile pigments continued to be formed and, since they could not be excreted through the liver, they accumulated in the blood and produced a condition analogous to jaundice. Mann and his associates also showed, by a spectroscopic method, that the blood of the splenic vein of a normal animal has a higher bilirubin concentration than that in the corresponding artery.

UROBILINOGEN, UROBILIN, THE CIRCULATION OF BILE PIGMENT. The bilirubin that enters the intestine undergoes reduction by bacteria to form urobilinogen (also called stercobilinogen). A part of

this is excreted in the stools and, by exposure to air, is oxidized to *urobilin* (*stercobilin*). The latter can be detected spectroscopically or by the green fluorescence which it gives with a solution of alcoholic zinc acetate. A certain proportion of the urobilinogen is reabsorbed into the portal circulation and passes to the liver where it is reconverted in part to bilirubin in the bile (fig 39 1). It is then almost entirely re-excreted both as bilirubin and as urobilinogen. Any urobilinogen which may escape into the general circulation and be excreted by the kidney becomes oxidized to urobilin after the urine has been voided. Normally, however, no urobilin or mere traces (0.5 to 2 mg) appears in the urine. Only traces are present in normal blood. Bilirubin itself does not appear normally in the urine, so the color of urine is due to neither of these pigments. That the urobilinogen normally present in bile merely represents reexcretion of this pigment after its absorption from the intestine was clearly shown by Elman and McMaster. When the entire output of bile was collected through a fistula (i.e., none was allowed to enter the intestine) there was complete disappearance of urobilinogen from the bile after the pigment already present in the intestine had been carried away in the feces. The fistula bile remained free from urobilinogen unless infection of the biliary tracts had occurred, under which circumstance bacterial action in these situations caused its formation. When a part of the bile was allowed to enter the intestine or bile was fed by mouth the derived pigment invariably appeared in the fistula bile.

Also, complete experimental obstruction of the common bile duct, since it prevented the re-excretion of the urobilinogen absorbed from the intestine, resulted in its accumulation in the blood and its excretion in the urine. These effects, however, can only occur for a short time after the duct has been obstructed, and are due to the absorption of pigment remaining in the intestine from the period prior to obstruction. After the pigment has been cleared from the intestine, the urine although it may contain large amounts of bilirubin, is quite free from the derived pigment. Depression of the excretory function of the liver by such hepatic poisons as chloroform, carbon tetrachloride, phosphorus, etc., caused urobilinogen to appear in the urine. hepatic damage from other causes, e.g., infectious hepatitis is also associated with the urinary excretion of urobilinogen even though the injury is slight and there is no bilirubinuria. When bilirubin formation is increased by hemolytic agents urobilinogen

FIG 39 1 Diagram illustrating the formation of urobilinogen from bilirubin in the intestine, its excretion in part into the feces and its absorption in part into the portal blood. Normally the absorbed pigment except in negligible amounts is practically all re-excreted in the bile. The dotted lines indicate its passage into the blood and its excretion by the kidney in cases of liver damage, excessive blood destruction or in the early stages of obstructive jaundice.

production is also increased, the liver even though its function is normal is unable to reexcrete the excess pigment absorbed from the intestine, and urobilin appears in the urine.

Urobilinogen is in rare instances formed in situations other than the intestinal tract and independently of bacterial action. Rabinowitch (1930) for example has reported a case in which large quantities of urobilinogen were present in the urine. A sterile ovarian cyst containing an old blood clot and a high percentage of urobilinogen was revealed by operation. When the cyst was removed the urobilinogen disappeared from the urine.

Lecithin and Cholesterol

Lecithin is present in human liver bile to the extent of from 0.02 to 0.05 per cent. The *cholesterol* content is normally from 0.04 to 0.16 per cent. The cholesterol is present in the free state, i.e., not in the form of esters. The percentages of these materials in the bile of the gall bladder is, as a result of the absorption of water and salts through the gall bladder mucosa, much higher than the percentages in liver bile. The ratio of the concentration of cholesterol in bile to that of the bile salts is from 1:20 to 1:30. The ability of the bile to hold cholesterol in solution is in large degree dependent upon the bile salts. If the ratio

falls to 1/13 precipitation of cholesterol occurs. Andrews and associates showed that if bile be dialyzed against water, bile salts are removed and the bile becomes turbid as a result of cholesterol precipitation. The importance of this observation in relation to gall-stone formation is considered on page 651. The fatty acid concentration of the bile is of as great if not greater importance than the bile salt concentration in holding cholesterol in solution. Little is known concerning the origin and function of the biliary cholesterol. It may be derived from the stroma of disintegrated red cells or from nervous tissue, which of course contains it in large amounts. According to Gardner the cholesterol of the bile does not vary with changes in the total blood cholesterol nor is its concentration raised by increasing the cholesterol content of the diet; it continues to be excreted upon a cholesterol-free diet. A biliary portal circulation of cholesterol has been shown to occur, i.e., excretion in the bile, reabsorption from the intestine and re-excretion by the liver.

REGULATION OF THE SECRETION OF BILE

Bile is secreted continuously. This is consistent with the fact that bile is an excretion as well as a secretion. On a normal feeding schedule more bile is secreted during the daylight hours than during the night. This is due to the fact that more bile is secreted after meals than in the fasting state and meals are normally eaten in the daytime. If an animal is fed at regular intervals throughout the 24 hours as much bile is secreted at night as in the day time. The stimulating effect of food on the volume output of bile is mainly due to its protein content. Kocour and Ivy (1937) studied a variety of foods for their effect on the output of bile and found that only meat and liver were consistently effective. Fat had some tendency to increase the output but was unreliable. Glucose given orally tended to decrease the output of bile provided the bile secreted was not returned to the intestine. When the secreted bile was returned to the intestine the glucose had no consistent effect on the output.

Before proceeding to discuss in detail the various agents that influence the flow of bile it is well to define some of the terms that will be used. A more extensive list of terms with definitions is given by Ivy (1944). A *cholagogue*, is any agent which increases the flow of bile into the intestine. The bile may come from the gall bladder so the word does not necessarily signify an increase in the secretion of bile by the liver. A *choloretic* is an agent which increases the output of bile from

the liver without necessarily changing its concentration, thus a choloretic will usually increase the outputs of bile solids as well as the liquid portion of the bile. A *hydrocholoretic* causes an increase in the volume of bile without a corresponding increase in the output of bile solids.

The natural bile salts have a powerful choloretic action on the liver and no doubt a great part of the increase in the flow of bile after a meal is the result of the discharge of bile from the gall bladder which increases the amount of bile acids in the intestine and consequently in the portal blood. Certain oxidized bile acids notably dehydrocholic acid, act as hydrocholoretics and are sometimes used in therapy to produce an abundant flow of dilute bile. The hydrochloric acid of the gastric juice when present in the intestine increases the volume flow of bile, this is probably a result of the release of secretin or possibly a more specific hormone from the intestinal mucous membrane by the action of the acid.

Although the intravenous injection of various secretin preparations is followed by an increase in bile flow, there is some doubt as to whether the action is really due to secretin. Friedman and Snape (1945) found that the effect of an intestinal extract on the secretion of bile by the liver was not always proportional to its secretin content as judged by its effect on the pancreas. Some secretin preparations were effective choloretics but had little effect on the pancreas. Their experiments suggest that there may be a specific liver hormone (*hepatocrinin*) in intestinal extracts. Since foods also caused release of secretin from the intestine it may be that some part of the action of food, aside from the action of hydrochloric acid, may also be attributed to secretin or hepatocrinin as the case may be. At any rate the purest secretin available increases the secretion of bile by the liver although it does not contract the gall bladder. Studies by Grossman and his coworkers (1949) indicate that in the human secretin acts as a hydrocholoretic.

Secretin causes only a moderate increase in bile flow and none at all if the liver is already secreting vigorously. The maximal rate of flow that can be induced by secretin is only about one-tenth the rate that can be attained by the administration of bile acids and this ratio cannot be increased by increasing the dose of secretin. The increase in the amount of bile formed is usually less than the increase in the amount of pancreatic juice secreted in response to a given dose of highly purified secretin and the latent period of the liver is longer than that of the pancreas (Fried

man, 1950) These facts suggest that secretin is not a major factor in the regulation of bile secretion. On the other hand hepatocerinin, if it exists as a separate hormone, may be a major factor.

In addition to humoral and hormonal factors affecting the secretion of bile, the nervous system may take part in the regulation of bile flow. The secretion of bile is increased by stimulation of the vagus nerves, but the principal effect of the autonomic innervation on bile secretion appears to be inhibitory. Denervating the liver, insofar as this is possible, causes an increase in bile flow, distention of the colon or stimulation of any one of a number of visceral afferent nerves causes inhibition of the flow of bile from the liver. It is not known whether the inhibitory effect is due to direct inhibition of the liver cells or to alterations in hepatic blood flow.

The Mechanism of Secretion of Bile by the Liver

In considering the mechanism of bile secretion it is convenient to divide the bile constituents into two classes (Brauer, 1938). Class A, which includes water, the inorganic salts, and other highly diffusible constituents and Class B, which includes the bile pigments, bile acids and certain foreign substances such as Bromsulphalein which may be used in liver function tests and appear in the bile. There is good evidence that water is secreted by the liver cells by an active process involving expenditure of energy. Pure mechanical filtration is ruled out by the fact that bile may be secreted under a pressure which is higher than the pressure of the blood in contact with the liver cells. As pointed out by Brauer, in order for a filtration process such as is utilized in the kidney to be effective it would be necessary that capillary pressure should exceed the maximum pressure of bile in the bile ducts by an amount at least equal to the colloid osmotic pressure of the blood, this condition is not attained in the liver. The flow of bile has been shown to be independent of blood flow or of blood pressure so long as the oxygen supply is adequate. Another bit of evidence is that cooling the liver greatly reduces the rate of flow of bile. For example, in the rat liver a 10°C reduction in the perfusion temperature between 18° and 38°C reduces bile flow by a factor of 4. Such a change in temperature should have little or no effect on a pure mechanical process. Ether anesthesia also reduces the flow of bile. The situation is not so clear with respect to the inorganic salts and it may be supposed that they are transferred along with the water. The evidence suggests that there is a free interchange of inor-

ganic salts between the blood and the bile as the bile passes through the bile ducts, thus osmotic equilibrium is established between the blood and the bile.

It is interesting that if the concentration of salts in blood plasma is increased so as to make the blood hypertonic, vacuoles appear in the polygonal cells of the liver. This is taken as evidence that these cells are involved in secretion of water into the bile. That these hepatic cells secrete the water is further evidenced by the fact that in certain forms of toxic hepatitis in which only the polygonal cells are damaged, a sharp reduction in the volume of bile is one of the earliest signs (Brauer, 1938). Bile may be reabsorbed into the blood if the pressure of bile in the bile ducts is elevated above a certain critical level but at normal pressures reabsorption of bile is negligible.

That the organic constituents of the bile are actively secreted has never been questioned. They appear in such concentrations in the bile relative to their concentration in the blood that an active process is inevitable. The liver cells exhibit a certain maximum capacity for secreting various of the bile constituents comparable to the tubular maximum of the kidney tubules for certain of the constituents of the urine. For example, there is a maximum rate of secretion of Bromsulphalein into the bile beyond which an increase in the dose or in the rate of infusion into the blood no longer alters the secretion rate. Similar phenomena have been observed for sodium dehydrocholate, bilirubin, and certain dyes. That the same cells are involved in the secretion of different organic compounds is indicated by the fact that the secretion of some of these by the liver cells limits the rate of secretion of certain others, for example, if the liver is actively secreting Bromsulphalein its capacity to secrete bilirubin is limited and if it is actively secreting bilirubin near its maximum capacity it is unable to secrete bile salts at their normal maximal rate. These facts indicate that there is competition within the individual liver cells among the various substances that are secreted into the bile.

It has been possible to observe in suitable preparations, the path taken by certain of the substances that are secreted into the bile. For example, fluorescein can be seen to appear first in the parenchymal cells of the liver, then to be secreted into the bile canaliculi and to be transported down the bile ducts. Similar observations are possible by different methods using radioactive isotopes. Thus it appears that all the

constituents of the bile, both organic and inorganic are normally secreted by the liver cells and, with the possible exception of the inorganic salts, by a process which involves the expenditure of energy

THE FUNCTION OF BILE IN DIGESTION

Only the salts of the bile acids are useful in digestion. The other constituents of bile are present as excretory products (with the exception of the inorganic salts which probably reach the bile by diffusion and are neither secreted nor excreted). The bile salts in the intestine aid in digestion and absorption of fat largely because of their surface tension lowering properties and their ability to form chemical compounds with fatty acids, thus increasing their solubility. The ability of bile salts to reduce the surface tension of water aids in emulsification of fats and increases the activity of pancreatic lipase. Fats, being insoluble in water, present special difficulties to the digestive apparatus since digestion is a hydrolytic process and the digestive enzymes are dissolved in water. Special means are necessary in order to bring the fat particles into contact with lipase which is dispersed in the aqueous phase. This can be accomplished by any one of several wetting agents, bile being a natural detergent accomplishes this purpose in the living body.

The fatty acids that are liberated by hydrolysis of triglyceride fat form soluble soaps in an alkaline medium but the intestinal contents are usually not sufficiently alkaline to maintain any considerable quantity of fatty acids in solution in this way. After liberation from the glycerol molecule the free fatty acids are said to combine with bile salts (Verzar and McDougall). It is believed that these soluble compounds can penetrate the epithelial cells of the intestine and thus facilitate absorption of fatty acids. Absorption of fats will be discussed in greater detail in the next chapter.

The idea put forward by Mellanby that bile acts as a stimulus for release of secretin from the intestinal mucosa and in this way brings about secretion of pancreatic juice has been proved to be erroneous. In certain circumstances bile may facilitate the release of secretin into the blood but this is not an important part of the secretin mechanism (Thomas and Crider, 1943). Bile in the intestine has a tendency to stimulate peristalsis and is often credited with having a mild laxative action. This action would probably be manifest only in a condition in which there was a pathological deficiency of bile in the intestine.

JAUNDICE

Definition and Classification

When bile pigment is present in excessive amount in the blood (hyperbilirubinemia) it diffuses from the capillaries, the skin, mucous membranes and conjunctivas then become stained a pale yellow tint. But the pigment is not merely dissolved in the tissue fluids but appears to be bound in some way to the tissues. The discoloration is called *jaundice* or *icterus*. The bilirubin appears in the urine and sweat but does not pass into the saliva or milk, nor as a rule into the cerebrospinal fluid.² Jaundice may be due to the production of bile pigment in excess of the amount with which the excretory power of the liver can cope. Or, it may result from the failure of a damaged liver to excrete the bilirubin produced in normal amounts. Jaundice may therefore be divided into two main groups corresponding to the mode of its production. These are, the *hemolytic* and the *hepatic*, the former resulting from increased production of bile pigment from hemoglobin, and the latter from depressed or suppressed excretion of pigment by the liver. In the hepatic form the retention of pigment may be due to (a) obstruction of the bile passages or (b) damage of the liver cells by toxic agents or infections. Jaundice is also sometimes classified into obstructive and nonobstructive, the latter being subdivided into hemolytic, on the one hand, and toxic or infective on the other. These principal varieties of jaundice are tabulated below.

	1 Hemolytic jaundice	
Hepatic	2 Toxic, or infective jaundice	nonobstructive
	3 Obstructive jaundice	

A third classification proposed by Rich has come into use based upon whether bile pigment has been taken up by the liver cells and then returned to the blood, or has been rejected by the cells (due to hepatic dysfunction or to an excess of pigment), and thus retained in the circulation. The first mentioned type is called *regurgitation jaundice*, it includes obstructive jaundice, and jaundice due to damage of liver cells, and, therefore of the walls of the biliary canaliculi which permits whole bile to "regurgitate" into the circulation.

In the second form, called *retention jaundice*, excessive amounts of bile pigment are produced (hemolytic jaundice) part of which is not taken

² Its appearance in the cerebrospinal fluid is not uncommon in children.

up by the hepatic parenchyma and is therefore retained in the circulation, or the function of the hepatic cells is so depressed that a large part of the circulating bilirubin, even though not produced in excess, fails to be excreted.

Hemolytic (Retention) Jaundice

It has already been mentioned that a small amount of bile pigment (0.2 to 0.8 mg per cent) is present in normal human serum and that any condition which increases red cell destruction also increases the formation of bile pigment. However, the functional reserve of the liver is so great that this is very doubtful whether overproduction of bile pigment ever taxes the excretory capacity of an undamaged liver to the limit. But when the hepatic reserve is reduced as a result of disease and hemolysis is excessive the normal balance between the production and the excretion of pigment cannot be maintained; retention occurs and the bilirubin concentration in the blood rises above the normal limits. *Hemolytic agents* of all sorts, such as the toxins of certain infections (septicemia, etc.), and various chemical poisons may induce icterus (p. 77) of this type. It also occurs to some degree in such states as *pernicious anemia*, *malaria*, etc., in which blood destruction is a pronounced feature. It may be produced in animals by the injection of such hemolytic poisons as toluylenediamine and arsenuretted hydrogen. The disease known as *acholuric jaundice* which tends to run in families and is associated with splenic enlargement and increases fragility of the red cells (p. 77), is of this type. Jaundice in the newborn, *icterus neonatorum* (*benign*) frequently occurs as a slight transient staining of the skin and is most probably the result of the destruction of the red cells that are in excess at birth (p. 12). It is perfectly innocent and indeed may be considered physiological. It does not appear until a day or two after birth and lasts for five or six days.

Obstructive (Regurgitation) Jaundice

Obstructive jaundice results from blockage of the hepatic or common bile duct by (a) a gallstone or parasites within its lumen, (b) compression of the duct by a tumor (e.g., in head of pancreas) or occlusion of its opening into the duodenum, (c) congenital obliteration of the ducts (a fatal form of *icterus neonatorum*).

In complete biliary obstruction the stools are clay-colored, urobilinogen (p. 642) is absent from the feces and urobilin from the urine. In this type of jaundice bile pigment is believed to pass into

FIG. 39.2. Illustrating the course taken by bile pigment: (1) normally; (2) in jaundice due to obstruction or to liver damage (regurgitation jaundice) and (3) in hemolytic (retention) jaundice. In (2) bilirubinate is formed by the liver cells and is absorbed into the circulation; in (3) part of the bilirubin itself or of bilirubinglobin is retained in the blood.

the liver cells where globin is split off and the pigment combined with glycuronic acid to form bilirubin glucuronide. The latter after its discharge into the biliary canaliculi is returned—regurgitated—into the blood as a result of the rupture or in parenchymatous liver disease disintegration of the canicular walls.

McMaster and Rous found, for example, that when obstructive jaundice was induced in dogs the ducts if occluded for long became filled with a fluid free from pigment and bile salts—the so-called *white bile* (p. 656). According to these observers the colorless fluid is not bile but a simple seromucoid material secreted by the membrane lining the ducts.

The excretory mechanism of the liver has been shown by McMaster and Rous to possess a very large reserve since in the dog jaundice does not develop until from 90 to 95 per cent of the excretory ducts have been occluded.

Toxic and Infective Jaundice—Liver Damage

Liver damage and consequent depression of the secretory functions of the liver may be produced by (a) various poisons, e.g., arsenamine, phos-

phorus, chloroform, etc., (b) *acute and chronic liver diseases*, e.g., infectious hepatitis, homologous serum jaundice (p. 42) acute yellow atrophy, cirrhosis, inflammation of the bile passages (catarrhal jaundice, suppurative cholangitis), (c) *toxins of various pathogenic bacteria*, (d) engorgement of the hepatic vessels as a result of *cardiac failure*. It has been pointed out by Meakins that in the latter condition the edema or ascitic fluid does not contain bilirubin and the skin over edematous regions is not stained. There is no explanation of this fact.

The Features in Different Types of Jaundice Compared (See Table 39.4)

In obstructive jaundice and in jaundice resulting from liver damage, the staining of the skin, mucous membranes and urine with bilirubin tends to be much more pronounced than in the hemolytic type. Except for a short time after the duct has been obstructed urobilin is absent from the urine and urobilinogen from the feces (p. 642). The plasma alkaline phosphatase shows a pronounced increase in obstructive jaundice, a smaller rise in parenchymatous liver disease, but little or no change in the hemolytic type. In obstructive jaundice the effects, e.g., *bradycardia*, *itching of the skin (pruritus)* referable to the retention of biliary constituents other than pigment may be evident. The cardiac slowing has been attributed to the action of the bile salts, though proof is lacking. Since the bile acids are conjugated in the liver it is not to be expected that their concentration in the blood will be raised in a purely hemolytic type of jaundice; this is found to be the case. On this account the latter type is sometimes spoken of as 'dissociated jaundice'. Also in severe liver damage bile acids may be absent from the blood although the hyperbilirubinemia is pronounced. In other instances of relatively mild degrees of hepatic insufficiency a converse type of 'dissociated jaundice' namely, increased concentration of bile acids in the blood without icterus, is sometimes seen.

The bleeding tendency in obstructive jaundice is a serious hazard should a patient be required to undergo a surgical operation. Only within recent years, as a result of the work of Roderick, of Quiek and his associates, and of Dam and Glavind, has the cause of the prolonged coagulation time been discovered. It is due to prothrombin deficiency, which is the result in turn of a virtual lack of vitamin K (p. 913), for when bile is absent from the intestine the vitamin is not absorbed in adequate amounts. The oral administration of

vitamin K with bile salts corrects the hemorrhagic tendency. Possibly an additional though minor factor in the lengthened coagulation time is the retention in the blood of certain organic sulfur containing compounds (e.g., cysteine and taurine) possessing anticoagulant properties (Carr and Foote). Jaundice due to liver damage is also sometimes associated with a prolonged bleeding time and then appears to be due to the incapacity of the liver to manufacture adequate amounts of prothrombin even though there is no lack of vitamin K in the diet or any failure in its absorption. The cause of the pruritus in obstructive jaundice is unknown. Rowntree and associates found that though a high concentration of bile acids in the blood was frequently associated with pruritus this symptom may occur with a normal bile-acid concentration or be absent when the latter is high.

In obstructive jaundice, with complete stoppage of the bile flow, urobilinogen is absent from the urine and feces but bilirubin excretion in the urine is pronounced whereas, in hemolytic jaundice the reverse is true, urobilinogen is excreted in the urine and feces in excess but little bilirubin appears in the urine (see table 40.4). In parenchymatous liver disease the albumin per globulin ratio is reduced and may be reversed due to an increase in the β and γ globulin fractions the albumin concentration often being reduced as well. In the other types of jaundice the ratio shows little change from the normal although there may be some reduction in the total protein concentration. Certain observations relevant to the foregoing discussion are given in table 39.4.

Jaundice Usually Due to a Combination of Causes

It should be pointed out that in any given case of jaundice two or all three causative factors may, and frequently do, coexist. Blood destruction alone, according to Rich, is not capable of producing jaundice except perhaps in rare instances when the hemolytic process is of extreme degree. In pernicious anemia for example, there is an associated hepatic insufficiency and even in the ordinary icterus of the newborn the immaturity of hepatic function is claimed to be a factor, also, many hemolytic substances are liver poisons as well. In obstructive jaundice the liver cells suffer damage from pressure and the retention of bile salts probably induces a certain amount of hemolysis. Furthermore, in many inflammatory conditions of the liver or bile ducts an obstructive element (due to plugging of the intrahepatic ducts by the so-called bile thrombi) exists in conjunction with the hepatic damage. In the jaundice of

TABLE 39 4

Chief differences in the three types of jaundice

	Types of Jaundice		
	Parenchymatous liver damage	Hemolytic	Obstructive (complete)
Serum bilirubin	Moderate increase	Slight or moderate increase	Great increase
Urinary bilirubin	Moderate increase	Little or no change	Great increase
Urobilinogen in urine	Great increase	Moderate increase	Absent
Bilirubin and urobilinogen (sterocobilin) in feces	Moderate increase	Great increase	Absent
Albumin globulin ratio	Greatly reduced or reversed	Little change	Little change
Van den Bergh test	Delayed direct or biphasic	Indirect	Direct
Plasma alkaline phosphatase	Little change	Little change	Great increase
Thymol turbidity cephalin flocculation and galactose tolerance tests	Positive	Negative	Negative
Jaundice	Moderate or slight	Moderate or slight	Pronounced with pruritus

cardiac diseases the hepatic engorgement produces obstruction of the finer bile capillaries as well as injury to the liver cells through anoxia. The occurrence of infarcts in the lung is also a factor in some cases, bilirubin production is increased through the breakdown of red cells in the infarcted areas.

Clinical Tests Employed in the Study of Jaundice

The van den Bergh reaction. This test—a modification of Ehrlich's diazo reaction—is employed for the detection of bile pigment in blood serum. There are two main types of the reaction—the *direct* and the *indirect*. The direct reaction occurs without the addition of alcohol, which is essential for the indirect reaction.

The reagents used in the test are

Solution A	
Sulphanilic acid	0.1 gram
Concentrated HCl	1.5 cc
Water up to	100 cc
Solution B	
Sodium nitrite	0.5 gram
Water	100 cc

To perform the test 10 cc of solution A and 0.3 cc of solution B are freely mixed. This mixture is used as the reagent in both forms of the test.

The *direct reaction* is that which follows the addition of 1 cc of the reagent to 1 cc of serum. It may occur in one of three forms, (a) *immediate* or *prompt*, a violet color due to the formation of

diazobilirubin develops in from 10 to 30 seconds (b) *Delayed reaction*, no change appears until several minutes (5 to 15 or more) elapse, then a reddish color develops which gradually deepens to violet (c) *Biphasic*, a red color appears promptly in (a) but takes a variable but longer time than in (b) to change to violet.

The *indirect reaction* is carried out as follows. One cc of serum is mixed with 2 cc of 95 per cent alcohol. After shaking and centrifuging, to 1 cc of the supernatant fluid, 0.25 cc of the reagent mixture and 0.5 cc of alcohol are added. A reddish violet color develops almost immediately.

Normal bile and the serum in obstructive jaundice give the prompt direct reaction. Normal serum, the serum in hemolytic jaundice and the bilirubin formed in old blood extravasations into the connective tissues, serous cavities, etc., give the indirect reaction and occasionally a delayed direct reaction. The sera in types of jaundice due to liver damage, e.g., hepatitis gives a direct reaction (usually of the delayed or biphasic type) all sera which give the direct reaction also give the indirect but the reverse does not hold. The qualitative van den Bergh reaction as a means of distinguishing between the different types of jaundice is regarded today with less favor than formerly.

The indirect reaction used as the basis for the *quantitative* estimation of bilirubin in all types of sera is of much more value. The serum after the color reaction has developed is compared in a

colorimeter with a standard solution made by dissolving 2.161 grams of anhydrous cobaltous sulfate in 100 cc of distilled water. The color of this standard corresponds to that developed by 1 unit of bilirubin. A unit is defined by van den Bergh as 1 part of bilirubin in 200,000 parts of serum. Normal serum contains from 0.4 to 1.5 unit (i.e., bilirubin is present in a dilution of 1 part in from 500,000 to 100,000 parts of serum, or from 0.2 to 1.0 mg. per 100 cc). In the quantitative estimation of bilirubin in sera showing the direct reaction the method has been rendered more accurate by the modification of Thannhauser and Anderson. This consists in first adding 0.5 cc of the reagent to 1 cc of the serum, and a minute or two later 2.5 cc of alcohol and 1 cc of a saturated solution of ammonium sulphate. By adding the diazo reagent before the alcohol the loss of bilirubin which results from its being carried down with the albuminous precipitate is avoided. When the alcohol is added later the diazobilirubin compound is not thrown down but remains in the supernatant fluid.

The quantitative van den Bergh reaction is of value in the detection of latent jaundice, i.e., a hyperbilirubinemia which has not reached the level at which jaundice appears, and in recording the progress of a case of manifest jaundice.

The difference between the direct and indirect van den Bergh reactions is due to the difference in the state of bilirubin in hemolytic and obstructive jaundice. Bilirubin that has passed through the liver cell and has been conjugated with glucuronic acid is soluble in water and is able to react at once with the reagents used in the direct test without addition of alcohol. Consequently bilirubin that has been secreted and reabsorbed as in obstructive jaundice gives the direct test. Circulating bilirubin that has not passed through the liver cell is insoluble except as a compound with some blood protein. It has to be set free and made soluble by addition of alcohol to the reagent before it will give the test.

The icteric index. The bile pigment concentration may also be estimated by comparing the color of the serum with that of a standard solution. A sample of blood is allowed to clot, after centrifuging, 5 cc of serum are pipetted off and the color of the sample compared in a colorimeter with a 1 in 10,000 solution of potassium bichromate. The colorimeter is set at 15 mm for the standard solution. This number is divided by the number on the serum scale when the color of the serum and of the standard solution match. The result is called the *icteric index*. Thus if the reading of the serum scale is 3 the icteric index is 5. The test is invalid

dated by the presence in the serum of other coloring matter, e.g., carotenoids.

Gallstones—Cholelithiasis

Gallstones are composed of constituents of the bile which have been thrown out of solution. Cholesterol is present in greater or less amounts in the commoner varieties of gallstone. Some stones may be composed almost entirely of this substance. In other types of stone, bile pigment or calcium is an important or the predominant constituent. Gallstones therefore differ considerably in size, color and inner structure according to the materials of which they are composed. They are classified according to their compositions into "pure" cholesterol, cholesterol-pigment-calcium, "pure" bilirubin, bilirubin-calcium and calcium carbonate stones. The latter are very rare in man but not uncommon in cattle. The "pure" cholesterol stone contains from 90 to 98 per cent of cholesterol, the remainder being made up of calcium, bile pigments, protein, etc. The "pure" pigment and the bilirubin-calcium stones, on the other hand, contain varying amounts of cholesterol. The cholesterol pigment-calcium stone is the commonest variety. Stones of this type are usually multiple and, as a result of pressure of one stone against another, show numerous facets upon their surfaces. They contain about 80 per cent of cholesterol which is deposited in cream-colored layers alternately with darker bilirubin-calcium laminae. The great majority of stones are formed in the gall bladder, but they may also form in the hepatic duct or even in the smaller ducts within the liver.

THE FORMATION OF GALLSTONES

The mechanism of gallstone formation is not clearly understood but the following are recognized as being the most important factors to be considered: (a) *Injury*, especially of an infectious nature to the gall bladder wall, (b) *disturbance in cholesterol metabolism*, (c) *stasis* of the bile, and (d) *reaction of the bile*.

(a) **INFECTION.** Following the classical work of Naunyn, infection was looked upon as the main, if not the only, cause of gallstone formation. Naunyn maintained, and it is now current teaching, that the cholesterol of the bile was not dependent upon the cholesterol level of the blood and could not be altered by diet. He also claimed, however, that abnormalities of cholesterol metabolism played a minor role in the production of gallstones. The mucosa of the gall bladder, he believed, normally secreted cholesterol and calcium and the secretory

process was stimulated by any local inflammatory state. Experiments in which human cholesterol stones were shown to be dissolved after a time in the gall bladder of the dog under sterile conditions, but not if infection were present, the production of gallstones by injections of microorganisms into the circulation after injury to the gall bladder, and the frequent occurrence of cholelithiasis after infective conditions, notably typhoid fever, were all taken to indicate that infection was essential for the production of biliary calculi. The solvent action of the bile salts upon cholesterol was also held to support this view and to be against the suggestion that this biliary constituent could be thrown out of solution in the absence of infection. It was argued that the bile as it came from the liver could never have so high a concentration of cholesterol that simple deposition could result, but that the cholesterol must be produced in excessive amounts by an inflamed gall bladder in order to be precipitated. Of the normal concentrating power of the gall bladder little was then known (see p. 655).

Though not denying the importance of gall bladder injury and the production of cholesterol from the inflamed mucosa in many cases of cholelithiasis, Aschoff and others have insisted that these conditions are not essential to the formation of calculi, and that certain types, especially the solitary cholesterol stone (see below) can arise in sterile bile and in the absence of any diseased condition of the lining membrane. This view is now generally accepted. Much of the earlier work upon cholesterol metabolism to which Naunyn pinned his faith has been proved to be erroneous.

The multiple cholesterol pigment calcium stones are usually looked upon as typical infection stones. They are laminated on cross section and have usually a framework of coagulated protein. These stones are often very numerous, sometimes numbered by hundreds, and an examination of their structure indicates that they have all been formed at about the same time. According to Aschoff, the starting point of their formation is the deposition of pigment in the form of fine rosette-like structures upon which coatings of cholesterol, pigment and calcium are subsequently laid. The inflammatory exudate is rich in protein material derived from the blood as well as in cholesterol and calcium. The protein, it is pointed out, carries an electric charge of opposite sign to that held by the cholesterol, pigment and inorganic constituents of the bile. It is believed that as a result of these physicochemical relations the deposition of cholesterol combined in varying degree with the other biliary constituents is effected.

(b) "METABOLIC." The typical 'metabolic' calculus is the large single stone of almost pure cholesterol—the *cholesterol solitaire*. This type of

stone, according to Aschoff, is formed quite independently of infection or injury of any sort and is due to the crystallization of cholesterol out of a bile surcharged with this material. The common mixed stones (cholesterol pigment calcium) are also composed predominantly of cholesterol and probably in many instances are metabolic rather than infective in origin. In certain conditions, e.g., pregnancy, in which gallstones are prone to develop, the blood cholesterol has been said to be higher than normal (hypercholesterolemia) and there is evidence of a disturbance in cholesterol metabolism. But as a matter of fact hypercholesterolemia, according to Gardner, (Gardner and Gainsborough 1930) is not common in pregnancy, the normal proportions of free cholesterol to cholesterol esters (cholesterol combined with fatty acids), however, are altered the former being increased, the latter reduced. Abnormalities in cholesterol metabolism leading to such changes are probably of more importance in the production of gallstones than a rise in the total blood cholesterol. It has already been mentioned that a high blood cholesterol does not cause an increase in the cholesterol of the bile. Also in certain forms of renal disease and in myxedema in which hypercholesterolemia exists there is little evidence that the latter leads to the production of gallstones, in other forms of renal disease the incidence of gallstones is higher than usual, yet hypercholesterolemia does not occur.

It has been mentioned that increasing the cholesterol of the diet does not raise the cholesterol concentration of the bile, so there is no logical reason, as pointed out by Gardner and Gainsborough for excluding cholesterol rich materials from the diets of those subject to cholelithiasis. Indeed, a high fat diet, by stimulating gall bladder contractions and so preventing undue concentration and stasis of bile may exert a beneficial effect.

The ratio of cholesterol in bile to the bile salts is an important factor in the formation of gallstones. The cholesterol bile acid ratio in normal bile is between 1/20 and 1/30. Since neither bile salts nor cholesterol are absorbed under normal circumstances from the gall bladder this ratio holds for both liver and gall bladder bile. According to Andrews, deposition of cholesterol occurs when the ratio falls to 1/13. He believes that infection, when it is a factor, plays its part in gallstone formation not so much through increasing cholesterol production as through reducing the bile salt concentration, for he claims that bile salts are absorbed through the inflamed gall bladder mucosa. Dalkart and associates attach more importance to the concentration of fatty acids in the bile than to that of the bile salts in preventing the precipitation of cholesterol.

"Pure" pigment stones (they contain calcium and cholesterol as well) also occur apart from in

fection They are small, and dark and, although usually occurring in the gall bladder, may be found in the bile passages Their origin is not clear, but since they often occur in conditions associated with an abnormally high bilirubin excretion, e g., acholuric jaundice, they may be the result of the precipitation of bilirubin from a bile which contains excessive amounts of the pigment

(c) STASIS OR SLOWING OF THE BILIARY FLOW within the bile passages may be responsible for the formation of small stones of pigment calcium in these situations When there is complete stasis, due to mechanical obstruction, the fluid in the larger bile passages contains none of the important biliary constituents The so called "white bile" fills the ducts and in consequence the formation of calculi is not possible (p 651) Complete biliary stasis appears also to be a very minor factor in the production of stones in the gall bladder

(d) REACTION OF THE BILE Until the work of Drury, Rous and McMaster this factor had received comparatively little attention These observers caused gallstones composed, in varying proportions, of calcium carbonate, pigment and cholesterol to be formed in the bile of dogs which had their gall bladders removed and their common ducts drained into a system of tubing Encrustations of biliary constituents as well as more or less discrete calculi formed upon the walls of the tubing These occurred under sterile conditions and in the absence of stasis The deposits are claimed to result from the alkalinity of the liver bile Normal bile of the dog as it flows along the bile passages was shown by Okada to be definitely alkaline whereas that of the gall bladder was acid Rous and his associates found the liver bile of dogs to have a pH of 8.20 or more while after its stay in the gall bladder its reaction became decidedly acid—pH 5.18 to 6.00 Bile from the human gall bladder, though less alkaline than liver bile, has rarely a pH below 7.0 One of the functions of the normal gall bladder (p 656) therefore appears to be depression of the pH of liver bile So long as this occurs in the usual manner the calcium carbonate of the bile remains in solution In an alkaline bile, such as is collected from the common duct in the absence of the gall bladder the calcium carbonate is thrown down, and with it the pigment and cholesterol constituents, to be deposited upon the walls of the delivery tubing These observations suggest therefore that in any condition which interferes with gall bladder function, e g., infection, injury, or intermittent stasis, the usual acidification of the liver bile will not occur, calcium carbonate will then undergo spontaneous precipitation, and serve as a center or centers upon which the other biliary constituents become deposited

An Enumeration of Hepatic Functions

Besides its secretory and excretory functions dealt with in this section the liver plays an important role in many other physiological processes For the reader's convenience a list of these with page references is given below

- (a) Blood formation in the embryo (p 99), storage of vitamin B₁₂ (p 81)
 - (b) Fibrinogen production (p 6)
 - (c) Prothrombin production (p 114)
 - (d) Heparin production (p 112)
 - (e) Iron and copper storage (pp 72-75)
 - (f) Blood volume regulation (ch 20)
 - (g) Reticuloendothelial activity (Kupffer cells) (p 102)
 - (h) Detoxication (p 721)
 - (i) Protein metabolism, deamination (ch 20), amino acid synthesis (ch 45), urea (ch 20), and uric acid (ch 47)
 - (j) Carbohydrate metabolism (ch 48)
 - (k) Fat metabolism (ch 49)
 - (l) Heat production (ch 52)
 - (m) Formation of vitamin A from carotene (ch 53)
 - (n) Liberation of a depressor principle (p 408)
- The hepatic circulation is dealt with in chapter 26

LIVER FUNCTION TESTS

Several of the specific functions of the liver have been utilized as tests for an investigation of the functional capacity of the liver as a whole, i.e., as a means of detecting the presence of hepatic damage and, in some instances, of gauging the extent to which such damage has occurred, and to distinguish between different types of jaundice Some of these tests will be very briefly described, the accounts being confined in the main to the general principles upon which the tests are based

Tests Based upon the Excretory Functions of the Liver

The quantitative van den Bergh reaction has been described (p 629) Since the excretion of bilirubin is an essential hepatic function a determination of the quantity of circulating bilirubin is a valuable means of estimating the extent of liver damage associated with jaundice, provided the hyperbilirubinemia is not the result of biliary obstruction or of blood destruction

The estimation of the quantity of urobilinogen excreted in the urine has also been employed as a test of liver function Increased blood destruction, as in pernicious anemia quite apart from liver damage will also cause urobilinogenuria but it is usually much less pronounced than that

due to parenchymatous liver disease. Also, infection of the biliary passages may increase the urobilinogen output out of all proportion to the reduction of liver function.

Other tests based upon the excretory function of the liver are the *Bromsulphalein*, *bilirubin* and *rose bengal* tests. In each of these tests the respective material is injected intravenously and the rate of excretion estimated from the quantity retained in the serum after the lapse of a specified time, the concentration of the material in the serum is determined colorimetrically. These three substances are excreted almost entirely by the liver and no significant amounts are taken up by the reticuloendothelial cells. In normal persons less than 5 per cent of bromsulphalein (5 mg per kg of body weight injected) is retained after 45 minutes, or of bilirubin (1 mg per kg of body weight injected) is observed at the end of 4 hours. In the case of rose bengal (10 cc of 1 per cent solution injected without regard to subject's weight) 50 per cent or more disappears from the serum within 8 minutes after the injection. These tests, like the van den Bergh test, will of course be of no value if obstruction of the bile ducts exists, obviously, whether damaged or not the liver cannot then excrete the injected substances. Colorimetric difficulties also render the dye tests inapplicable in the presence of hyperbilirubinemia from whatever cause. The bilirubin injection test is employed only in the absence of jaundice, for if the liver's power to excrete the endogenous bilirubin is depressed it is a foregone conclusion that it will show a corresponding incapacity to excrete the injected pigment. In the absence of jaundice, however, the bilirubin injection test is one of the most reliable means of estimating the degree of liver damage. Determination of the serum alkaline phosphatase level is one of the most sensitive tests of liver function (ch. 59).

Tests Based upon the Metabolic Functions of the Liver

(a) **THE GALACTOSE AND LEVULOSE (FRUCTOSE) TOLERANCE TESTS** In the *levulose tolerance* test the blood sugar curve is determined after the ingestion of from 40 to 50 grams of pure levulose dissolved in 250 cc of water—the dose of sugar is varied according to the subject's weight. The test is performed in the morning that is after a 12 hour fast. The blood sugar level is first determined before the ingestion of the sugar and every half hour for 2 hours thereafter. The liver converts levulose to glycogen; the greater quantity of sugar so converted the less pronounced will be the rise in the blood sugar. In absence of hepatic disease the ingestion of 40 grams or so of the sugar causes a maximum rise of the blood sugar curve of 30 mg per cent or less above the fasting level (when this is between 80 and 100 mg per 100 cc) within 1

hour, the curve returns to within 10 mg per cent of the fasting level within 2 hours. Definite hepatic injury is indicated by a rise in the blood sugar of over 30 mg per cent when the fasting level is between 80 and 100 mg per cent and a rise of 35 mg per cent, and of 40 mg per cent when the fasting levels are from 70 to 80 and from 60 to 70 mg per cent respectively. Failure of the curve to return to within 15 mg per cent of the fasting level after 2 hours, regardless of the height of the curve is also definitely abnormal.

A similar test may be made using galactose. At the end of a 12 hour fast the blood sugar level is determined and 40 gm of galactose given in 400 cc of water. The blood galactose level is then estimated at half hour intervals for 2 hours. Normally the maximum value is reached in 1 hour and does not rise to more than 63 mg per 100 cc and falls to 0 by the end of the 2 hours. Normally by the end of the fifth hour the total urinary excretion is less than 25 gm. Higher values than these in blood and urine are found in hepatic insufficiency (Peters and Van Slyke 1946).

(b) Tests based upon the function of the liver to deaminate the amino acids with the production of urea or upon its detoxicating function have also been devised. Although in the dog hippuric acid is synthesized (from glycine and benzoic acid) only in the kidney in the rabbit and in man this function is performed to an important extent by the liver as well. In carrying out this test benzoic acid (59 grams) is given orally 1.77 gram of sodium benzoate (equivalent to 1.50 gr benzoic acid) is given intravenously and the hippuric acid excretion is determined. Normally at least 1 gram of hippuric acid is excreted within an hour and the quantity of hippuric acid excreted in the urine at hourly intervals for 4 hours thereafter is determined. If the liver possesses some reserve from 3 to 3.5 grams are excreted within this time. The determination of the *prothrombin time* (ch. 12) is also employed as a liver function test. In damage of the liver, the prothrombin time is prolonged.

Tests Based upon the Protein Constitution of the Plasma

When damage to the hepatic parenchyma exists the albumin globulin ratio of the plasma is reduced due to an absolute increase in the β and γ globulin fractions and usually as well to an absolute reduction in the albumin fraction. The tests to be described are based upon the rise in the globulin fractions and the reduction in albumin, for the latter fraction tends to protect the globulin from the action of the reagent and thus to inhibit the reaction. The higher the serum globulin and the lower the albumin the more pronounced will the reaction be. The tests to be described cannot be correlated specifically with any given liver function and are, therefore, largely

empirical The first test of this type to be introduced is known as the *Taka Ara test*, after its originators In the presence of an excess of globulin a reagent composed of sodium carbonate, mercuric chloride and acid luchsins when added to the abnormal serum, causes the precipitation of the mercuric chloride A similar test is the *colloid gold test* of Gray But the most commonly used and the most satisfactory tests of this group are the *thymol turbidity test* of MacLagan, and the *cephalin cholesterol flocculation test* of Hanger In the former, 3 cc of the thymol reagent¹ are added to 0.05 cc of serum and the degree of turbidity measured after $\frac{1}{2}$ to 1 hour in a spectrophotometer at a wave length of 650 m μ The turbidity is believed to be due to the precipitation of a globulin-thymol phospholipid complex The cephalin cholesterol flocculation test consists of adding an emulsion of cephalin (100 mg from sheep's brain) and cholesterol (300 mg) to the serum and allowing the mixture to stand for from 24 to 48 hours Normal serum remains clear whereas the serum from a patient with parenchymatous liver disease (inflammatory or degenerative) shows flocculation

Several investigators have studied the reliability of the different liver function tests by comparing the results obtained with the histological findings in biopsy samples of hepatic tissue Sherlock obtains a cylinder of hepatic tissue by the use of a needle 1 mm in caliber and provided with a trocar The liver is punctured through the skin under local anesthesia She finds the most useful and reliable tests were determinations of serum bilirubin serum alkaline phosphatase and the albumin globulin ratio In experiments upon dogs in which the liver was damaged by carbon tetrachloride Drill and Ivy found that the number of hepatic functions affected increased with the severity of the liver damage The excretion of Bromsulphalein was the first to become depressed Serum alkaline phosphatase showed a rise about the same time or slightly later Next in order of sensitivity was the test for the prothrombin time, the galactose tolerance test was the least sensitive of the four tests employed From these results Drill and Ivy suggest that the association of hepatic functions rather than their dissociation (i.e., the singling out of one or other function by liver damage) should receive emphasis

It is to be remembered that the foregoing are purely functional tests and that a negative result does not necessarily indicate the absence of liver injury On the contrary liver disease may exist without its condition being revealed by any of these means This is obvious from the observations of McMaster and Rous and of Mann and his associates upon the reserve function of the liver The

first mentioned observers showed that in the dog 95 per cent of the excretory function could be abolished before jaundice appeared, Mann and his associates found that the liver tissue of the dog could be reduced by 80 per cent or more without a fall in urea production occurring

The Gall-Bladder and Bile Ducts

ANATOMY

The human gall bladder has a capacity of about 50 cc Its wall is composed of a thin layer of muscle fibers and fibroelastic tissue with a lining of mucous membrane The muscle fibers are sparse and loosely interlaced with one another and with the strands of fibroelastic tissue The mucosa is surmounted by a layer of columnar epithelium

The *cystic duct* through which the bile enters and later leaves the viscus is tortuous, or S shaped and shows spiral folds of mucosa—the *valves of Heister*—within its lumen These so called valves have not a valvelike action for they offer little resistance to the passage of bile in either direction, nor do they seem to prevent a too rapid flow of bile as some have supposed They develop late in phylogenetic history being associated apparently with the erect posture they are found only in primates The folds are formed in the embryo by the twisting or winding of the duct during development Their function as suggested by Keith and supported by Lichtenstein and Ivy is to stiffen the wall of the duct and prevent its kinking

The *common bile duct*, formed by the union of the hepatic and cystic ducts passes very obliquely through the muscular wall of the duodenum and joins with the pancreatic duct to form the *ampulla of Vater* (fig. 39.3) The latter opens into the duodenum through an orifice situated at the summit of a small papilla about $3\frac{1}{4}$ inches below the pylorus The ampulla of Vater is surrounded near its outlet into the duodenum by a ring of muscle fibers—the *sphincter of Oddi* Boyden has studied the circular fibers surrounding the common bile duct at its duodenal end (i.e., the smooth muscle usually referred to as the sphincter of Oddi) and distinguishes three sets of fibers (a) *sphincter choledochus* (or *Boyden's sphincter*), fibers which surround the duct between its penetration of the duodenal wall and the point where it is joined by the pancreatic duct, (b) fibers encircling the pancreatic duct where it opens into the ampulla and (c) those which surround the ampulla itself These latter are present in only about one sixth of human subjects, when in spasm they may block the ampullary portion of the common bile duct and permit bile to pass into the pancreatic duct or pancreatic juice to ascend the common bile duct The mucosa of the common duct is devoid of the usual mucous glands, but contains special branched tubular glands lined with tall columnar

¹ This consists of 1.33 grams barbitone, 1.03 grams sodium barbitone, 3 grams thymol, 500 ml doubly distilled water

FIG 39 3 Showing the smooth muscle surrounding the duodenal end of the common bile duct (After Boyden, slightly modified) D chol, common bile duct, D panc, pancreatic duct, Sph chol, sphincter choledochus (Boyden's sphincter), Sph amp, sphincter ampullae, Sph panc, sphincter pancreaticus surrounding the pancreatic duct, T. musc. cells. These glands furnish a thin fluid which dilutes the bile.

The gall bladder, though it possesses important functions, is not indispensable since it can be removed with impunity. After such an operation, however, the larger bile ducts undergo dilation, which may in part compensate for the removal of the viscus. The gall bladder is absent in some animals whose habits and digestive processes are not essentially different, apparently, from those of animals that possess one. It is absent in the horse, deer and rat but present in cattle, sheep, dogs, cats and mice. It is present in fish, amphibia, reptiles and birds, but is absent from orders lower than these.

Contractions of the Gall-Bladder and Common Bile Duct

The gall bladder shows spontaneous *rhythmical contractions* which occur at the rate of from 2 to 6 per minute (in the dog), and also a *tonic contraction* which lasts for from 5 to 30 minutes or more. The rhythmical contractions (in the dog) are capable of producing a pressure change of from 250 to 300 mm. of water which is about the maximum pressure at which bile can be secreted by the

FIG 39 4 Examples of normal gall bladder contractions. Time marker, 1 second (After Taylor and Wilson)

liver (fig 39 4). Rhythmical contractions of the common bile duct have also been demonstrated in animals.

THE FUNCTIONS OF THE GALL-BLADDER

The Concentration and Storage of Bile—The Secretion of Mucus

Gall bladder bile may be some ten times more concentrated in total solids than bile collected from the hepatic duct. Water and inorganic salts are absorbed through the lymphatics and blood vessels of the gall bladder wall. The composition of the absorbed fluid is virtually that of physio-

logical saline Bile pigments bile salts and cholesterol are not absorbed to any appreciable degree under normal circumstances

It is undecided whether cholesterol is excreted by the normal gall bladder mucosa although Elman and Taussig present evidence for such a process In this connection it may be mentioned that a pronounced diffuse deposition of a cholesterol ester in the connective tissue of the human gall bladder amounting to from 35 to 60 per cent of its dry weight is seen as a pathological condition The tissue of the vesicle is stiff and greatly thickened as a result of its impregnation with lipid material The disturbances leading to this condition which is spoken of as *cholesterosis of the gall-bladder* or from the appearance of the mucosa as the *strawberry gall-bladder* are unknown the existence of this condition cannot however be used as evidence for the secretion of cholesterol by the gall bladder mucosa under physiological conditions (see Elman and Graham)

To the work of Hammarsten and more recently to that of Rous and McMaster we owe the greater part of our knowledge of the absorptive powers of the gall bladder By means of a cannula placed in the bile duct the latter observers collected the bile as it came from the liver and compared its composition with that in the gall bladder The bilirubin percentages of the respective fluids were used as a measure of the degree of concentration that had been effected in the bile during its stay in the gall bladder The bladder bile was found to be darker thicker and more syrupy than the bile collected from the ducts It contained from 31 to 108 times more bilirubin than the liver bile Absorption occurred with remarkable rapidity in some instances In one experiment about 50 cc. of bile which entered the gall bladder was reduced to less than 5 cc. in about 22 hours In experiments involving the drainage of the gall bladder through a cannula inserted into its fundus it has been shown that the mere passage of bile through the organ causes a nearly fivefold concentration Inflammation of the gall bladder reduces or abolishes its concentrating power

The gall bladder mucosa also adds to the viscosity of the bile by the secretion of a thick mucinous material Little or none of this material is furnished by the bile ducts Nor were the latter observed to have any concentrating power but were found on the contrary to dilute the bile with a thin watery fluid

When the ducts were obstructed by ligation and the gall bladder tied off after some days a clear

colorless fluid was found to have collected within the ducts This fluid—the so-called *white bile*—is not uncommonly seen during an operation upon an obstructed bile duct associated with a functionless gall bladder The white bile under these circumstances is furnished solely by the mucosa of the ducts It contains no pigment bile salts or cholesterol and bears almost no resemblance to bile The secretion of the latter had been suppressed by the rise in pressure (to 300 mm. or so of water) within the ligated duct system

If the gall bladder is healthy and left in communication with the obstructed system the sequence of events is entirely different Biliary stasis then causes thick *greenish bile* to collect in the ducts and bladder as a result of the latter's concentrating activity and of the mucinous material which it secretes After a lapse of weeks the imprisoned bile develops an almost tarry consistency The functions of the ducts and of the bladder are therefore antagonistic the former tending to dilute the latter to concentrate the biliary fluid The diluting effect is at first overbalanced by the concentrating action of the gall bladder and when this remains in communication with the duct system the net result is marked thickening of the bile There is however a tendency with time for the activity of the ducts to overcome that of the gall bladder The biliary constituents disappear and ultimately the contents of the system are entirely replaced by the thin simple secretion of the ducts and mucinous material from the bladder (hydrops) (Rous and McMaster)

Another type of white bile is sometimes produced In dogs a clear colorless fluid is secreted by the liver cells when their true secretion is suppressed by some severe liver injury such as that induced by the administration of chloroform (Drury and Rous) White bile of this type is sometimes seen in the human subject as a result of hepatic disease

Other functions of the gall-bladder subsidiary to its concentrating power are the reduction in the *alkalinity* of the bile and the *equalization of pressure* within the biliary duct system Without the ability to absorb fluid and reduce the bulk of the bile its power to equalize pressure would be negligible It is to be remembered that the amount of bile secreted in 24 hours is some twenty times or so greater than could be contained in the gall bladder The loss of its action in equalizing the pressure within the duct system is probably a factor leading to the dilation of the bile ducts which so frequently follows removal of the gall bladder (cholecystectomy) After this operation the flow of bile into the intestine is at

first nearly continuous, but later the adaptation of the ducts permits intermittent discharge.

The importance of the gall bladder in the control of pressure within the biliary ducts is apparent from the results of the experiments of Mann and Bollman. They found that after ligation of the common duct in dogs a rise in the bilirubin concentration of the blood did not occur until from 24 to 36 hours had elapsed, and jaundice did not appear for 2 days. If, on the other hand, the gall bladder was removed at the time that the duct was ligated jaundice was fully developed within 24 hours due, presumably, to the rise in duct pressure, and the "regurgitation" of bile into the blood.

In dogs, cholecystectomy causes some impairment of liver function, as shown by the serum phosphatase test, for at least 70 days following the operation. In man, the excretion of Bromsulphalein is reduced for a short time after this operation, presumably until the ducts can function vicariously for the gall bladder.

The Filling and Evacuation of the Gall-Bladder

The bile as it leaves the liver flows into the hepatic duct and thence into the common bile duct. During fasting its entrance into the duodenum is blocked by the tonic contraction of the sphincter muscle (*sphincter choledochus*) at the duodenal end of the duct. As the bile accumulates within the duct its pressure rises, and reaching a height of from 50 to 70 mm. of water, forces it way along the cystic duct into the gall bladder. During fasting therefore the viscus becomes gradually distended with retained bile.

The nature of the force by which the gall-bladder is evacuated has been a question of some debate. As the wall of the gall bladder is relatively thin and its muscle fibers so sparse, it seemed unlikely that it could exert the pressure required to discharge its contents—especially since the gall bladder is evacuated with considerable difficulty by manual compression. Intraabdominal pressure, "milking" action exerted by the duodenal movements, and simple leaking into the duodenum as a result of relaxation of the sphincter of Oddi have been variously suggested as possible factors. It has however been proved quite definitely as a result of evidence derived from several modes of investigation that the contractions of the gall bladder itself, despite the apparent muscular weakness of its walls, are responsible for the expulsion of its contents. The times of emptying of the gall bladder are related to gastric digestion. During fasting it remains

distended with bile although the sphincter guarding the common duct is relaxed, plainly indicating that the viscus is competent to retain the bile without the aid of the sphincter of Oddi. That changes in intra-abdominal pressure are not responsible for its emptying was shown by Mann and Higgins working with guinea pigs, whose gall bladders can be readily mobilized.

The abdomen was opened under local anesthesia the gall bladder exposed and drawn out side the abdominal wound, which was then sutured around the cystic duct. The vesicle was observed to contract and expel its contents in response to food placed in the duodenum. It was also shown that in fish which of course have no diaphragm and in which apparently, the intraabdominal pressure remains constant, intermittent evacuations occurred. In dogs the influence of the sphincter was removed by suturing a catheter into the common duct, the abdomen was left open in order to minimize the effects of intraabdominal pressure. The gall bladder remained distended only during the digestion of a meal did it discharge its contents.

When the walls of the gall bladder contract bile is discharged along the cystic and common ducts into the duodenum. The sphincter or sphincters guarding the lower end of the common bile duct normally can withstand a pressure of 100 to 120 mm. of water but the pressure developed by the contractions of the gall bladder in dogs was shown by Mann and his associates to amount to over 250 mm. H₂O. Moreover, it is probable that relaxation of the sphincter occurs as part of a coordinated mechanism when the bladder wall contracts, and that the passage of bile through the sphincter is not simply a matter of the latter "giving way" before the biliary pressure created by the gall-bladder contractions. The duodenal muscle surrounding the oblique intramural portion of the common bile duct is capable when contracted of offering a resistance of over 750 mm. of water. Since this is much higher than the pressure which contractions of the gall bladder can exert, the flow of bile is completely blocked during contractions of the duodenal muscle but during the latter's relaxation the compression of the duct is relieved (fig. 39.5). Therefore, during the evacuation of the gall bladder and active duodenal movements, the bile may be observed to enter the duodenum in squirts. This is not due to the "milking" action of the peristaltic movements of the bowel but is the result of the alternate blockage and release of the duct, the bowel movements are incapable

FIG. 39.5 This figure shows the relation between duodenal contractions and flow of bile (indicated in drops near bottom of figure) from the common duct into the duodenum (after Lueth)

of causing any flow of bile when the gall-bladder is not contracting

The most effective stimulus for the discharge of bile is fatty food, particularly egg yolk, cream or olive oil. It appears that some degree of digestion of the fat must occur before evacuation results. The effect of fat upon the gall bladder was shown definitely by Boyden. He found that during a period of fasting the gall bladder in the cat was distended with bile, and its walls so stretched that they were reduced to about one-fifteenth of their thickness in the collapsed state. It emptied slowly after a meal, being collapsed, or nearly so, in from $1\frac{1}{4}$ to 2 hours. The effect of meat upon the discharge of bile is much less than that of fat. Pure protein, such as egg white, and carbohydrate food is almost without effect. These findings have been amply confirmed by several observers. Whitaker, for example, observed changes in the contour of the gall bladder after filling it with iodized oil and examining it radioscopically. The human gall bladder when rendered opaque to the X rays by the administration of tetraiodophenolphthalein can also be seen to discharge its contents in response to a meal of fat. Its contractions during operations have also been observed frequently. The products of fat digestion, hydrochloric acid of a strength comparable to that in the chyme, or magnesium sulphate when placed in the duodenum, cause evacuation of the gall bladder and relaxation of the sphincter of Oddi. Bile salts injected intravenously, on the other hand, cause relaxation of the gall bladder. Liquid petrolatum introduced into the duodenum is without effect.

The emptying time of the gall-bladder is prolonged in duodenal ulcer, during pregnancy and in pernicious anemia (Boyden).

THE MECHANISMS CONTROLLING EVACUATION OF THE GALL-BLADDER (a) *Nervous* It has been mentioned that relaxation of the sphincter of Oddi probably occurs as the gall bladder contracts. A coordinated action of this nature points

to a nervous mechanism. The latter may depend upon intrinsic nervous plexuses in the walls of the biliary passages. The gall bladder contractions initiated by the stimulus of a meal might be due similarly to short reflexes through the intrinsic plexuses of the stomach or duodenum and biliary tract. Nervous mechanisms are also indicated by the following observations. Electrical stimulation of the stomach and duodenum in animals is followed by contractions of the gall bladder. Contractions are occasionally induced by psychic influences, e.g., the smell or taste of food. The gall bladder also responds to experimental excitation of the vagus or sympathetic nerves. Experiments attempting to demonstrate the precise actions of the extrinsic nerves upon the gall-bladder movements have, however, given very conflicting evidence. Several observers have obtained weak motor effects from both vagal and sympathetic stimulation, a motor action of the latter is also indicated by the fact that adrenaline is excitatory.

The results of the experiments of Johnson and Boyden, however, seem clear cut. Section of the right vagus nerve of the cat retarded emptying of the gall bladder, apparently, as a result of the interruption of motor fibers to the gall bladder and of inhibitory fibers to the sphincter of Oddi. The left vagus was found to carry motor fibers to the gall bladder, but apparently does not contain inhibitory fibers for the sphincter. Reflex effects upon the movements of the gall bladder may be initiated from other abdominal viscera. Stimulation of the cecum, for example, causes inhibition of the movements. This reflex is abolished after section of the splanchnic nerves or excision of the celiac ganglion. In the cat, Boyden has demonstrated an inhibitory effect upon gall bladder motility of electrical stimulation of the duodenum by means of tied-in electrodes. But in a similar human experiment (an electrode being passed into the duodenum through a Rehfuess tube) an inhibitory effect could not be demonstrated. From this and from the fact that the rate of gall bladder

emptying is little altered in subjects of double vagotomy, Boyden concludes that in man nervous control of the gall bladder is of little importance as compared with hormonal control

(b) *Hormonal* Even in animals nervous mechanisms are not essential to gall bladder activity, this is evident from the fact that the reaction to the introduction of fat into the duodenum occurs after all nervous connections between the biliary and gastrointestinal tracts, and between the former and the central nervous system have been severed. That gall bladder contractions can occur under such circumstances suggests, of course, a hormonal or humoral mechanism. Boyden found that the blood of an animal taken at the height of digestion, when injected into a fasting animal causes the evacuation of bile, blood from a starved animal has no such effect.

Ivy obtained an acid extract from the mucosa of the upper part of the intestine which caused contraction of the gall bladder when injected intravenously into animals. The injection of acid alone is without effect. Nor will fat or its derivatives excite contractions of the gall bladder when administered intravenously. Acid and other substances which are excitatory when placed in the duodenum or fed therefore act apparently by causing the production or liberation of a hormone in or from the intestinal mucosa. The active principle is related to secretin but is quite distinct from this hormone, for it does not cause pancreatic secretion, and secretin does not cause gall bladder contractions. In crossed circulation experiments the introduction of acid into the duodenum of one animal caused contractions of the gall bladder of the other. Ivy and Oldberg named this hormone "*cholecystokinin*". As little as 0.2 mg. of the solid material prepared from a potent extract causes definite contractions of the gall bladder. It is free from histamine and other vasodilator substances. Its effect has been demonstrated upon man. The transfusion of blood from a human subject digesting egg yolk has been found to cause evacuation of the gall-bladder of the recipient. No effect was observed with blood from a fasting donor.

The actions of drugs upon the motility of the gall bladder Adrenaline, pitressin, histamine and mecholyl stimulate the smooth muscle of the gall bladder, whereas morphine, ergotamine and atropine are inhibitory.

CHOLECYSTOGRAPHY

Graham and Cole showed in 1924 that if the chlorine radical of a dye such as tetrachlorophenolphthalein, which is excreted selectively by the

liver, is replaced by iodine or bromine, the compound, after concentration in the gall bladder is opaque to the X rays. Sodium tetraiodophenolphthalein or the corresponding bromine compound (sodium tetrabromophenolphthalein) is given intravenously or by mouth in a special coated capsule. After a fasting period of about 14 hours a radiogram is taken. The normal gall bladder at this time shows a well defined shadow. The gall bladder is then stimulated to contract by means of a meal containing egg yolk and cream and a second radiogram taken 5 hours later when the normal organ should be found practically empty. The depth of the shadow after dye administration depends directly upon the concentrating power of the gall bladder. For this reason a diseased gall bladder may throw only a faint shadow or none at all.

Gallstones especially those of a high cholesterol content which are relatively transparent to the X rays show up against the gall bladder shadow. Gallstones containing more than 0.5 per cent of calcium are visible without the aid of an opaque dye.

Affections of the Gall Bladder and Bile Ducts

Among the common diseases of the gall bladder are *inflammation (cholecystitis)*, *gallstones (cholelithiasis)* and *new growths*. The factors involved in the formation of gallstones have been considered (p. 650).

In the absence of inflammation stones in the gall bladder give rise, as a rule to no definite symptoms, but in their passage along the ducts severe pain—*biliary colic*—may be experienced as a result of the spasmodic contractions of the gall bladder and consequent distension of the duct walls. Vomiting may occur as a reflex phenomenon. In the dog pain is produced when the gall bladder is distended by a pressure of 540 mm. of water. This of course is a much higher pressure than the contractions of the gall bladder can create. Pain is produced, however, by distending the ducts with a pressure of 270 mm. of water—just about the maximal pressure which the gall bladder contractions can produce. The cause of the expulsion of the stone from the gall bladder is not altogether clear. Although contractions of the gall bladder have been observed to cause movements of stones within its cavity, and even to force a stone into the cystic duct, gall bladder contractions do not in the majority of instances offer satisfactory explanation for the expulsion of the stone. According to some inflammation and distension of the gall bladder are important factors leading to the passage of the stone into the cystic duct.

BILIARY DYSKINESIA It is now generally recognized that biliary colic may occur in the absence of stone inflammation or of any anatomical ab-

normality, such as kinking of the cystic duct, which would hinder the expulsion of bile from gall-bladder. In such instances the colic has a functional origin, being due to the gall bladder contracting against a sphincter of Oddi in a state of spasm. Normally as already mentioned the sphincter relaxes when the gall bladder contracts. In biliary dyskinesia the nervous mechanisms upon which this reciprocal action depends are, apparently, disordered. It has also been claimed that a sphincterlike action may be exerted at the junction of the cystic duct with the gall bladder and that spasm of this ring of muscle during contraction of the gall bladder may give rise to biliary colic. Also, sudden distention with saline of the common bile duct of conscious patients causes pain resembling that of biliary colic. The pain is felt in the upper right quadrant of the abdomen and in the interscapular or the right scapular region. Nausea and vomiting may occur. The pain impulses travel by splanchnic fibers and enter the cord by the posterior nerve roots from the fourth to the ninth thoracic segments, inclusive.

Gall bladder disease frequently gives rise to derangements of other organs, particularly of the stomach. Anacidity or hypacidity and increased motility of the pyloric part of the stomach are commonly encountered. Ivy and Fishback (See Ivy, 1934) experimenting with dogs found that mild stimulation of the biliary tract inhibited gastric motility and lowered gastric tone. They suggest that in the human subject stimulation of this nature is conducive to gastric flatulence and belching. A sudden sharp distension of the bile duct caused pylorospasm and vomiting in their animals. According to some authorities dyspeptic symptoms in from 40 to 50 per cent of subjects are due to biliary tract disease. Cardiac irregularities may result through reflexes initiated from the gall bladder or bile ducts.

SECRETION AND ABSORPTION IN THE INTESTINE

The food substances in the gastric chyme are far from being ready for absorption. The products of peptic digestion of protein are still relatively large molecules containing many amino acids. Starch digestion is incomplete and fat digestion has barely begun. In the intestine the enzymes of pancreatic juice carry the digestion of protein a step further but leave most of it still in the form of peptides which need further digestion before being absorbed. Starch and dextrins are reduced to maltose which is unabsorbed as such. Fat digestion is, presumably, accomplished by pancreatic lipase but even this may be aided by lipase from the intestine. Final preparation of food for absorption is accomplished by enzymes contained in the intestinal secretions.

Secretions of the Small Intestine

METHODS OF STUDY

The secretion of the intestine may be collected in anesthetized, operated animals by opening the abdomen and inserting a tube into the part of the intestine from which the secretion is to be collected. This method has the serious disadvantage that operative trauma and anesthetic drugs depress the secretory activity of the intestinal glands. The effects of anesthesia may be largely overcome by decerebrating or decapitating the animal under anesthesia and then allowing time for the anesthetic to be eliminated, as was done by Wright and his coworkers (1940). It is also advantageous to immerse the animal in physiological saline, which eliminates the irritant effects on the intestine of drying and exposure. The best results have been obtained by study of unanesthetized animals with surgically isolated loops of intestine. A loop is prepared by cutting through the intestine at two points, thus isolating a segment and re-establishing the continuity of the bowel by end to end anastomosis. To make a *Thiry (1864) loop* one end of the isolated segment is closed and the other end brought out through the abdominal wall to form a fistula. The preparation was modified in 1883 by Vella

when brought both ends of the loop out through the abdominal wall, such a preparation is known as a *Thiry-Vella loop*. These loops maintain their mesenteric connections and retain so much of their innervation as reaches them through the mesentery but are separated from the myenteric and submucous plexuses of the intestine above and below.

Intestinal loops without a nerve supply have been prepared by isolating a segment of intestine, as in the preparation of a Thiry loop and implanting it under the skin of a mammary gland of a lactating female animal (Ivy *et al.* 1927). The reason for choosing a lactating female is that the subcutaneous tissue in the vicinity of the mammary glands in such an animal has a very abundant blood supply. At first the mesenteric pedicle is left intact but after a time the local blood vessels grow into the intestine and provide it with a new blood supply. It is then possible to sever the mesenteric pedicle without causing degeneration of the intestinal loop. When this is done a portion of intestine is obtained which is entirely deprived of nervous influences. Such a preparation is used to detect hormonal influences on secretion.

In man, and in animals with a simple intestinal fistula, it is possible to collect intestinal secretion by means of a multilumen intestinal tube (Miller and Abbott, 1934). Two of the lumens of the tube are used to inflate balloons, a third lumen having an opening between the balloons can be used to collect the secretion that accumulates in this area. In these as in all studies of intestinal secretion it is important to remember that mechanical stimulation, and especially distention of the intestine, is a profound stimulus to secretion, consequently, when the quantity of secretion is to be determined, or when quantitative differences in secretion obtained under different circumstances are sought, it is essential that mechanical stimulation of the mucosa be avoided. For example, a Thiry fistula into which a catheter has been inserted for collecting the secretion

will produce a greater than normal amount of succus entericus

THE INTESTINAL GLANDS

The mucous membrane of the small intestine is everywhere covered with minute projections (about 1 mm in height and somewhat less in diameter) called intestinal villi. The villi are invested by a layer of columnar cells, of the type characteristic of the intestinal mucosa, set upon a basement membrane beneath which is a fine layer of a smooth muscle fibers continuous with the muscularis mucosae. In the center of each villus is a lymphatic vessel continuous with the lymph vessels of the mucous membrane. This lymphatic is somewhat enlarged into a small sinus lined with endothelium. In some of the larger villi there are several lymphatics. Between the epithelium and the central sinus is a network of blood vessels. Contraction of the smooth muscle of the villus causes a characteristic type of movement which will be described in chapter 41. Between the villi are the openings of the *intestinal glands, or crypts of Lieberkuhn* which are simple tubular glands. The crypts do not penetrate the muscularis mucosae. The epithelium covering the villi is of the same type as that lining the crypts and consists of a single layer of columnar cells with certain specialized cells interspersed among them. The free end of each columnar cell, next to the lumen of the intestine, is provided with a specialized cuticular border, resembling the brush border of certain renal tubular cells. Its appearance suggests that it either contains fine pores or is constituted of substances of varied chemical nature arranged in the form of columns. (This border may play some essential role in absorption) (Verzar and McDougall, 1936).

Here and there among the columnar cells are goblet cells that secrete mucus and specialized cells that stain with silver and are called *argentaffine or enterochromaffin cells*. Other cells with a large acidophile nucleus known as *Paneth cells* are also present. The argentaffine cells are of particular interest because they secrete serotonin or at least synthesize its precursor, 5-hydroxytryptophane (Erspamer and Asero, 1952). The functions of serotonin in the body are not known, but it has many powerful pharmacologic actions, among which are stimulation of gastrointestinal motility and inhibition of gastric secretion (Olson and Gray, 1958).

In the bottoms of the crypts many of the epithelial cells may be seen to be undergoing mitosis and at the tips of the villi one can see that cells

are being shed into the lumen of the intestine (Lehland and Stevens, 1948). It seems reasonable then, to believe that there is going on in the intestinal mucous membrane a process of continuous replacement of the epithelial lining, new cells being produced in the bottoms of the crypts and the older cells continuously shed at the tips of the villi. The importance of this process will be more evident when we come to consider the mechanism of secretion of the intestinal enzymes.

In the first part of the duodenum, in addition to the regular intestinal glands are special mucous glands known as *Brunner's glands*. These are similar in structure to the pyloric glands of the stomach. They are made up of long tubules frequently branched and often tortuous which penetrate the muscularis mucosae. Their ducts empty into the crypts of Lieberkuhn. Brunner's glands are very numerous in the duodenum between the pylorus and the entrance of the bile and pancreatic ducts. Below this level they are seen less frequently and none are found beyond the duodeno-jejunal junction.

INTESTINAL SECRETION OR SUCCUS ENTERICUS

The composition of the fluid secreted by the intestinal mucous membrane varies somewhat in different parts of the intestine. For example, in the duodenal area, due to the secretion of the mucous glands of Brunner, the secretion contains more mucus than is found elsewhere. In general the secretion of the small intestine is a thin, colorless, or slightly straw-colored fluid somewhat opalescent and containing flecks of mucus. On centrifuging and examining the sediment it can be seen that the cloudy appearance of the juice is partially due to mucus and partly to cellular debris, including some intact cells of the type characteristic of the intestinal mucous membrane (Florey *et al.*, 1941). When collected from the duodenum only, the juice has a more glary appearance and a heavier consistency, and evidently contains a greater proportion of mucus. In chemical composition, the juice consists of water, inorganic salts, and organic material. The inorganic salts are those commonly present in body fluids, except that the bicarbonate concentration is higher than it is in blood or interstitial fluid. The alkalinity on titration is said to vary between 0.02 and 0.67 per cent sodium bicarbonate equivalent. Various estimates of the pH of the intestinal secretion have been given ranging from 6.3 to 9. The higher values undoubtedly are the result of loss of carbon dioxide from the

juice. It is certainly an alkaline fluid and may probably have a true pH as high as 8.3.

Except in the duodenum the quantity of fluid secreted by the small intestine is never very great, a few cc per hour being the usual amount that it is possible to obtain experimentally, even under conditions of stimulation. It is difficult to determine with accuracy the amount actually secreted because of the tremendous absorptive capacity of the intestine. Many times more than the amount that it is possible to collect may be secreted and reabsorbed during an observation period. That the mucosa is capable, under some circumstances, of passing enormous amounts of fluid into the lumen of the intestine is evident from the great water loss that occurs through the intestine in pathologic states such as cholera, diarrhea, or intestinal obstruction.

The organic matter of the juice consists of mucus, enzymes and cellular debris. The source of the enzymes is unknown but is assumed that they are produced by the columnar cells, although the argentaffine cells or the Paneth cells may be responsible for some of them. A really formidable array of enzymes have been reported as occurring in intestinal secretion. A pepsinlike protease, (from the duodenum only) an amylase, a lipase, at least two peptidases, sucrase (invertase), maltase, lactase, enterokinase, alkaline phosphatase, nucleophosphatases, and nucleosidases have been described.

Protease A weak proteolytic enzyme with properties similar to pepsin was described as occurring in the duodenal secretion by investigators of the Pavlov school (Salaskin, 1902). The similarity of the Brunner's glands to the pyloric glands and the fact that the pyloric portion of the stomach secretes pepsin in small amounts made this observation seem plausible. However, Wright and his associates (1940) who made the most thorough study of intestinal secretion yet reported, could find no protease in duodenal secretion.

Peptidases One of the major functions of intestinal digestion is final reduction of the products of peptic and tryptic digestion to amino acids, this is accomplished by intestinal peptidases. The presence of peptidases has been reported by all investigators who have studied the problem. The ones usually described are aminopeptidase, which act on the peptide linkages of terminal amino acids possessing a free amino group, tripeptidases and dipeptidases which split tri- and dipeptides respectively into their constituent amino acids.

Lipase Most investigators have reported finding a weak lipase action in intestinal secretion (Baldyreff, 1904, 1912).

Disaccharidases The various disaccharidases, sucrase, lactase and maltase are present in succus entericus under all normal circumstances.

Enterokinase Enterokinase, the enzyme which converts trypsinogen to trypsin (see under Pancreatic Secretion), is present in the intestinal secretion under normal circumstances. However, Savich (1904) stated that if pancreatic juice was excluded from the intestine, enterokinase gradually disappeared from the secretion as it did also from an intestinal loop in which the pancreatic juice did not circulate. Waldschmidt-Leitz and Hartencek (1925) likewise concluded that pancreatic juice was necessary for liberation of enterokinase from the epithelial cells. Florey, Wright and Jennings (1941) considered that the evidence in neither case was sufficient. The point is of considerable interest and merits further investigation.

The studies of Wright, Jennings, Florey and Laum in 1940, raised a question as to a source of the enzymes ordinarily found in intestinal secretion. They reported that when they took precautions to prevent injury to the mucous membrane while collecting the secretion, and then immediately centrifuged the collected secretion so as to remove cellular debris, only amylase and enterokinase were consistently present in the supernatant fluid. They consider that these enzymes and possibly maltase, are secreted by the intestinal glands in the usual sense. The others, they believe, are intracellular enzymes which exist in the cells of the mucous membrane and appear in the juice only as a result of the shedding of these cells and their disintegration in the intestine. They point to the opinions of many physiologists that most of the digestion of peptides and disaccharides takes place in the epithelial cells while these substances are being absorbed. This is not, however, a necessary conclusion from the observed facts. The rapid rate of mitosis in the depths of the glands of Lieberkuhn and the continuous shedding of epithelial cells from the tips of the villi may represent a special kind of holocrine (see chapter 36) secretory process by which endocellular enzymes are secreted into the intestinal juice, the secretory product being the entire epithelial cell with its contained enzymes. Under normal circumstances the presence of active trypsin in the intestinal contents would seem to insure the rapid disintegration of these cells and liberation of their con-

tained enzymes into the intestinal secretion. In this connection it may be significant that enterokinase is secreted directly and so insures that activation of trypsinogen does not depend on the disintegration of shed epithelial cells.

REGULATION OF INTESTINAL SECRETION

Control of Brunner's Gland Secretion

Secretion of Brunner's glands is controlled by nervous and humoral mechanisms which do not affect the other intestinal glands, or if they do so it is to only a slight extent. The secretion of Brunner's glands increases on stimulation of the vagus nerves or the administration of parasympathomimetic drugs such as pilocarpine and physostigmine. It is not augmented by stimulation of the sympathetic nerves (Florey and Harding, 1934). The amount of secretion is increased after meals (Blickenstaff *et al.*, 1949) even in transplanted denervated pouches of the duodenum (Florey and Harding, 1935b). This proves that there is a humoral mechanism for regulating the secretion in addition to whatever nervous mechanism there may be. The nature of the humor has been the subject of some discussion and is still undetermined. Florey and Harding (1935a) were convinced that it is pancreatic secretin. They were led to this conclusion by the fact that practically all the stimuli which increase pancreatic secretion, including contact of hydrochloric acid with the duodenal mucous membrane, also increase the secretion of Brunner's glands. They also found that what they considered to be a highly purified secretin preparation stimulated duodenal secretion when given intravenously. Sonnenschein and his associates (1947) were unable to confirm the results with secretin. Using what they believed was a crystalline picrotonate of secretin they observed little effect on Brunner's glands, although crude secretin caused an abundant secretion. Grossman (1950) has suggested that there is a special hormone for these glands which he proposes to call "duocrinin", however, writing in 1958, he still considers the subject to be "subjudice".

Functions of the duodenal secretion. Florey and Harding (1933) emphasized the protective function of the secretion of Brunner's glands and considered it an important factor in preventing duodenal ulceration. In addition it may assist in emulsification and suspension of fat and other food particles. Since, like other intestinal secretions, it contains enterokinase it helps to activate the trypsinogen of pancreatic juice. Duodenal

secretion is also said to contain "intrinsic factor" and therefore, probably assists in absorption of vitamin B₁₂. The various hormones known to be produced by the duodenal mucosa are probably not secreted into the lumen of the intestine except incidentally and in small quantities and are not functional in this situation.

Control of Secretion of Succus Entericus

Nervous regulation. It was demonstrated in Pavlov's laboratory that stimulation of the vagus nerve in animals in which the spinal cord has been severed in the neck caused a moderate secretion of intestinal juice from the duodenum and also from the rest of the small intestine after a latent period of from 1 to 1½ hours (Savich, 1917). Wright and his coworkers (1940) were able to obtain an increased secretion from the duodenum on stimulation of the vagus in decerebrated or decapitated animals, but were unable to obtain clear evidence that vagal stimulation caused secretion from the jejunum or ileum.

Stimulation of the sympathetic causes no secretion but cutting the nerves results in a marked increase in secretion. This paralytic secretion as it is called, is increased by physostigmine and inhibited by atropine, it is therefore considered to be dependent upon some cholinergic mechanism in the intestine. Parasympathomimetic drugs in general increase the paralytic secretion and sympathomimetic drugs tend to inhibit it. From these observations we can conclude that secretion is augmented by a cholinergic mechanism and that this mechanism is antagonized by the sympathetic. Whether this antagonism is direct or is caused by contraction of the blood vessels remains uncertain. One interpretation of the paralytic secretion is that section of the sympathetic nerves results in dilation of the blood vessels of the intestine and in this way greatly increases the blood flow. Such an increase in blood flow would provide a greater amount of fluid for secretion and, presumably, might produce the augmentation of secretion seen on section of the sympathetic nerves (Starling, 1906). Babkin (1950) has pointed out that cutting the sympathetic nerves to the small intestine increases its motility, which undoubtedly has a massaging effect on the mucous membrane, in view of the fact that one of the most effective stimuli for intestinal secretion is mechanical stimulation of the mucosa, this factor alone may be sufficient to account for the increased secretion.

Humoral regulation. The most effective stimulus for secretion of succus entericus is local,

mechanical or chemical stimulation of the intestinal mucous membrane. Such stimuli are always present in the digesting intestine due to the presence of chyme and the food particles which it contains. Feeding is not very effective in increasing the rate of intestinal secretion from an isolated intestinal loop, provided the nerve supply is intact, but if the sympathetic nerves have been severed a noticeable increase in secretion takes place when the animal is fed. This indicates that some factor, either nervous or humoral, operates to increase the secretion during digestion. The early investigators were of the opinion that pancreatic secretin was an effective stimulus for intestinal secretion (Delzenne and Frouin, 1904). This point of view was a result of experiments in which injections of secretin-containing preparations resulted in undoubted increases in secretion of intestinal juice. However, as more highly purified preparations of secretin became available the influence on intestinal secretion became less so that now it is doubtful whether secretin as such acts on the intestinal glands. On the other hand, intestinal extracts, from which secretin has been totally eliminated remain potent stimuli for intestinal secretion. This subject has been investigated most fully by Nasset and his coworkers (1933) who have prepared an extract of the intestinal mucous membrane which is free from secretin, from vasodilator material and from toxic substances, but has a powerful effect upon the secretion of the small intestine when given intravenously. Subcutaneous injection is less effective but in large doses produces some secretion. The material undoubtedly contains a hormone which augments the intestinal secretion, it is called "enterocrinin." The fact that a hormonal mechanism is involved in normal intestinal secretion has been amply demonstrated by Nasset and his coworkers (1935) by means of denervated loops of intestine, such loops secrete when acid and certain other substances are placed in the intact portions of the intestine, and also after meals.

Regulation of enzyme secretion. There is little published data on the control of secretion of organic compounds in the succus entericus. However Nasset (1956) is of the opinion that the parasympathetic nerves control the output of enzymes from the intestinal glands as they do the secretion of organic matter in saliva. He also suggests that crude enterocrinin may contain a specific hormone for the secretion of intestinal enzymes comparable to pancreozymin which promotes secretion of pancreatic enzymes.

The Function of the Succus Entericus

Enzymatic digestion of food, in all its phases, is a hydrolytic process, an abundance of water to serve as one of the reacting substances is therefore essential. The succus entericus provides this water in the area in which the major part of digestion of food occurs. Water is also necessary to serve as a solvent and as a medium of suspension and transport for the solids which are either dissolved or suspended in the chyme. The enzymes, either in the secretion or in the cells, complete the digestion of protein and carbohydrate by reducing the peptides, resulting from peptic and trypsin digestion, to amino acids and the disaccharides, resulting from amylolytic digestion of starch to glucose. Other disaccharides that may be present in the food are likewise digested liberating their constituent monosaccharides. In fat digestion the succus entericus serves as a source of water and as a medium for suspension and emulsification of the fat particles. It also provides a certain amount of lipase.

Secretion of the Colon

The mucosa of the mammalian cecum and colon is in many respects similar to that of the small intestine, crypts are present but there are no villi. As in the small intestine, the cells at the bottoms of the crypts exhibit numerous mitoses, suggesting the continuous replacement of shed epithelial cells. Goblet cells are more numerous than in the small intestine and the epithelial cells between the goblet cells differ among themselves but in the majority the protoplasm is clear and free from secretory granules. The secretion is scanty (Wright *et al*, 1938) as is to be expected from the fact that a major function of the large intestine is absorption of water. The decrease in volume of intestinal contents that occurs in this area indicates that secretion does not keep pace with absorption. Actually, it is usually not possible to collect any secretion from a colonic fistula unless the mucous membrane is stimulated mechanically by insertion of a catheter or other instrument. Even with this stimulation only a few tenths of a cubic centimeter per hour can be collected. When anything can be collected it consists of watery fluid with clumps of white mucus often it is viscous and opalescent. The reaction is alkaline due to sodium bicarbonate which may be present in concentrations as high as 80-90 m eq per liter, according to deBeer *et al* (1935). Of the solids 0.63 percent is organic and the remainder is inorganic material.

The secretion of the cecum apparently contains enzymes corresponding to those found in the small intestine, with the exception of enterokinase which is not present. The secretion of enzymes becomes progressively less and ultimately disappears toward the distal colon. The large intestine has an extraordinary capacity to secrete mucus and under certain circumstances may secrete a surprisingly large amount of the material. As elsewhere in the intestine, mucus is secreted in response to strong local stimulation or irritation, hence, mucus is likely to be secreted in unusual amounts in the presence of bacterial infection or other causes of local irritation, such as irritant cathartics. The secretion is an active process involving utilization of oxygen, it is inhibited by perfusion of the intestine with cyanide.

NERVOUS CONTROL OF COLONIC SECRETION

Florey (1930) and Wright *et al* (1938) found that stimulation of the nervus erigens caused the colon to secrete a clear mucoid fluid, in contrast to the practical absence of spontaneous secretion, stimulation produced as much as 55 cc. in one 8 hour period from the distal half of the colon, the average rate was about 5 cc. per hour. Reflex secretion was observed on stimulation of the cut end of one nervus erigens, the other being intact, the reflex center was located in the lumbar spinal cord. Larson and Bergen (1933) observed secretion of mucus in an isolated segment of the colon at the time of defecation. It should be recalled that the nervus erigens supplies only the distal portion of the colon with parasympathetic fibers, the parasympathetic supply for the proximal colon comes from the vagi. Acetylcholine and pilocarpine increase colonic secretion whereas atropine inhibits it. Histamine has been reported to cause a slight increase in secretion. The secretion is reduced by anesthetics. Cutting the sympathetics does not produce paralytic secretion in the large intestine, but stimulation of the sympathetics diminishes the secretory response to stimulation of the nervus erigens.

The relationship of the secretory function of the colon to the autonomic nerves has a bearing upon the occurrence of certain diseases of the colon in which there is excessive secretion of mucus, for example, *mucous colitis*. This is a disease in which excessive amounts of mucus appear in the stools constituting, in some cases, tubular casts of the colon. This has often been considered a psychosomatic disease and has a close relationship to abnormal emotional states.

The Intestinal Mucosa as an Excretory Organ

The feces contain small amounts of fat, even during prolonged starvation, indicating that some fat is eliminated by way of the intestine. Probably a great deal more fat is excreted into the intestine than escapes in the feces, the majority being reabsorbed (Sperry and Bloor, 1924). It has been claimed also that the colon excretes calcium, phosphorus, iron and various heavy metals. Although this is probably true, it is not likely that the intestine constitutes an important avenue of excretion for these substances once they have been absorbed.

Although probably not normally an important organ of excretion, the intestinal mucous membrane, by virtue of its permeability to numerous diffusible substances can be made to function as an organ of excretion. For example, if a double lumen tube is placed in the intestine with one opening high up and the other low down and fluid perfused through so that it enters at a high level and escapes through the tube after passing through the intestine, it will carry away diffusible substances from the blood. Use has been made of this mechanism in cases of renal failure in which nonprotein nitrogenous substances and other toxic waste products accumulate in the blood. Since any diffusible substance will tend to establish an equal concentration in the blood and the intestinal contents, any mechanism which continually replaces and removes the intestinal contents will remove these substances from the body, thus the intestine may be used as an "artificial kidney." One great difficulty with this procedure is that not only the toxic substances which it is desired to remove, but all the diffusible constituents of the blood are removed in this manner. It is necessary, therefore, that the fluid used for perfusion should approximate the composition of the blood plasma with respect to all normal diffusible constituents insofar as possible. The normal excretory function of the intestine, of course, has to do with the disposal of the residues remaining after completion of digestion and absorption in the small intestine. This is accomplished mainly in the large intestine where the water and salts of the intestinal contents are recovered and the solid residues formed into feces (see ch. 42).

The Absorptive Function of the Intestine

The mucous lining of the small intestine is one of the most remarkable organs of the body. It

secretes a variety of hormones which help to regulate gastric secretion and motility, the secretion of the pancreas and of the intestine itself, and the movements of the gall bladder and the intestinal villi. Thus endocrine activity, which is mainly concentrated in the upper intestine, has led Dr. E. S. Nasset to characterize the duodenum as the "hypophysis of the abdomen." The same tissue which secretes hormones into the blood forms an external secretion containing a variety of digestive enzymes, at least as numerous as those found in the pancreatic juice. During absorption the mucosal cells perform a variety of hydrolytic and synthetic operations upon the food substances passing through them, greatly modifying the character of the absorbed material. Even while producing their own secretions the epithelial cells are transferring water and dissolved substances from the lumen of the intestine into the interstitial fluid to be taken up by the blood. This absorptive activity is highly selective and frequently involves the expenditure of considerable energy. Probably nowhere, except possibly in the liver, is so great a variety of functions performed by a single tissue.

The ultimate aim of digestion is absorption. Only after the products of digestion have passed through the epithelial lining of the digestive tract and entered the blood stream are they able to serve their purpose of providing nourishment for the tissue cells of the body. Absorption of such materials takes place almost entirely from the small intestine. Although the stomach is capable of absorbing small amounts of water and certain food substances, notably glucose and some foreign substances such as alcohol, the absorption that occurs here is negligible, partly because the food is not digested sufficiently in the stomach to be readily absorbed, but mainly because the gastric mucous membrane is not adapted for absorption as is that of the small intestine. A possible exception is iron, which may be absorbed in significant quantities from the stomach. Although absorption of food occurs mainly in the small intestine, water and salts are absorbed in significant amounts from the large intestine.

The mucous lining of the small intestine is admirably adapted to its absorptive function. The structure of the epithelium has been described in connection with the discussion of intestinal secretion. The intestinal villi will be referred to in the chapter on movements of the alimentary canal. It has been estimated that the presence of the villi results in an increase of seven or eight-

fold in the surface area of the mucous membrane of the intestine.

Methods for study of intestinal absorption. The methods described in the section on intestinal secretion are also available for the study of absorption. In acute experiments one places the material, the absorption of which is to be studied, in an isolated loop of intestine and, after a measured time, removes it and observes the volumetric or chemical changes that have taken place. The Thiry or Thiry-Vella loop may be used in the same manner. In the case of substances that can be readily detected in the blood, the material can be placed in the intact intestine and its absorption estimated by the rate of its appearance in the circulating blood, or in the portal blood, or the intestinal lymph, if the experiment is of such a nature as to make these vessels available. In recent years it has been possible through the use of food materials tagged with radioactive isotopes to gain much information that could not have been obtained by means of the older methods.

The development of *in vitro* techniques for the study of excised segments of intestine have also greatly increased our knowledge in recent years. A variety of techniques for this purpose have been described by different authors, all depend upon maintaining the vitality of a portion of the intestine that has been removed from the body by keeping it in contact with oxygenated fluid of appropriate composition. The preparation can be so arranged that the fluid inside the intestine which is in contact with the absorbing surface can be kept separate from that on the outside in contact with the serosal surface and the changes in composition of the internal and external fluid used to measure the degree of absorption by the mucosa. Studies of this sort are done chiefly on smaller animals, such as rats, guinea pigs and hamsters since their relatively thin intestines are more easily maintained in a viable condition in an artificial medium.

ABSORPTION OF WATER

Much that has been published on the absorption of water from the intestine is of little value because, until recently, it has been impossible to distinguish between the water that was secreted *into the intestine* and water that left the intestine by absorption. Changes observed in the volume of water in the intestine did not represent total absorption of water but merely the difference in the volume of water secreted into the intestine and that absorbed. Since there is reason

to believe that water moves freely through the intestinal mucosa it is essential that we know how much water entered the intestine in a given time if we are to make an intelligent estimate of the amount leaving by way of absorption in the same time. It has been possible to get around this difficulty and to determine accurately the amount of water leaving the intestine by absorption in a unit of time by the use of heavy water. Water containing heavy hydrogen can be readily detected in the blood and also the amount remaining in the intestine can be accurately measured. Since in a short period of time the water secreted into the intestine will be normal water, the change in heavy water content represents water actually absorbed. Or if, as in experiments on human subjects, it is not possible to determine the amount of water remaining in the intestine, the amount of heavy water appearing in the blood can be used as an estimate of the water absorbed.

Scholer and Code (1954) studied absorption of water from the human stomach and small intestine using heavy water as a tracer. They found that when 50 grams of water were given 25 per cent of this amount was absorbed per minute so long as it remained in the stomach. When the water was placed in the small intestine it was absorbed at about ten times that rate. 26.1 per cent of the dose being absorbed per minute. If the water remained in the stomach it required 34.2 minutes to absorb 67 per cent of the administered amount whereas in the intestine this percentage was absorbed in 3.7 minutes. In the intestine 80 per cent of the administered water was absorbed in ten minutes. In these experiments only absorption was measured and the net volume change was not observed; hence, no account was taken of the water that might have been secreted into the stomach or intestine during this same period of time. One interesting fact brought out in these studies is the extremely rapid absorption of water from the intestine. Another is that there is an appreciable absorption of water from the stomach. The statement often seen in the literature that water is not absorbed in appreciable amounts from the stomach is based on the net change in volume in which no account is taken of the concurrent secretion of fluid into the stomach. Considering net absorption only, that is the decrease in the volume of intestinal contents, it appears that water is absorbed more rapidly from the terminal ileum than from other parts of the small intestine.

Most of what remains is absorbed from the large intestine.

The net absorption of fluids from the intestine is influenced by hydrostatic and osmotic pressures. Bickensstaff and others (1952) found that there was a significant difference in the rate of absorption of chloride and water at different levels of hydrostatic pressure. Between the extremes there was an optimal pressure at which absorption was most rapid. He also noted that water was absorbed more rapidly from dilute than from concentrated solutions. Absorption is accelerated by an increase in hydrostatic pressure up to the point where the pressure begins to interfere with the blood supply to the intestinal mucous membrane. Nasset and Parry (1934) found that negative hydrostatic pressure tended to accelerate the net flow of fluid into the intestine whereas increasing the pressure favored net absorption provided the pressure exceeded 25 cm. of solution. Between 5 and 25 cm. there was no change. It has been suggested by Verzar and McDougall (1936) that absorption of water from the large intestine is largely dependent on the relatively high hydrostatic pressure said by them to be maintained in this organ. Other things being equal it has been found that, within physiological limits, the rate of absorption of water is directly proportional to the hydrostatic pressure in the intestine. When considering net absorption only, the rate of absorption of water decreases with increasing osmotic pressure of the intestinal contents but this relationship is not linear. More water is absorbed from hypotonic than from isotonic solutions and more from isotonic than from hypertonic solutions.

ABSORPTION OF INORGANIC SALTS

Of the inorganic salts that are presented to the intestine for absorption, the more important are sodium, potassium and calcium chlorides, and phosphate. Absorption of iron will be considered in chapter 8. The absorption of chlorides of sodium and potassium are always accompanied by absorption of water and the more rapidly the water is absorbed the more rapidly will the salts be absorbed. The salt concentration in the solution passing through the mucosa from the lumen of the intestine toward the blood is not necessarily the same as that of the intestinal contents. From an isotonic solution in the intestine the fluid absorbed tends to be hypertonic so that as absorption progresses the fluid in the intestine becomes hypotonic due to loss of salt (Visser et al., 1944). The salt concentration in the ab-

sorbed mixture is proportional to the concentration in the intestinal contents but due to the osmotic effect of concentrated salt solutions on the net movement of water, less salt may be absorbed from a concentrated than from a dilute solution. Rabinovitch (1927) found that the greatest percentage absorption of water was from salt solutions ranging in concentration from 0.4 to 0.6 per cent and that the absolute amount of salt absorbed increased with increasing concentration of salt up to 0.8 per cent. He noted also that water and chloride are absorbed more rapidly when potassium ions are present and that absorption was accelerated even more by calcium ions in the solution. An interesting paradox is that atropine, which inhibits most intestinal functions, accelerates net water and salt absorption. This is due to the inhibitory effect of atropine on intestinal secretion.

Calcium salts, including the phosphate, are absorbed more readily from the upper intestine than from the ileum. A problem in calcium absorption is the relative insolubility of the commonly occurring calcium salts, such as the phosphate in alkaline and neutral solutions, consequently, calcium is absorbed better from an acid than from an alkaline medium, this fact may explain the better absorption of calcium from the relatively acid upper intestine. It has been noted that the phosphates enter the intestine chiefly as phosphoproteins or phospholipids which may not be readily digested in the upper intestine where the principal calcium absorption occurs, hence, calcium and the phosphates may be absorbed in different regions of the intestine, thus avoiding the formation of insoluble calcium phosphates. Nevertheless in the absence of normal hydrochloric acid secretion by the stomach, calcium absorption tends to be poor, so that *achlorhydrics often suffer from a calcium deficiency*.

Calcium is said to be absorbed more readily by individuals suffering from a calcium deficiency, indicating some control of calcium absorption by systemic factors. The presence of an excess of magnesium is said to interfere with calcium absorption as does phytic acid which occurs in cereal grains and which may be responsible for the tendency of these grains to produce rickets when fed exclusively or in excess. The administration of vitamin D accelerates absorption of calcium from the lower ileum but not from other parts of the intestinal tract. Vitamin D counteracts the effect of phytic acid so that when given in ade-

quate amounts it offsets the tendency of cereal grains to cause rickets.

The mechanism of water and salt absorption. Considering the apparently free permeability of the intestinal mucous membrane to water and the simple inorganic salts it is tempting to try to explain the absorption of these substances on the basis of simple diffusion or osmosis. As we have seen, the physical and chemical laws are operative in the transfer of water through the intestinal mucosa, but as our knowledge has increased it has become increasingly evident that these principles are inadequate to explain all the observed phenomena. Ingraham and Visscher (1936, 1938) showed that, in the presence of a sulfate solution, sodium chloride was absorbed against a concentration gradient, that is, its absorption went on until the concentration in the intestine fell far below that in the interstitial fluid and in the blood. Likewise the osmotic activity of the fluid in the intestine decreased in their experiments until it fell to as much as half an atmosphere below the osmotic pressure of the blood plasma, thus leaving no doubt that the absorption took place as the result of osmotic work by the intestinal epithelium. In a later study (1944) in which they used isotopic tracer techniques so that they could measure absorption and accretion separately and determine precisely the amount of water and salt absorbed, they were able to determine that the rate of movement of water from gut to blood (absorption) was often as much as 100 times as rapid as it would have been under the same circumstances if only the laws of diffusion and osmosis were operating. Likewise the amount of salt moved in either direction was often found to be at variance with the amount determined by calculation on the basis of the laws of diffusion and osmosis. Studies on isolated preparations have given results with a similar significance.

McHardy and Parsons (1957), studying intact animals, found that chloride was absorbed from solutions containing from 20 to 50 m eq per liter less than the blood plasma. Sodium was absorbed from isotonic solutions containing from 45 to 75 m eq per liter less sodium than the plasma. They noted a statistically linear relation between the total absorption of solutes and the absorption rate of water indicating an interrelationship between the absorption of these two types of products but they were unable to determine which was dependent on the other. In isolated preparations, Smyth and Taylor (1957) found that the transfer of water from the muco-

sal to the serosal side of excised rat small intestine was dependent upon the presence of glucose and oxygen in the medium and was affected by temperature. It was prevented by various metabolic inhibitors indicating that the transfer was an active metabolic process. Others have found that the transfer of a salt solution from the mucosal to the serosal side failed in the absence of oxygen.

It is necessary to conclude that the absorption of both water and salts, although influenced by physicochemical forces, is for the most part an active process dependent upon the metabolic activity of the mucosal cells of the intestine. Little is known of the chemical mechanisms involved but oxygen appears to be necessary. There remains the possibility that only one of the two substances, water and salt, is moved actively since the movement of either would necessitate the transfer of the other in order to maintain osmotic equilibrium, thus either water or salt may be absorbed actively and the other carried passively, but the evidence favors active transfer of salt. For example, in a salt restricted diet sodium practically disappears from the contents of the terminal ileum (Field *et al.*, 1955). This suggests a sodium conserving action of the upper intestine and strongly implies selective absorption of sodium.

ABSORPTION OF CARBOHYDRATES

Only the monosaccharides are readily absorbed by the intestinal mucous membrane. Some disaccharides may enter the blood by diffusion, but if they do they are promptly excreted and not metabolized. The intestinal epithelium is, in general, impermeable to the polysaccharides. The important monosaccharides are dextrose, levulose and galactose. Dextrose occurs as the final product of starch digestion and as one of the two products of hydrolysis of sucrose and lactose. Levulose occurs as a product of sucrose digestion and also in certain natural products such as some fruits and in honey. Galactose is one of the constituents of lactose. Other simple sugars such as mannose and pentoses are quantitatively unimportant. The three simple sugars galactose, dextrose and levulose are all actively absorbed from the small intestine galactose more rapidly and levulose less rapidly than glucose.

The ability of the intestine to absorb glucose against a concentration gradient has been repeatedly demonstrated, that is to say that glucose can be absorbed when the concentration of glucose in the intestinal contents is lower than the

concentration in the blood. In an excised preparation, glucose passes from the mucosal to the serosal side even when the concentration on the mucosal side of the preparation is lower than it is on the serosal side. Active absorption of glucose is prevented by phloridzin, a substance that inhibits the enzymes involved in phosphorylation, this suggests that the phosphorylation of glucose which is known to occur in the mucosal cells, is essentially involved in the mechanism of active absorption. Glucose may still be absorbed in the presence of phloridzin but only if a favorable concentration gradient exists. Absorption in this case is by simple diffusion.

Phosphorylation of glucose is of interest as being probably typical of the mechanisms through which active absorption can occur. It is believed that the glucose molecule enters the mucosal cell by simple diffusion where it is promptly transformed into glucose-6-phosphate through the action of glucokinase plus adenosine triphosphate (ATP). Since glucose-6-phosphate is a different compound from glucose, its accumulation in the cell does not lower the concentration gradient from lumen to cell so that glucose continues to diffuse in to be phosphorylated. The glucose-6-phosphate is hydrolyzed as the sugar passes out of the cell and into the interstitial fluid from which it is transferred into the circulating blood as glucose. The process involves expenditure of energy which is obtained by oxidation of a certain percentage of the glucose, thus appears as lactic acid which is also absorbed. Probably levulose and galactose are similarly phosphorylated on absorption. Some of the levulose is converted into glucose in the epithelial cells but the conversion occurs mainly in the liver as it does also with galactose. In addition to active absorption, since the intestinal mucosa is permeable to the simple sugars, some are absorbed by simple diffusion when a favorable concentration gradient exists. This is usually the case with galactose and levulose since these sugars are never present in the blood in any considerable concentration (Cantow and Shepartz, 1954).

The sugars are absorbed much more rapidly from the upper than from the lower small intestine. Fisher and Parsons (1949), have shown that there is a linear gradient in the intestine in its ability to absorb glucose from the intestinal contents. The rate of absorption is directly proportional to the distance of the segment in question from the ileocecal valve (see figure 40.1). Absorption of sugars is diminished in the presence of sodium chloride deficiency such as may occur in

adrenal cortical insufficiency. This suggests that the neutral salts play a part in the active absorption of sugar, possibly by being secreted into the intestinal contents to make up for the osmotic loss when the sugar is taken away. Absorption of sugars is accelerated in hyperthyroidism and depressed in hypothyroidism and in the latter case administration of thyroxine improves absorption. Pantothenic acid, thiamine and pyridoxine, members of the B vitamin group, are essential for normal sugar absorption.

It is interesting to note that although the pentoses are more diffusible than the hexoses, the pentoses are absorbed at a much slower rate, proving again that the hexoses are actively absorbed. With most sugars, particularly those that are not actively absorbed, the rate of absorption increases with increasing concentration in the intestinal contents. With glucose and galactose however, this is true only up to about a 5 per cent concentration, which for these sugars is approximately isotonic with the blood. Further increase in concentration of these sugars fails to increase or decrease their rate of absorption. Furthermore, if glucose and galactose are given simultaneously each suppresses the absorption of the other (Cori, 1931) so that the total amount of sugar absorbed is not more than would be absorbed if only one of the sugars were present. These facts indicate that the mechanisms for active absorption can be saturated in a manner somewhat analogous to the tubular maximum for glucose in the renal tubules.

A certain amount of absorption of glucose and other simple sugars may take place in the large intestine but in the human this is relatively unimportant. Absorption of carbohydrates from the small intestine is usually so complete that by the time the intestinal contents reach the terminal ileum there is no sugar present. However, glucose solution may be injected into the large intestine in situations in which oral feeding is impractical. Such sugar is absorbed, although much more slowly than from the small intestine. In certain animals in which cellulose constitutes a considerable fraction of the diet, a major part of the digestion of carbohydrate may occur in the large intestine since it depends upon the action of bacteria and not upon digestive enzymes secreted by the animal. In such animals absorption of sugars from the large intestine may be a necessary mechanism.

PROTEIN ABSORPTION

Some absorption of native protein and of intermediate products of protein digestion may take place in the small intestine but by far the greater part of the protein in the food is reduced to amino acids before being absorbed. Protein absorption is, therefore, essentially amino acid absorption. All available evidence indicates that amino acids are readily absorbed throughout the entire length of the small intestine. They are taken up about as rapidly as they are produced by the action of digestive enzymes; consequently only small amounts of amino acids can be found at any time in the intestinal contents. Also, any excess in the blood due to absorption disappears rapidly so that it is difficult to trace the absorption of amino acids from the intestine by chemical means. Although all the amino acids are rapidly absorbed from the intestine, some are absorbed more rapidly than others. The following list is in the order of rapidity of absorption: glycine, alanine, cystine, glutamic acid, valine, methionine, leucine, tryptophane, isoleucine, norleucine, isovaline (Verzar and McDougall, 1936).

Wiseman (1953) has shown that the levorotatory, or naturally occurring forms of alanine, phenylalanine, isoleucine, valine, methionine and histidine are absorbed more rapidly than the dextrorotatory isomers and that the levo-forms could be transferred through the intestinal wall against a concentration gradient, whereas the

dextro-forms tended to reach the same concentration on the two sides of the membrane (as did glutamic and aspartic acids) Eldsen and others (1950) have found that if a racemic mixture of amino acids is introduced into the intestine, the levorotatory isomers will be absorbed as much as six times more rapidly than the dextro-isomers. These facts—and the fact that there are differences in the rate of absorption of amino acids that are not related to their diffusibility—as well as the rapid disappearance of amino acids from the intestine, all point to the fact that there is an efficient mechanism for the active absorption of many of the amino acids and that their absorption does not depend upon diffusion and osmosis. This conclusion is further supported by the fact that amino acid absorption is inhibited by absence of oxygen and by several metabolic inhibitors such as dinitrophenol and desoxyripyridoxine (Friedlander and Quastel 1955). Phloridzin, which interferes with phosphorylation and prevents active absorption of glucose, does not interfere with active absorption of amino acids. Nevertheless amino acids are said to compete with sugars for the absorptive mechanisms; that is, sugars are absorbed more slowly from a sugar-amino acid mixture than from a pure sugar solution (Cori, 1931).

Considerable transamination of amino acids occurs in the mucosal cells; consequently, they are not necessarily delivered to the blood in the same form in which they are absorbed; for example, glutamic and aspartic acids may be converted to alanine during absorption. If the absorption rate is slow, practically all the glutamic and aspartic acids undergo such change; on the other hand, during rapid absorption there is relatively less transamination and considerable quantities of glutamic and aspartic acids appear in the blood (Nعام and Wiseman, 1957). It has been suggested that in this way the intestinal mucosa modifies the amino acid mixture that is being absorbed from a particular meal, reducing the amount of amino acids that are in excess in the digesting mixture and increasing the amount of those that are in short supply so as to more nearly meet the needs of the organism for specific amino acids.

Since many of the intermediate products of protein digestion are soluble in water and some are diffusible, the question naturally arises as to whether some proteoses and peptones may be absorbed from the intestine without being reduced to amino acids. Peptone solutions certainly disappear from intestinal loops but this does not

prove that the peptone was absorbed as such. It will be recalled that the peptidases of the intestinal secretion are believed by some to be intracellular enzymes which are not actually secreted but appear in the intestinal contents as a result of a breakdown of shed epithelial cells. It seems unlikely that peptides could get through the mucosal cells in any considerable quantity without being reduced to amino acids by the intracellular peptidases. The same reasoning does not apply to native protein which may have escaped digestion for one reason or another by the pepsin of gastric juice or the trypsin of pancreatic juice. Except for traces of pepsin in the Brunner's gland secretion, there are no proteases in the intestinal secretion or in the mucosal cells that are known to be able to attack native protein. It is not surprising, therefore, to find that egg albumin and milk protein can sometimes be demonstrated in the blood by immunological methods, after these proteins have been placed in the intestine. Absorption of native protein is not necessarily a result of a pathological condition of the intestinal mucosa, although the absorption may be greatly increased by an inflammatory condition. Grushav and Cooke (1955) have found that after feeding 1 gram of crystalline egg albumin per kilogram of body weight to normal children, they could detect in the plasma of these children between 0.45 and 7.3 μg of egg albumin per ml of plasma. In children recovering from diarrhea the amount ranged from 4 to 53 μg per ml. It seems likely that many cases of food allergy result from such absorption of native protein, either from a normal or from an inflamed intestine. Since the absorption is greater in inflammatory states it appears that some caution is indicated in the feeding of patients suffering from enteritis.

ABSORPTION OF FAT

Fat absorption is a complicated process which, even now, is not fully understood. It is known that bile and pancreatic juice are essential for normal fat absorption, yet appreciable amounts of fat can be absorbed from the intestine in the absence of both. Elaborate mechanisms exist in the intestine for splitting triglycerides into fatty acids and glycerol, and yet the fat that appears in the lymphatics after absorption is nearly all triglyceride fat.

Efforts to explain fat absorption have been embodied in two main theories. The older, known as the *lipolytic theory*, was proposed by Pflüger in its original form and modified and supported by Verzar (Verzar and McDougall, 1936). According

to this theory all fat is hydrolyzed in the intestine to fatty acids and glycerol by the action of pancreatic, gastric and intestinal lipases. Previous to hydrolysis the fat is emulsified by the action of bile and, after some hydrolysis has occurred, by soaps produced by the interaction of the liberated fatty acids with the alkali of the intestinal fluids. Since the upper intestine is usually acid and the ileum only slightly alkaline the fatty acids are insoluble in the intestine at the usual pH levels of the intestinal contents, they are made soluble through the formation of complexes with the bile acids, glycocholic and taurocholic acids chiefly. During absorption these complexes enter the mucosal cells where the bile acids are split off and, for the most part, returned to the intestinal lumen. The fatty acids are recombined with glycerol to form triglycerides which are then transferred to the lymphatics. Somewhere in the process, either during absorption into the epithelial cells or during synthesis into triglycerides, phosphorylation takes place, the function of which is not clear but which is assumed to be essential to the process. Verzar leans to the opinion that phosphorylation is essential to the resynthesis of triglycerides. According to this theory, although some fatty acid may be absorbed by way of the portal vein, the amount is negligible. No fat is absorbed directly as triglyceride.

Frazer (1946) has raised objections to the hydrolytic hypothesis and presented one of his own which has come to be called the *partition hypothesis*. According to Frazer's view bile and soap are not adequate emulsifying agents under the conditions found in the intestine, chiefly due to the acid reaction in the duodenum. However, emulsions can be formed in an acid medium, if in addition to bile, mono- and diglycerides are added to the mixture. These agents are produced by the hydrolytic action of lipases in the intestine as steps in the process of hydrolysis of triglycerides. According to Frazer's view, the function of the lipases is mainly to form these compounds for the purpose of emulsifying the fat. Some free fatty acids are produced in the process and these are absorbed into the portal blood, after forming complexes with the bile acids as postulated by Verzar. According to Frazer, the important step in absorption is not lipolysis but emulsification and when the fat has been reduced to particles not exceeding 0.5 micron in diameter they enter the epithelial cells as triglycerides and are directly transferred to the lymphatics. The small fat particles are known as *chylomicrons* and

appear in the lymph and the blood as such. Each chylomicron has a coating consisting of lipoprotein and phospholipid and it may be that the phosphorylation is concerned with producing the necessary phospholipids for the formation of chylomicrons. Resynthesis of fat in the epithelial cells is not a necessary part of the process of absorption according to this theory.

Neither theory conforms to all the known facts but certain features of each are well substantiated. Resynthesis of fatty acids into triglycerides within the epithelial cells, as postulated by Verzar, has been abundantly confirmed by many investigators. For example, Bergstrom and others (1954) found that when free oleic acid labelled with carbon-14 was fed, 63 per cent of the fed acid was recovered in the lymph as neutral fat. When triolein was fed 65 per cent was recovered in the lymph. These authors also found that when fatty acids containing 10 or fewer carbon atoms were fed they were absorbed by way of the portal blood where they were transported mainly as free fatty acids. Longer chain fatty acids were synthesized in the epithelial cells into triglycerides and absorbed by way of the lymphatics. Kujasu, Bloom and Chaikoff (1952) also found that short chain fatty acids were transported mainly by the portal pathway and long chain saturated fatty acids by way of the lymph. Therefore, a sort of partition does occur in the intestine, but not based on the degree of hydrolysis as proposed by Frazer.

Not all fat has to be reduced to free fatty acid and glycerol before it is absorbed. Reiser and his coworkers (1952) fed animals triglyceride in which both the glycerol and the fatty acid were labelled by means of appropriate isotopes. They found that only 25 to 45 per cent of the triglyceride was completely hydrolyzed. The remainder was hydrolyzed to monoglyceride and absorbed as such, resynthesis to triglyceride occurred in the mucosal cells. If monoglycerides and diglycerides are fed, only triglycerides are found in the intestinal lymph. It is interesting that the labeled glycerol was not utilized in the resynthesis but apparently took some other metabolic pathway. The mucosal cells, evidently, not only are capable of synthesizing glycerol for incorporation into triglycerides but actually do so preferentially even when glycerol is available from the hydrolytic products.

During digestion of fat there is synthesis as well as hydrolysis of glycerides in the intestinal lumen (Knoebel and Nasset, 1957), consequently the triglycerides that are absorbed may have an

entirely different arrangement of the fatty acids within the fat molecules than that which is fed. However, some of this redistribution probably takes place during resynthesis in the epithelial cells (Bergstrom and Borgstrom, 1956).

Although exclusion of bile from the intestine greatly reduces absorption of ordinary fat, if the fat is fed as an emulsion ligature of the bile duct makes no significant difference in the amount of fat absorbed (Coffee *et al.*, 1940). However, even with emulsified fat removal of the pancreas seriously interferes with absorption (Wells *et al.* 1955). These observations suggest that bile is concerned in the emulsification rather than the absorption of fat and raises a question as to the role of the bile salts in absorption of fatty acids. The results with pancreatectomy also suggest that hydrolysis of fat is more important than emulsification in determining total absorption. Studies of the excised intestine of the rat (Smyth and Taylor 1957) and of the golden hamster (Johnston 1958) show that fatty acids are absorbed or may be absorbed by the intestinal mucous membrane against a concentration gradient and that this activity is prevented or greatly reduced in the absence of oxygen. There is also suppression of absorption by dinitrophenol and in the absence of glucose, but phloridzin has little effect. These observations indicate that fatty acids are absorbed by an active process which involves oxidation but not necessarily phosphorylation (the effect of phloridzin is somewhat equivocal, see Jervis *et al.*, 1956).

It is commonly stated that fat absorption takes place most rapidly in the upper intestine, particularly in the duodenum and upper jejunum, but several recent studies have suggested that the ileum is the site of the major part of fat absorption, this may have something to do with the more alkaline reaction of this portion of the intestine. For example, Kremen and his coworkers (1954) found that in dogs the proximal 50 to 70 per cent of the small intestine could be removed with no apparent ill effects on food absorption, particularly fat absorption. However if the distal 50 per cent were removed there was a profound interference with fat absorption associated with loss of weight, under these circumstances, from 80 to 90 per cent of the fat intake was lost in the feces. Benson and others (1956), also found that in animals that were sacrificed after a fat meal, the mucosa of the third quarter of the intestine as measured from the pylorus contained a greater amount of fat apparently in

processes of absorption than did any other portion of the intestine. However, fat is certainly absorbed from the upper intestine in appreciable quantities, as anyone who has opened the abdomen of an experimental animal that has recently eaten a fat meal will testify.

Fat absorption is seriously impaired following bilateral adrenalectomy, due to the absence of cortical hormones. The role of the cortical hormones in fat absorption has not been clarified but it has been suggested that they play a part in the synthesis of triglycerides in the mucosal cells (Verzar). Another suggestion is that the loss of salt which follows adrenal cortical insufficiency is responsible for the poor fat absorption. This idea receives some support from that fact that fat absorption is improved in adrenalectomized animals by administration of sodium chloride solutions in adequate quantities.

Absorption of cholesterol. Cholesterol absorption takes place only in the distal one-half of the intestine (Byers *et al.*, 1953). Absorption occurs only in the presence of bile and a source of fatty acid. Since the cholesterol that appears in the intestinal lymph is practically all in the form of cholesterol esters with fatty acids, the function of the fatty acid is probably to provide material for esterification. Absorption of cholesterol is also reduced in the absence of pancreatic juice. Optimal absorption of cholesterol occurs from a mixture of fatty acid, taurocholate and cholesterol in which the molar concentrations are in the ratios of 8, 4 and 1 respectively (Vahouny, 1958). Cholesterol continues to appear in the intestinal lymph for some time after it has disappeared from the intestinal contents. This suggests that there is a considerable accumulation of cholesterol in the mucosal cells during absorption.

ABSORPTION OF VITAMINS

The water soluble vitamins are assumed to be freely absorbed by the intestinal mucosa along with the other constituents of the foods in which they occur. It is generally believed that thiamin is less readily absorbed by older people than by young people in good health. This may be applicable also to some of the other vitamins and provides the basis for administration of vitamin supplements in the dietary of older people.

Absorption of the fat soluble vitamins particularly vitamins D and K, takes place under the same conditions as the absorption of fat. In any disease or dietary deficiency in which fat absorption is inadequate the absorption of these vitamins is apt to be impaired. This is well demon-

strated by the deficient absorption of vitamin K in obstructive jaundice. A deficiency of this vitamin causes inadequate prothrombin production by the liver and a tendency to hemorrhage, hence jaundiced patients are apt to bleed on the operating table. The situation is remedied by the parenteral administration of vitamin K over a period of time preoperatively until the prothrombin level is normal. Absorption of vitamin E is also said to be impaired in the absence of bile.

Absorption of vitamin B₁₂, which is essential for normal red cell production and perhaps for cell division in general, presents special problems. Although it is absorbed from the intestine, its absorption takes place only in the presence of a certain constituent of the gastric juice known, for want of a better name, as intrinsic factor. There may also be some intrinsic factor in duodenal secretion. This name comes down to us from the days when vitamin B₁₂ itself was unknown, (see ch 9).

Vitamin A is absorbed chiefly in the form of esters of the vitamin A alcohol with fatty acids. The esters are hydrolyzed in the intestinal lumen but re-esterified in the epithelial cells. This mechanism parallels the one that is supposed to operate in the absorption of fat, it is not surprising therefore to find that the conditions that favor fat absorption also favor absorption of vitamin A. The presence of bile in the intestine apparently is necessary for the absorption of carotene, a precursor of vitamin A, but not for vitamin A itself. The absorption of the fat soluble vitamins is adversely effected by the presence in the intestine of unabsorbable oil, such as mineral oil, it is therefore necessary to pay particular attention to the supply of these vitamins if mineral oil is to be administered in any considerable quantity over a period of time.

MOVEMENTS OF THE ALIMENTARY CANAL: MASTICATION, SWALLOWING, MOVEMENTS OF THE STOMACH

Mastication

The first mechanical process to which the food is subjected in its progress through the alimentary tract is mastication, or chewing, which serves to break down the food particles into smaller masses, to enable the saliva to lubricate and moisten dry food and to distribute the salivary constituents throughout the food mass. The decrease in the size of the food particles is accomplished by the action of the teeth through the movements of the lower jaw. The moistening is accomplished by the addition of saliva to the food and lubrication is due to the mucus secreted by the salivary glands. Starch digestion in the mouth by the salivary amylase is unimportant but the presence of food in the mouth gives rise to stimuli which serve to initiate reflexes that are important in the later stages of digestion. This relationship has been discussed in connection with the reflex phase of gastric secretion (ch 37).

The importance of mastication as a health measure has been the subject of considerable discussion, much of it speculative. Among the few efforts to obtain scientific information on the subject, are the experiments of Erik Becker (1927) who undertook to determine the completeness of digestion and absorption of protein, fat, carbohydrate and minerals in a patient by studying the losses in the stool of these various substances. He studied his patient during a period of time when her teeth were in very poor condition and not satisfactory for chewing, then again after her teeth had been removed and before she had been fitted with a prosthesis, and finally after she had been fitted with a good set of false teeth which enabled her to chew satisfactorily. There were no significant differences in the three sets of data. For example, when the patient had no teeth she lost 15.2 per cent of the ingested protein in her stool, 5.2 per cent of the ingested fat, 4.2 per cent of the ingested carbohydrate and 25.9 per cent of the ingested minerals. After

being fitted with false teeth, the corresponding figures were 16.0 per cent for protein, 5.4 per cent for fat, 5.2 per cent for carbohydrate and 25.9 per cent for minerals. The total calories lost were 6 per cent with no teeth and 6.7 per cent after being fitted with teeth. These experiments are open to the criticism that no observations had been made when the patient had a good set of natural teeth. These might have given better results.

The Form and Structure of the Teeth

A tooth consists of a *crown*, a *neck* and a *root*. The crown is the part projecting beyond the gum, the root fits into the socket or *alveolus* of the jaw bone. The neck is the junction between crown and root, and normally, lies just below the gum. Three kinds of tissue, *enamel*, *dentin* and *cementum*, compose the hard portion of the tooth. The cavity occupying the center is filled with a soft substance, called the *pulp*, composed of connective tissue fibers and a gelatinous matrix in which the nerves and blood vessels are embedded (fig 41.1).

The enamel, which is of epithelial origin, is a white translucent, and very hard material—the hardest in the body. It is composed of calcium salts (95 per cent) in the form of apatite crystals (ch 59), with from 3 to 5 per cent of organic material. Its structure consists of thin prisms or rods running through its entire depth, perpendicular to and resting on the dentin, the prisms are cemented together by protein material or one containing protein. The dentin surrounds the pulp cavity except at the apex of the root where the nerves and vessels enter, it resembles bone chemically and structurally, but is harder, and contains numerous canaliculi—the *dental tubules*—which radiate from the pulp cavity. In the pulp lying against the dentine are large elongated cells with a radial and epithelioid arrangement, they are called *odontoblasts* and send fine processes (fibers of Tomes) into the overlying dental tubules. The cementum surrounds the root outside the dentin, it is a bony material, but (except in old age), lacks Haversian canals. It is penetrated by bundles of coarse fibers (Sharpey's fibers) derived from the *periodontal membrane*, this membrane lines

the alveolus for which it serves as periosteum, and acts as a close bond between the cementum and the bone. Bone cells are embedded in the cementum near the apex of the root. The viability of the cementum is dependent upon the integrity of the periodontal membrane, it undergoes necrosis when the latter is destroyed.

Like bone, tooth structure is in a continuous state of flux, minerals, calcium and phosphorus being continually removed and replaced.

Dental Decay, or Dental Caries

Calcium salts, which constitute such a large proportion of dental tissue, are soluble in acid, an increase in the acidity of the saliva was thought, therefore, to favor decalcification of the teeth, and in this way prepare them for the inroads of microorganisms. But the saliva is normally slightly acid, and any significant increase in its acidity has not been demonstrated in caries (Gies).

Bacterial decomposition of carbohydrate food with the production of lactic acid especially in regions where food is likely to collect, as in crevices between the teeth and at the margin between the tooth and gum, has long been recognized as an important element in tooth decay. Sugar, especially if highly refined is undoubtedly potent in increasing susceptibility to the disease. Sugar has been shown to facilitate the penetration of the H⁺ ion into the enamel.¹

Another local factor which has been suggested as predisposing to caries is the mucin content of the saliva. A juice rich in mucin flows less freely and as a result of its high viscosity is less likely to penetrate into, and flush out the smaller crevices where microorganisms lurk and flourish upon food debris. Mucin may also encourage decay by forming a tenacious coating upon a sheltered surface of the tooth and thus serve to protect underlying bacteria from the action of the saliva.

The investigations of Pincus suggest that decalcification of the teeth by acid is of less importance than an attack upon the organic substance of the enamel by proteolytic bacteria. Such a process has been suggested earlier by Hines. Pincus claims that digestion of the protein material permits the enamel prisms to fall apart and this occurs apparently without a preliminary production of acid. Sulfuric acid liberated by the hydrolysis of chondroitin sulfate, according to Pincus causes, secondarily, decalcification of the enamel. Atkinson and Matthews agree that the

¹ This action is analogous to the effect of sugar in favoring the penetration of toxins.

FIG. 41-1 Section through a molar tooth

primary point of attack is upon the organic matrix of the enamel but that decalcification of both enamel and dentine is produced by the liberation of aspartic and glutamic acids. They found some 18 amino acids present in normal dentine including aspartic and glutamic acids. These two amino acids were found in the free state in carious dentine but not in healthy dentine. The well known brown discoloration of carious teeth is due to a melanin which is thought to be formed by the oxidation of tyrosine by proteolytic bacteria.

The researches of M. Mellanby on the teeth of dogs suggest that in some cases at least the structure of the teeth themselves—maldevelopment, or an inherently poor tooth structure—or dietary deficiencies (especially of vitamin D) may play a part in the occurrence of the disease. Contrary to the general belief, caries in wild animals is not so very uncommon. It starts with few exceptions in the dentine or cementum of the root where this has become bare, and not in the enamel. The decay is most likely to occur in situations where food tends to pack and stagnate. In domestic animals and animals in captivity, caries is much commoner and the first signs of decay appear in the enamel, as in man. A survey of some 280 wild animals belonging to 60 different species was made by Spraxson, and the tooth enamel compared with that in human teeth. The structure of the animal enamel was found to be less dense, less fully calcified and on the average of poorer quality than that of human enamel, a finding which, taken in conjunction with the less common occurrence of caries in wild animals, suggests a dietary factor in the production of the disease in man.

The beneficial effects of small amounts of fluorine upon tooth structure has received no small amount of attention since Dean and his

associates pointed out the low incidence of caries in districts where there was evidence of high concentrations (over 1 part per million) of fluoride in the drinking water. Excessively high concentrations of fluoride in the drinking water cause mottling of the enamel. Fluorine has also been shown to inhibit acid production by the *Lactobacillus acidophilus* and in a concentration of 0.5 to 1 part per million to be protective against dental caries. Another possible action of fluoride is to reduce the solubility of the enamel by acid. Stannous fluoride is more effective as a preventive than the sodium salt. From the dental examination of some 7,000 children in over 20 American cities it was found that the incidence of caries was inversely related to the concentration of fluoride in the drinking water. Mottling of the enamel does not occur in concentrations below 1 part in a million.

A curious condition known as *dermeus* occurring in domestic animals and man is seen in North Africa and is attributed to a high concentration of calcium fluoride in the drinking water. It is characterized by dystrophy of the second dentition. Kilborn has also reported the endemic occurrence of a severe arthritis and spondylitis in a region of Southwest China which apparently is induced by the drinking of water rich in fluoride.

It is quite evident that the problem of dental caries is not a simple one. Several factors are involved in its production and much work must be done before the details of their actions are known and the relative value of each can be appraised. But from the point of view of prevention the most valuable measures are the curtailment of sugar in the diet and the addition of fluoride to the drinking water in those communities in which the latter has a low concentration of this element.

The movements of the lower jaw in chewing are accomplished by the muscles of mastication which include the masseter, the temporal muscles and the internal and external pterygoid muscles, all of which receive their nerve supply from the mandibular division of the trigeminal nerve. The buccinator muscle, which may also be considered a muscle of mastication, is supplied by the facial nerve. Through the action of the muscle of the jaw the mandible may be moved in any one of several directions. Simple closing of the mouth as in biting or crushing food is accomplished by the combined action of the masseter, temporal and internal pterygoid muscles. Opening the mouth is accomplished by the action of the relatively weak digastric and mylohyoid muscles

and aided by gravity. The grinding movements of the molar teeth are accomplished by a rotational movement of the jaw which results from contraction of the pterygoid muscles of one side. Contraction of the right pterygoid muscles, for example, causes protrusion of the right half of the mandible, whereas the left half remains relatively stationary. This results in a rotational movement with the lower teeth on one side sliding over the upper teeth of the same side. The jaw is returned to a midposition and then rotated to the opposite side by contraction of the left pterygoid muscles. This kind of chewing is accomplished by the alternate contraction of the right and left pterygoid muscles. When all four pterygoid muscles contract, protrusion of the jaw results. Retraction of the jaw is accomplished by contraction of the posterior fibers of the temporal muscles and the geniohyoid muscles.

The force of the bite apparently is limited by the sensitivity of the periodontal membrane and not necessarily by the power of the muscles of mastication. In the human the molars have been observed to exert a pressure in excess of 270 pounds (122+ kg.) (Black 1895). The pressure exerted by the incisor teeth is necessarily less due to the lesser mechanical advantage in this location. According to Howell and Manly (1948) pressure exerted by the incisors ranges from 11 to 25 kg. These authors found a force of 29 to 90 kg for the molars. A dog, when chewing bones, may exert a force as great as 165 kg. (Trisca 1924).

Chewing may be carried on voluntarily but for the most part it is a reflex act. The dual nature of the nervous mechanism is indicated by the fact that chewing movements may be elicited by electrical stimulation of appropriate areas of the cerebral cortex (Ferrier 1886; Magoun and others 1933) as well as by sensory stimulation of the mouth in decerebrate animals (Sherrington 1917; Bazzett and Penfield 1922). Magnus (1945) reports that there is a center in the medulla which mediates rhythmic movements of the jaw in response to stimulation of receptors in the mouth, but that this center is dominated by a thalamocortical center which is responsible for the finer regulation of the movements. Efficient chewing is accomplished only when the higher centers are functioning.

Deglutition

Magendie (1838) described the act of swallowing as occurring in three stages which he de-

scribed as follows "For the better understanding of the subject we shall divide deglutition into three stages. In the first the aliments pass from the mouth into the pharynx, in the second they pass over the opening of the glottis and nasal fossae and arrive at the esophagus, in the third they pass through this canal into the stomach." It is convenient to refer to Magendie's first stage as the oral stage, the second stage as the pharyngeal stage and the third as the esophageal stage.

THE FIRST OR ORAL STAGE OF SWALLOWING

During the first stage the food is moved by the action of the muscles of the cheeks and tongue into position on the dorsum of the tongue, the tongue is pressed against the roof of the mouth progressively from the front backward, causing the food to move backward toward the oral pharynx. In this situation the food mass is put under pressure, mainly by contraction of the mylohyoid muscle, and the act passes into the second stage.

According to Hegner (1936) who made his observations with a laryngoscope, the first phase may vary depending upon the circumstances at the time the food is swallowed. He distinguishes what he calls "pure swallowing" from "mastication swallowing." Food swallowed during mastication passes from the mouth into the pharynx with very little muscular effort and goes down the side on which it is being chewed. In pure swallowing, with conscious effort, it may pass down on both sides but usually also in this case, down the accustomed side, this is most often the right side. The lack of muscular effort in the first stage distinguishes mastication swallowing from pure swallowing

THE SECOND OR PHARYNGEAL STAGE OF SWALLOWING

Understanding of the second or pharyngeal stage of swallowing will be easier if we keep in mind the fact that the alimentary tract crosses the respiratory tract in the region of the pharynx so that the swallowing movements have to serve two quite different functions. One, to propel the food through the pharynx and into the esophagus, and the other, to protect the airway, both above and below, from the possible entrance of food particles. Although the propulsive and the protective mechanisms operate simultaneously, it is simpler to describe them separately.

Food is propelled from the mouth, through the pharynx and into the esophagus by muscular movements which increase the pressure in the

mouth and oral pharynx and decrease it in the upper end of the esophagus. Pressure in the oropharyngeal space is increased by contraction of the mylohyoid muscle which presses the tongue against the roof of the mouth. The intrinsic muscles of the tongue assist by making the tongue firm and insuring a proper distribution of the pressure, which increases progressively from the front backward. Although the pressure is rising in the mouth and oral pharynx, it is decreasing in the laryngeal pharynx and upper esophagus (Barelay, 1930). The cricopharyngeus muscle, which serves as a sphincter for the upper end of the esophagus, relaxes and at the same time the laryngeal assembly, including the hyoid bone, larynx and cricoid cartilage, moves forward and upward carrying the anterior wall of the esophagus with it. Since the posterior esophageal wall remains in contact with the prevertebral muscles the movement of the anterior wall tends to create a space between the walls and so lowers the pressure in the upper end of the esophagus.

When the bolus reaches the base of the tongue its movement is accelerated by a rapid downward and backward movement of the tongue, which takes place at the same time as the forward movement of the larynx mentioned above. As a result of the combined forces acting on it the bolus moves with such speed that it is often projected deep into the esophagus. In a remarkable study made with fluoroscopic motion picture technique, Rushmer and Hendron (1951) observed that a bolus approached the pharynx with a velocity of 9 feet per second. Passing through the pharynx it attained a velocity of $10\frac{1}{2}$ feet 24 feet and $28\frac{1}{2}$ feet per second, in successive frames, then slowed to 12 feet per second and finally to 5 feet per second as it passed into the esophagus. These data were obtained with the subject in a horizontal position, in the erect position the bolus moved even faster. The pharyngeal muscles doubtless participate in the second stage in some way but their action is not essential. The relative importance of the oral and pharyngeal muscles in this stage is indicated by the fact that in the experiments of Kronecker and Meltzer (1883) denervation of the pharyngeal muscles in the dog caused little or no disturbance in swallowing, whereas the animal was unable to swallow after the mylohyoid muscle had been denervated.

The development of negative pressure in the upper esophagus during the second stage of swallowing has been denied by some investigators but has recently been confirmed by Code

**DEGLUTITION PRESSURES
AT THE PHARYNGO-ESOPHAGEAL JUNCTION**
Recorded At High Speed (5 cm./second)

FIG 41.2 Records of pressure changes in the pharynx, pharyngoesophageal junction (sphincter) and upper esophagus during the second stage of swallowing. The increase in pharyngeal pressure and primary decrease in esophageal pressure are clearly shown. From Code *et al.* 1958. Courtesy of Charles C. Thomas Co. Springfield, Ill.

and his coworkers (1958) (see figure 41.2) in a careful study of the esophageal pressure by modern, highly accurate techniques. The negative pressure is of brief duration and is therefore easily missed; the entire second stage occupies less than 1 second (Kupferle, 1913).

We must now consider how the airway is protected while the food is passing the pharyngeal crossroads. It will be recalled that there are four possible outlets from the oral pharynx through which food may be expelled. These are back into the mouth, up into the nasopharynx, forward into the larynx and downward into the esophagus. The swallowing reflex has to be so coordinated that the food takes only one of these possible paths, namely that into the esophagus. Return into the mouth is prevented by the position of the tongue against the roof of the mouth and the high pressure developed in this area. Passage into the nasopharynx is normally prevented by the combined action of the tensor veli palatini and the levator veli palatini muscles which together stiffen the soft palate and cause it to press against the posterior pharyngeal wall. It thus forms a protective partition between the oral pharynx and the nasopharynx. If these muscles are paralyzed or if there should be a defect in the soft palate, food enters the nasopharynx and swallowing becomes extremely difficult or impossible. An important factor in preventing entrance of food into the respiratory

tract during swallowing, is the inhibition of respiration which occurs during the second stage of swallowing (Magendie, 1838).

The exact mechanism by which the larynx is protected during the passage of the bolus has been the subject of much study and controversy. It seems clear from the various descriptions that are available that the laryngeal opening is closed during the act of swallowing by the approximation of both the true and the false vocal chords. In addition, the epiglottis serves to divert the oncoming bolus to one side or the other of the larynx. Only when liquid is being swallowed in considerable volume does the swallowed material cascade over the end of the epiglottis. In any case, it usually prevents the passing material from coming directly in contact with the upper surface of the larynx. The position of the epiglottis at the moment of the passage of the bolus has been the subject of considerable argument, however most observers agree that it is carried into a horizontal position by the backward movement of the tongue and the forward movement of the larynx. This same combination of movements results in the larynx being drawn up under the base of the tongue where it is completely out of the way of the oncoming bolus.

Many authors prefer to combine the first and second stages into a buccopharyngeal stage. The buccopharyngeal stage has been described by Pancoast, Pendergrass and Schaeffer (1940) as

occurring in four phases, first, filling of the mouth and movement of the base of the tongue backward toward the postpharyngeal wall, second, as the bolus begins to move backward from the mouth, the base of the tongue comes against the postpharyngeal wall and the epiglottis goes backward and downward. Simultaneously the larynx rises and the arytenoid cartilages come in contact with the under surface of the epiglottis so that the tongue, epiglottis and arytenoids form a single homogenous X-ray shadow. The meeting of these three structures closes the air passage to the larynx. Third, the bolus enters the laryngeal pharynx and immediately passes down into the esophagus, and fourth, the structures return to the resting position.

The depth to which the bolus penetrates into the esophagus depends on the consistency of the material being swallowed and also on the position of the individual. In a horizontal position, if the food is solid, it usually comes to rest at about the level of the clavicle and is not immediately propelled into the thoracic esophagus until the third stage of swallowing begins. In the upright position even solid food may be projected into the thoracic esophagus. Liquids, on the other hand, are apt to be carried all the way to the cardia if the subject is in the upright position, and some may pass directly into the stomach (Meltzer, 1897).

THE THIRD OR ESOPHAGEAL STAGE OF SWALLOWING

A peristaltic wave appears in the upper end of the esophagus associated with each swallowing effort, regardless of whether the food is swallowed. This wave consists of a constriction of the esophagus caused by contraction of the esophageal muscle at the site of the wave, and relaxation beyond. The contraction and associated relaxation move together down the esophagus and eventually reach the cardia. The advancing wave of relaxation affects the cardiac sphincter, causing it to relax. Although the contraction phase carries the bolus ahead of it the relaxation phase facilitates its passage through the esophagus, especially in the region of the cardia, failure of the cardiac sphincter to relax can be a cause of difficult swallowing. If there is a succession of swallows, as for example, in drinking a glass of water, the relaxation phase of the second swallow inhibits peristalsis initiated by the first and so on throughout the series, a peristaltic wave follows only the last of the series (Meltzer, 1899). The type of peristalsis which is always associated

DEGLUTITION PRESSURE SEQUENCE IN MID-ESOPHAGUS

Pressure Pick-Up Units 5 cm. Apart

FIG. 41.3 Pressure changes caused by passage of a primary peristaltic wave over the midportion of the esophagus. The arrow on the myograph record indicates the moment of voluntary swallowing effort. From Code *et al.* 1958. Courtesy of Charles C Thomas Co., Springfield, Ill.

with the act of swallowing, and does not require the presence of food for its appearance, is known as *primary esophageal peristalsis* (Figure 41.3).

If for any reason the esophagus is not emptied, by the primary wave, contact of the food mass with the wall of the esophagus will initiate additional peristaltic waves, these comprise *secondary esophageal peristalsis*. They do not require the swallowing reflex for their initiation but occur whenever the esophagus contains a bolus, usually they continue until the esophagus is empty, or until the reflex responsible for their initiation is fatigued.

As will be explained later, if the vagus nerves are cut, swallowing immediately becomes impossible, however, in some animals in which the lower portion of the esophagus contains smooth muscle, as it does in the cat, monkey and human, some degree of peristalsis ultimately reappears in the smooth muscle portion. This enables the esophagus to empty itself of such material as has accumulated in the upper portion. This phenomenon was first observed and given the name of *tertiary esophageal peristalsis* by Cannon in 1907. This is the only type of esophageal peristalsis recognized physiologically as tertiary, however, in the clinic, "tertiary" peristalsis may mean any one of several types of abnormal movements seen in the lower third of the esophagus.

in elderly patients or in patients suffering from some form of neurosis

There is considerable difference in the rate of progress of food through the esophagus in different animals and in man in different positions, for example, in the goose food takes from 9 to 12 seconds to reach the stomach, but in the dog it takes only 4 to 5 seconds (Cannon and Moser, 1898). Food moves more rapidly in the upper two-thirds of the esophagus than in the lower third, this is in accordance with the difference in the rate of contraction of striped and smooth muscles. In man food takes longer to reach the stomach in the horizontal position than in the vertical position; this difference is especially pronounced if liquids are swallowed. Hurst in 1907 and Schreiber in 1915 studied swallowing in the human in the inverted position. Hurst reported that in the inverted position fluid could be seen steadily ascending the esophagus at about one-third the rate it travels in the normal position. Sometimes a little fluid could be seen flowing back from the stomach into the esophagus. Well chewed bread behaved like liquids. Cachets, however, moved very slowly. Schreiber noted that 30 seconds after a single swallow, with the subject standing on his head, the contrast medium was only at the level of the seventh cervical vertebra at the entrance of the esophagus. When a large amount was swallowed the esophagus filled and became distended but the liquid did not enter the stomach. Both sets of observations point to the fact that in the human, gravity is an important factor in the progress of foods through the esophagus. However it is obvious that in animals such as the goose and the horse, which normally drink with the head down peristalsis is capable of moving liquids against gravity.

Associated with the swallowing reflex there is cessation of activity and loss of tone in the entire gastric musculature but whether this is an extension of the relaxation phase of the esophageal peristalsis or the result of a separate reflex is not clear at the moment. This behavior of the stomach was described by Cannon and Lieb in 1910 and is known as the *receptive relaxation of the stomach*. The relaxation also commonly involves the first portion of the duodenum where (in the dog, at least) it persists for a considerable time after the last swallow (Thomas and Crider, 1935).

★ THE SWALLOWING REFLEX

The first stage of swallowing, like chewing, may be initiated voluntarily but is normally a

reflex action. A large part of the second stage and all of the third stage of swallowing are entirely involuntary. If one wishes to swallow when the mouth is free of food or foreign material a little saliva is passed backwards by the tongue and thus serves as a mechanical stimulus for the initiation of the second and third phases of the act which are purely reflex. If the mouth is kept perfectly free of saliva deglutition becomes impossible.

Like chewing, swallowing may be produced by stimulation of appropriate areas of the cerebral cortex (Miller, 1919; Rioch and Brenner, 1938) or by stimulation of local receptors even in the decerebrate preparations (Ferner, 1886; Bazett and Penfield, 1922). The receptors for initiation of the swallowing reflex are situated in the vicinity of the entrance to the oral pharynx in all animals but are distributed somewhat differently in different species.

The most sensitive areas for initiating swallowing in a rabbit is the membrane of the soft palate above the tonsils. Receptors are also located on the upper surface of the epiglottis and the posterior wall of the oral pharynx below the soft palate. In this animal the soft palate is innervated by the second division of the trigeminal nerve and the pharyngeal wall by the glossopharyngeal, the epiglottis is supplied by the superior laryngeal nerve. In the dog the posterior pharyngeal wall (the dorsal surface and the base of the epiglottis) and the soft palate contain receptors for the swallowing reflex. Cutting the second division of the trigeminal nerve eliminates the reflex from the upper part of the pharynx and the soft palate. The posterior pharyngeal wall is innervated by the glossopharyngeal. The superior laryngeal contains afferent fibers for the swallowing reflex in the dog but is said not to be stimulated by food that takes the usual pathway (Kahn, 1903). In cats the distribution of receptors and afferent nerves is similar to that in the dog. In monkeys the upper part of the palatine arch near the tonsils is the most sensitive area. This region is innervated by the trigeminal nerve. Less sensitive areas are the soft palate and the postpharyngeal wall. Reflexes may also be obtained in the monkey from the false vocal chords and the base of the epiglottis (Kahn, 1903).

In the human the receptors for the swallowing reflex are distributed in a ringlike fashion around the entrance to the oral pharynx and are found in the mucous membrane covering the anterior and posterior pillars of the fauces, the tonsils, the soft palate, the base of the tongue and the posterior pharyngeal wall. According to Pomerenko (1928) the most sensitive areas in the

human are in the vicinity of the anterior and posterior pillars of the fauces and the tonsils

THE SWALLOWING CENTER

INNERVATION OF THE MUSCLES OF DEGLUTITION Coordination of the numerous somatic and visceral muscles involved in the act of swallowing is controlled by a group of neurons in the floor of the fourth ventricle known as the swallowing center, first described by Markwald in 1889. He found that destruction of the brain substance above and somewhat lateral to the *alae cinereae* of the medulla eliminates the swallowing reflex while leaving respiration intact. Destruction of the *alae cinereae* stops respiration but does not interfere with swallowing. Thus the swallowing center is closely associated with, although distinct from, the respiratory center. This fact is of considerable clinical interest because in diseases of the medulla as *bulbar polio* or *brain tumor*, difficulty in swallowing often precedes respiratory failure and is therefore an ominous sign in such conditions.

The efferent nerve fibers involved in the act of swallowing are chiefly in the hypoglossal, glossopharyngeal and vagus nerves. The hypoglossal and glossopharyngeal nerves are chiefly concerned with the buccopharyngeal stage, the vagus, with the esophageal stage of swallowing. The vagus nerves supply the striped muscle of the esophagus with motor fibers, hence, one of the more serious consequences of cutting the vagi above the origin of the main esophageal branches is interference with swallowing. The striped muscle of the esophagus is permanently paralyzed after a high vagotomy (e.g., in the neck), but the smooth muscle of the lower third shows some degree of recovery, peristalsis in this portion may return and swallowing may again become possible (Cannon, 1907). In animals such as the dog and rabbit in which the entire esophagus is made up of striped muscle, high vagotomy results in permanent inability to swallow. Paralysis of the esophagus with the resultant accumulation of food and liquid in the esophagus and pharynx, associated with the loss of the sensory innervation of the larynx, results in the aspiration of food and liquids into the lungs, the animal either suffocates or dies of aspiration pneumonia. Aspiration pneumonia is the most common cause of death after a high vagotomy in dogs.

The fact that peristalsis, at least in the striped muscle portion of the esophagus, is coordinated outside of the esophagus itself, within the central nervous system, was demonstrated in experi-

ments by Mosso in 1876. He made a transverse section through the esophagus of the dog and placed a small wooden ball in the part below the cut. The animal was then stimulated to swallow, one or two seconds after contraction of the pharyngeal muscles the peristaltic wave began to traverse the esophagus. The wave did not stop at the point of the incision but in due time appeared below and carried the ball into the stomach. These observations were later confirmed by Meltzer in 1899. Meltzer observed that if he used ether ~~and the~~ he obtained results similar to those of Mosso. However, if the animal was narcotized with morphine alone the peristaltic wave did not progress beyond the transverse incision. Likewise it stopped at a longitudinal incision which permitted the contents of the esophagus to escape. Evidently under these circumstances, local reflexes initiated by the contact of food with the mucosa of the esophagus were essential to the normal progress of peristalsis. Meltzer concluded that peristalsis in the striped muscle portion of the esophagus is coordinated in the central nervous system, but is aided by local reflexes arising within the esophagus.

Consideration of the manner of ending of the motor nerves to the esophagus will aid us in understanding this situation. The striped muscle is directly innervated by the vagus nerves, the fibers ending on the muscle cells without the intervention of any local ganglion cells. In the smooth muscle portion, however, there is an extensive local plexus including nerve cells and their branches similar to the myenteric plexus in other parts of the gastrointestinal tract. In this part the vagus fibers do not go to muscle cells but end on nerve cells within the esophageal plexus. It is true that a less dense plexus extends into the striped muscle portion, but this is perhaps concerned with secretion of fluid by the esophageal mucous membrane rather than with contraction of the muscle. As we have already noticed, the local nerve plexus is capable of coordinating peristalsis in the smooth muscle portion of the esophagus, even in the absence of the extrinsic nerves.

The Cardia

The muscular ring encircling the lower end of the esophagus is commonly known as the cardiac sphincter, although, as a matter of fact, in man the thickness of the muscle in this situation is scarcely greater than that in the rest of the tube. We have already seen that the cardia is held

tonically contracted, but relaxes upon the approach of a peristaltic wave or may even remain relaxed during a series of swallows, as in drinking (p 687)

Experiments upon animals suggest that the cardia is supplied with both motor and inhibitory fibers from the vagus, stimulation of this nerve, although followed in many cases by relaxation of the sphincter, at other times causes contraction. Although in some animals a tonic contraction of the cardiac sphincter follows section of the vagi, Hwang and his associates found that bilateral vagotomy in the dog in no instance caused increased tone of the sphincter, as would result had they an inhibitory function, but hypotonia was sometimes the result of this operation. However, the character of the response, inhibitory or excitatory, depends, apparently, upon the degree of tone, high or low respectively, exhibited by the sphincter at the moment of stimulation. Species differences may also be responsible for the variability of results. Observations upon cardiospasm (qv) suggest that in the human subject the chief influence exerted by the vagal fibers is inhibitory.

CARDIOSPASM Cardiospasm is the term applied to a condition in which the sphincter does not relax properly during deglutition, difficulty in swallowing (dysphagia) results the subject complaining that the food 'sticks in his throat'. Ray examination frequently shows that the lower portion of the esophagus is dilated into a funnel shaped or fusiform structure. The condition is usually one of incoordination between the muscle of the esophageal wall and the sphincter—*achalasia*—rather than one of actual spasm. Hurst showed that in most instances a tube weighted with mercury passed readily through the obstruction and suggested the term *achalasia* in these cases in preference to cardiospasm. The mode of its production is not known for certain. In some instances it may be reflex in nature and due to the irritation of afferent fibers in the stomach, gall bladder or other abdominal viscus. In two cases reported by Rake from which tissue was obtained for histological examination, degeneration of Auerbach's plexus (which receives vagal fibers) was found. Degenerative changes in the ganglion cells of this plexus have been described by several investigators. The recent observations of Code and his coworkers (1958) led them to the conclusion that *achalasia* is associated with degeneration of Auerbach's plexus and is characterized by absence of peristalsis in the body of the esophagus. A remarkable finding in their cases was increased response of the esophageal muscle to Meckel's—*a* choline compound that acts like acetylcholine.

The cardia is also innervated by the sympathetic, but there has been uncertainty again as to whether this nerve exerts an inhibitory or an excitatory action. As in the case of the vagus, both inhibitory and motor effects have been reported (Luckhardt) to result from its stimulation. In man the sympathetic has been thought to have a motor action. The fact mentioned earlier—that in some animals bilateral vagotomy causes spastic contraction of the cardia—would also suggest that the usual action of the sympathetic upon the sphincter is excitatory, were it not for the observations of Hwang and associates that sympathetic ganglionectomy is without any effect upon sphincter tone, whereas vagal section may be followed by hypotonia. Knight, in experiments upon cats, found that although vagal stimulation in all instances, caused relaxation of the cardia, sympathetic stimulation invariably resulted in contraction.

Thus, as in the case of the vagus, the conflict of experimental results in respect to the sympathetic innervation of the cardia does not permit any clear cut statement to be made. The confusion is likely due to species differences. Observations in cases of cardiospasm (see below) have suggested a motor action of the sympathetic in man but Grimson and his associates have thrown doubt upon such a function as they could find no change in sphincter action after double supra diaphragmatic vagotomy.

The cardia relaxes much more readily to pressure applied to its esophageal aspect than to pressure from within the stomach. In animals, a pressure of 5 to 7 cm. of water on its upper surface is sufficient to cause relaxation, but a pressure of 25 cm. is required to be exerted from the stomach side. Alvarez found however, that in the human subject the mere pressure of the stomach contents upon the cardia may cause it to relax. This fact was brought out by placing persons in the head-down position. The tonicity varies in degree in different individuals and in some, simply bending over forces the cardia, and causes a reflux of fluid into the pharynx or mouth, as a result, no doubt, of the compression of the abdomen, and the consequent elevation of intragastric pressure. It is to be recalled in this regard that the pressure in the esophagus is, like that within the rest of the thorax generally, subatmospheric. In individuals in which the tone of the cardia is lessened, the 'negative' pressure in the esophagus (together with any increase of pressure in the abdomen) will

encourage the regurgitation of fluid from the stomach

The tone of the cardia is inhibited by mild stimulation of the gastric mucosa and by sensory impulses arising in the mouth and pharynx. Its tone increases as digestion proceeds. The factor responsible for the increased tone does not appear to be the acidity of the gastric contents; the hypertonicity apparently is a part of the general increase in tone that occurs in the fundic portion of the stomach with the progress of digestion.

The tone of the sphincter may be increased reflexly by abnormally strong stimulation of the stomach or of more remote regions of the alimentary tract. Afferent impulses arising from a diseased gall bladder and other abdominal organs have been held responsible for abnormally hypertonic states of the cardia.

ANTIPERISTALSIS IN THE ESOPHAGUS

HEARTBURN, BELCHING

According to Alvarez reverse wavelets or ripples commencing at the cardia and passing upwards along the esophagus to the pharynx are not an uncommon occurrence in man but true reverse peristalsis is not seen unless some obstruction exists. The reverse ripples in the esophagus are thought to be responsible for some of the symptoms of dyspepsia, e.g. the deposition of food upon the back of the tongue, bad breath and regurgitation of fluids into the mouth. Evidence for the existence of reverse movements in the esophagus was obtained by Kast who found that *lycopodium* spores swallowed in a capsule were recoverable from the mouth washings next morning in over 50 per cent of a series of human subjects. The possibility of material from even the lower bowel reaching the mouth is strongly suggested by the fact that *lycopodium* spores introduced into the colon by enema have been recovered some hours later from washings of the stomach.

HEARTBURN is ascribed by Alvarez to the stimulation of the mucosa of the upper part of the esophagus by acid fluid regurgitated from the stomach. Payne and Poulton suggest that a tonic spasm of the esophagus set up by the acid stimulus is responsible for the sensation. Jones and Richardson produced it in normal persons by distension of the lower third of the esophagus. The introduction of acid, cold water or gastric contents into this part of the esophagus also caused the burning sensation. Spasm of the wall of the tube was observed at the level in contact

with the material and reversed peristalsis above. It is generally agreed that the sensation does not originate within the stomach itself.

BELCHING. The tendency after a meal for small amounts of gas to be expelled from the stomach into the esophagus and mouth is experienced by most normal persons. It is brought about most probably by reverse waves originating in the cardiac region of the stomach and ascending the esophagus. The repeated belching of gas is however abnormal. The gas in these instances is not as a rule produced by digestive or fermentative processes in the stomach but is simply air which has been previously swallowed (aerophagy); it has the composition of atmospheric air. The greater part of the swallowed air does not enter the stomach but is held in the lower part of the esophagus until a sufficient volume has collected to give the subject a certain satisfaction when it is belched. The condition is seen in the nervous type of subject or in one who has some gastric discomfort; he resorts to the air swallowing trick in an effort to gain relief. The intragastric pressure is not increased above the normal, apparently, in subjects who have the sensation of gas on the stomach and the pressure is not lowered after gas has been belched.

Movements of the Stomach

Before attempting to describe the movements of the stomach it is desirable to define the anatomical terms that will be used (see figure 41.4). The stomach as a whole consists of a *fundus*, *body* and a *pyloric portion* (antrum). The fundus is that portion of the stomach which in the human in the upright position lies above a horizontal plane passing through the esophageal opening. The body of the stomach (*corpus ventriculi*) extends from the fundus to the *incisura angularis* on the lesser curvature and to a corresponding notch on the greater curvature. The *incisura* is a conspicuous notch on the lesser curvature which serves not only to separate the anatomical divisions of the stomach but also marks the position of a band of smooth muscle which has a higher degree of tonus than most of the remainder of the gastric muscle and causes a narrowing of the gastric lumen at this point. The pyloric portion (*pars pylorica*) extends from the *incisura angularis* in the lesser curvature and the corresponding notch on the greater curvature to the junction of the stomach with the duodenum. The pyloric portion differs from the remainder of the stomach in having much heavier musculature.

The cardia is simply the esophageal orifice.

FIG 41.4 Diagram showing the position and subdivisions of the stomach. A, B, and C represent J, reversed L, and steer horn types of stomach respectively. D, stomach of the J shaped type with the greater curvature lying well below the level of the umbilicus. Antrum is also known as the vestibule.

that is, the opening between the esophagus and the stomach. Properly speaking it refers to no anatomical structure, nevertheless the term is often used to refer to the entire region of the stomach surrounding the cardia and in that sense it includes the mucous membrane and muscle in the immediate vicinity of the orifice. The cardia is surrounded by a sphincter muscle known as the cardiac sphincter. This sphincter, although it appears thicker and heavier than the adjacent muscle when in the contracted state, is difficult to see in the dead stomach. The pylorus is the opening between the stomach and duodenum and, like the cardia, refers to no anatomical structure. However, the term is often used to designate the pyloric portion of the stomach. Likewise the pyloric sphincter is sometimes referred to as the pylorus. These usages are incorrect and often give rise to misunderstandings. The lumen of the pyloric portion may be divided into an antrum and a pyloric canal. The separation between these two portions is marked by a sulcus intermedius when this is present. The portion to the right of the sulcus is known as the pyloric canal and the portion to the left as the pyloric antrum, the antrum, too, is not a structure but a space, nevertheless, the entire pyloric

portion is often called the antrum in clinical literature.

THE PERIODIC ACTIVITY OF THE EMPTY STOMACH

The smooth muscle of the stomach is seldom completely inactive, but its activity increases during gastric digestion and periodically when the stomach is empty. The activity of the empty stomach was first observed by Schirokitch (1901) whose observations were extended by Tescheskow (1902) and later by Boldyreff (1904) all working in Pavlov's laboratory in St. Petersburg. Boldyreff, in particular, noted periodic activity of other organs of digestion including the small intestine and pancreas. The contractions of the empty stomach were further studied by Cannon and Washburn at Harvard in 1912. These authors recognized the relation between the contractions and the sensation of hunger and proposed for them the name *hunger contractions*. Later, hunger contractions were studied and described in detail by Carlson (1916) and his co-workers at the University of Chicago.

Hunger contractions are peristaltic waves superimposed on contractions of the gastric smooth muscle as a whole. In contrast to digestive peristalsis, which is evident chiefly in the distal part of the corpus and pyloric portion of the stomach, the hunger waves travel the entire length of the stomach.

Carlson recognized three types of hunger contractions. Type I occurs when the tone of the stomach is feeble. It consists of single contractions superimposed on a low tone level. The tonus of the stomach does not rise between contractions and there is always an interval of time between the end of one contraction and the beginning of the next. Each contraction lasts for about 30 seconds and the interval between contractions is from $\frac{1}{2}$ second to 3 or 4 seconds. These contractions occur during a *hunger period* which lasts for from 15 to 30 minutes. The hunger periods are separated by rest periods lasting for from $\frac{1}{4}$ hour to 3 hours. Type II hunger contractions occur when the tonus of the stomach is strong. There is no intervening pause between the contractions each of which lasts for 20 to 30 seconds. The tonus of the stomach tends to rise as the contractions follow one another. Often toward the end of a series of contractions there is a period of incomplete tetanus of the stomach lasting for 1 to 5 minutes. This type of hunger contraction tends to be continuous in the sense that there are no rest periods between the hunger periods. Type III hunger contractions ap-

FIG. 41.5 Diagram showing the method used to record the gastric hunger contractions. pear when the tonus of the stomach is very high and tends to increase with the first contraction. The characteristic performance of the stomach is an incomplete tetanus which lasts for 1 to 10 minutes. Superimposed on the high tone level are individual contractions lasting from 12 to 15 seconds each.

Carlson noted that hunger contractions are

apt to begin soon after the stomach has emptied. In the beginning they tend to be type I and the hunger periods at first are of short duration. As the fast continues the hunger periods become longer and the rest periods shorter and eventually the contractions become type II in character. Type III contractions are seen in animals after prolonged fasts, they rarely occur in hu-

mans Hunger contractions are more vigorous in young than in older persons and the sensations associated with the contractions vary a great deal in different people. In some people they are definitely painful, whereas others are conscious merely of a vague feeling of emptiness which is exaggerated during the contraction phase but is apt to be more or less continuously present.

Associated with severe hunger contractions are certain systemic effects which are of interest in explaining the discomfort and inefficiency that is associated with severe hunger. There is for example, an increased excitability of the reflex centers of the central nervous system which can be demonstrated by studying the knee-jerk. At the same time there is general restlessness and increased movements in those animals that are governed by instinct; this doubtless has to do with the search for food. There is an increase in heart rate during the actual contractions and an increase in the salivary flow with each contraction. The latter is evident during strong contractions only. There is apt to be a feeling of weakness and a general indisposition to make any vigorous effort mental or physical. Along with the sensation of emptiness which is referred to the epigastrium there is often headache. The headache of hunger is peculiar in that it is relieved at once on taking food, it is probably reflex in origin. Finally there is apt to be a sensation of nausea with severe hunger. As pointed out by Ivy and his associates in 1923, this latter effect is probably due to contractions of the duodenum. The duodenum and upper jejunum usually participate in hunger contractions.

Hunger contractions are inhibited by taking food. The presence of almost any substance in the stomach is sufficient to inhibit the contractions for a time, food in the mouth or in the intestine is also effective. Strangely enough, hunger contractions cease on the presentation of food even though the food is not eaten.

HUNGER CONTRACTIONS AND APPETITE Although the sensation of hunger is associated with changes in the viscera which can be easily demonstrated by physical means, this is not true of appetite. Appetite is largely due to anticipation of the pleasure of eating, although it is frequently associated with hunger, it is not necessarily so. One may have his hunger completely satisfied and still have an appetite for palatable food. Likewise one may be hungry but because the food presented is distasteful, or the surroundings disagreeable, he may suffer from

loss of appetite. Extreme hunger, may, of itself, reduce appetite through producing a sensation of nausea. This subject is discussed more fully in chapter 43.

DIGESTIVE PERISTALSIS

As soon as food is taken the hunger contractions cease and, after a variable period of time, they are replaced by digestive peristalsis. The outstanding characteristic of this type of gastric peristalsis is the constancy of its rhythm. When the stomach contains food, peristaltic waves occur regularly at a frequency of about three per minute in the human, four per minute in the dog and about five per minute in the cat. Each wave begins as a slight circular constriction of some part of the body of the stomach or corpus ventriculi (Cannon 1898, 1911b). The exact point of origin varies with conditions, one of which is the amount of food in the stomach. The contraction appears in the X-ray silhouette as a slight indentation on the greater and lesser curvatures which travels toward the pylorus, becoming deeper meanwhile, until it finally ends with a contraction of the pyloric sphincter (Wheelon and Thomas, 1920, 1921). Not all gastric waves reach the pylorus in this manner. Some appear to terminate at the incisura angularis (Hofmeister and Schutz, 1886) or they may end at some point on the pyloric portion most frequently in the region of the pyloric canal. When this happens the portion of the stomach beyond the point of termination of the wave appears to contract concentrically, expelling its contents either into the duodenum or back into the proximal portion of the stomach.

The difference between waves that go all the way to the pylorus and those that appear to stop short may be explained by assuming that all waves progress peristaltically until they become deep enough to obliterate the gastric lumen. This would cause a sudden rise in pressure in the space beyond and might act as a stimulus causing the muscle surrounding this space to contract. It is probably significant that the antral muscle shows a greater tendency to contract in response to the stimulus of stretching than do the other gastric muscles (Gellhorn and Budde, 1923).

A peristaltic wave takes one minute, more or less, to travel from its point of origin to the pylorus. Since there are three waves per minute, the stomach will usually be occupied by three waves at one time, or by four or more if the origin is near the fundus (figure 41.7). If the origin

FIG. 41.7 Serial X-ray photographs of human stomach taken at 2 second intervals during digestion (From Cole)

is low only one or two may be seen. Cole recognized this fact and spoke of one-, two-, three-, or four cycle stomachs, depending on the number of waves that were visible at one time.

During digestion the body and fundus of the stomach, which serve the reservoir function primarily, behave quite differently from the pyloric portion which serves mainly the function of mechanical digestion and propulsion. The muscle of the body and fundus are relatively thin and participate to only a moderate extent in visible peristalsis. It is this portion of the stomach that undergoes the greatest changes in size and shape, accommodating itself through changes in tonus to the volume of its contents.

THE TONUS OF THE STOMACH

Tonus is a word that has a variety of meanings and is difficult to define precisely, nevertheless, there are certain characteristics of smooth muscle for which no other name is available. Tonus, as applied to smooth muscle, refers to the relation between the length of the muscle and the tension which it maintains, thus, it may mean either the tension in the muscle when maintained at constant length or the length which the muscle assumes under constant tension. This is another way of saying that a change in the tonus of a muscle constitutes a change in its elastic properties. In the digesting stomach, the length of the muscle fibers is determined largely

by the volume of the gastric contents. In these circumstances changes in tonus express themselves primarily in terms of tension and are indicated by the pressure within the stomach. If the stomach is empty, changes in tonus will express themselves largely by changes in the length of the muscle fibers and thus becomes manifest through changes in the shape of the stomach. The shape of the human stomach is subject to wide variations. Some of the shapes which it may assume are illustrated in figure 42.4, a, b, c, d. The shape of the stomach is, of course, also influenced by the volume of its contents and by the posture. In the reclining position it tends to assume a more nearly transverse position, whereas in the upright position the midportion of the stomach has a tendency to descend, producing more of a J shape.

The tonus of the gastric muscle, in so far as it is inversely related to the average volume capacity of the stomach, must increase progressively as the stomach empties during digestion, otherwise the intragastric pressure would fall to a level too low to maintain emptying. Whether this necessary gain in tonus takes place by continuous gradual shortening of the fibers as postulated by Cannon (1911b), or in a stepwise manner as proposed by Cole (1911, 1917) is still uncertain. Cole described what he called "systole" and "diastole" of the stomach. These are contractions and relaxations, respectively, of the

entire gastric musculature occurring approximately once every twenty seconds in man. During each systole the peristaltic waves increase in force as indicated by deeper indentations on the greater and lesser curvatures as seen in the X-ray silhouette. Decrease in the vigor of peristalsis is associated with the phase of diastole. If Cole's description is correct, the problem of gain in tone becomes merely a matter of a slightly lessened relaxation after each successive systole, the resulting decrease in volume corresponding to the volume of material expelled from the stomach.

The tonus of the gastric muscle and the peristaltic movements are closely related, anything that decreases gastric tonus depresses peristalsis and any increase in tone is apt to be associated with an increase in the vigor of the peristaltic waves. For example, if the vagus nerves are cut the stomach becomes hypotonic and propulsive peristaltic waves cease. After several weeks or months the tonus is partially restored and with it peristaltic activity. The apparent dependence of peristalsis on tonus suggested to Cannon (1911a) the thought that rhythmic peristalsis arises in muscle fibers that are under a certain optimal degree of tension, depending on the relationship between the volume of the gastric contents and the tonus of the muscle. Since systole and diastole of the stomach as described by Cole occur approximately once every twenty seconds, which is also the interval between peristaltic waves, it may be that each peristaltic wave is initiated by an increase in the tone of the entire gastric muscle.

As already pointed out, the tonus of the stomach increases progressively during a prolonged fast and eventually the stomach becomes tubular in shape. When food is taken the stomach begins to relax progressively with each swallow so that the intragastric pressure does not rise during the act of eating; this is the receptive relaxation of the stomach referred to earlier in this chapter. Once the stomach is filled, the tonus begins to recover and after it reaches a certain level digestive peristalsis makes its appearance.

THE RELATION BETWEEN HUNGER CONTRACTIONS AND DIGESTIVE PERISTALSIS

Hunger contractions and digestive peristalsis have been described as though they were entirely separate and distinct types of activity. This is largely the result of their having been investigated by different authors under different experimental conditions. In the pyloric portion

at least, one cannot distinguish between a hunger contraction and a peristaltic wave such as might occur during digestion. The contractions of the entire stomach that are seen during the hunger periods are very similar to the systoles and diastoles described by Cole (1911) as occurring when the stomach was filled with a barium mixture. It is not unlikely that such real differences as there are between hunger contractions and digestive peristalsis are due merely to the different conditions under which they occur, and that they really represent the operation of a single motor mechanism.

COORDINATION OF ANTRUM, SPHINCTER AND DUODENUM The fact that there is a relationship between duodenal motility and the gastric peristaltic cycle was first noted by Joseph and Meltzer. In a study on rabbits they observed that "during each contraction of the pyloric part of the stomach, the duodenum stops its rhythmic activity and loses tone, only to resume both again as soon as the contraction of the stomach passes off." They remarked that the phenomenon resembles the relaxation of the stomach that occurs during the act of swallowing. Later Wheelon and Thomas (1922) and Thomas and Crider noted a similar relationship in dogs. As interpreted by Thomas and Crider (1935), a typical gastroduodenal cycle is as follows: as the gastric peristaltic wave approaches the pylorus, the tone and the rhythmic activity of the first part of the duodenum are progressively inhibited, reaching their lowest point just before the gastric wave reaches the pylorus. As the gastric wave ends in a contraction of the pyloric sphincter the duodenum resumes its tone and rhythmic activity. The contraction of the sphincter is therefore accompanied by a contraction of the duodenum. Since the rhythmic contractions of the pyloric sphincter coincide with contractions of the duodenal cap they are probably concerned primarily with control of regurgitation of duodenal contents into the stomach.

THE GASTRODUODENAL PRESSURE CYCLE

Numerous efforts have been made to measure pressures in the stomach and intestine, but the methods used were so inadequate that the observations contributed little to an understanding of gastric function. About 1940, Brody, Werle, Meschan and Quigley devised methods for the precise determination of intraluminal pressures in the gastrointestinal tract. They utilized modern precision manometers connected to small open tubes or tubes ending in small, metal-

shielded balloons. The open ends of the tubes or the end that was fitted with balloons was placed in the areas from which pressures were to be recorded. The experimental animals were unanesthetized dogs provided with appropriate fistulas. Ordinarily the receiving ends of the pressure tubes were placed just above and just below the pylorus, hence, intragastric pressures were recorded from the terminal antrum and duodenal pressures from the duodenal bulb. In some of their studies graphic methods were combined with X-ray and fluoroscopic observations. This method yielded, in addition to pressure measurements, significant information regarding gastric and duodenal motility, pyloric sphincter activity and the passage of contents through the pylorus. Brody and Quigley and their associates extended the study to human subjects.

When the stomach is at rest (peristalsis absent) or in the intervals between gastric peristaltic waves the antral and duodenal (bulbar) pressures are low, being slightly above or below atmospheric levels. These pressures are referred to as basal pressures. Basal pressure in the antrum is 1 to 2 cm of fluid above the basal pressure in the duodenum. Taking food increases basal pressure in both the antrum and the duodenum, but the pressure rise is greater in the antrum, hence the pressure difference between the antrum and the duodenum is increased. When a peristaltic wave approaches the pylorus the antral pressure increases, usually to between 15 and 30 cm H₂O, followed by an increase in bulbar pressure. However, the bulbar pressure rises more rapidly than the antral pressure so that the two reach their peaks simultaneously, after which they both fall again to basal levels. This cycle is repeated, with only quantitative variations with each gastric cycle. By other means it was established that contraction of the pyloric sphincter usually begins near the start of the rise in bulbar pressure but outlasts the increase in bulbar pressure.

In the fluoroscopic studies, passage of gastric contents through the pylorus could be seen to begin as the antral wave approached the pylorus but before the elevation in antral pressure could be detected. Evacuation continued through the early part of the rise in antral pressure but ceased sometime during the succeeding rise in bulbar pressure (and the sphincteric contraction). Consequently the time during which gastric contents could be seen passing into the duodenum could be divided into two distinct but continuous phases—one during which only basal pressures

served as a driving force and resistance at the pylorus was low (designated evacuation period "A") and another during which the antral pressure substantially exceeded the duodenal pressure and the pyloric resistance was rising (called evacuation period "B") (Quigley, 1943, 1944).

Figure 41.8 is an attempt to correlate the gastroduodenal pressure cycle with the motility cycle described in the preceding section. The antral pressure rise is seen to be related to the terminal phase of the antral contraction. The bulbar pressure rise is clearly a result of the contraction phase of the duodenal cycle. Both are closely related in time to the contraction of the sphincter muscle. By way of explanation let us assume that a strong antral wave is approaching the pylorus. Presumably it obliterates the gastric lumen at some point and would put pressure on the contents of the terminal antrum if they were not free to escape by way of the pylorus.

FIG 41.8 Composite diagram showing the successive contractions of the pars pylorica (antrum), pyloric sphincter, and duodenum during a single gastric cycle and the associated intraluminal pressure changes. Evacuation periods A and B are also shown. The contraction curves are traced from a kymographic balloon water manometer record. The pressure curves are approximate copies of the curves published by Quigley *et al* 1950. Vertical lines mark simultaneous points.

However, they do escape at first (evacuation period "A") hence no pressure rise is evidenced. Presently as the wave approaches the sphincter the contraction of that muscle begins, the pyloric lumen narrows, resistance increases and the trapped contents of the terminal antrum are put under pressure, recorded as the antral pressure rise. At first the pressure is sufficient to overcome the increasing resistance at the pylorus (evacuation period "B") but the rapidly contracting sphincter soon closes the pylorus and puts an end to this cycle of evacuation. It is not to be inferred that the stomach always empties in the manner described. Liquids have been observed to leave the stomach without any rhythmic changes in intragastric pressure or any evidence of gastric peristalsis (Thomas, 1957, Shay and Gershon-Cohen, 1934).

GASTRIC FILLING AND EMPTYING

It is possible to determine how solid or semi-solid food arranges itself within the stomach of an animal by marking successive portions of the food with dyes or pigments so that they can be identified later. After the stomach is filled the animal is killed and the stomach removed and frozen, or otherwise fixed, and sectioned. In this way it has been found that the first food eaten lies against the greater curvature in the body and fundus of the stomach. Successive layers lie progressively nearer the lesser curvature until the last portion eaten is near the upper end of the lesser curvature in the vicinity of the cardiac orifice. Liquids, on the other hand, tend to remain near the lesser curvature of the stomach and to flow toward the pylorus along a V-shaped groove formed by the muscle in this region. This is the so-called *magenstrasse* which is evident in some animals but less so in the human. In any case, if a large volume of liquid is swallowed it flows around the food mass and tends to be distributed over the entire interior of the stomach between the food mass and the stomach wall.

A relatively small part of the energy expended by the gastric muscle is utilized in propelling food from the stomach into the intestine through the pyloric orifice. The vigor of the gastric muscular contraction is such that if it were all utilized in propulsion the stomach would empty itself within a very few minutes. By far the greater part of the work is utilized in mechanical digestion, serving to macerate the food particles and break them up into small fragments. This work is done largely by the pyloric portion which in some ways resembles in function the gizzard

of birds. The powerful contractions of the pyloric muscle drive the food against the pylorus. All but the small part that escapes into the duodenum is forced back through a narrow orifice formed by the contraction wave, into the body of the stomach. It is this manipulation of the food mass which results in its being broken down and mechanically digested in the pyloric portion of the stomach.

The rate at which food leaves the stomach is determined by a variety of factors among which are the total volume of the gastric contents and the consistency, chemical composition, pH, and osmolar concentration of the food. Hunt and his coworkers (1951) have shown that for any individual and type of meal the amount evacuated in a unit of time is a function of the volume of the gastric contents. The effect of consistency on rate of emptying is best seen by comparing the emptying of liquids with the emptying of solids. Inert liquids, which neither stimulate the stomach chemically nor osmotically, leave the stomach rapidly. Water, for example, begins to leave the stomach almost as soon as it is swallowed. Solids, on the other hand, are not normally evacuated from the stomach until they are reduced to a fluid or semifluid consistency. Undigested solids are not normally allowed to pass the pyloric sphincter but are returned to the body of the stomach (Cannon 1911b).

The influence of the chemical composition of the food on emptying is shown by the relative rate of emptying of the three major foodstuffs. Cannon (1904) showed that for meals of a given size a meal consisting mainly of carbohydrate left the stomach more rapidly than one consisting mainly of protein or fat and that a protein meal left more rapidly than a fat meal. Fat, especially if eaten in large quantities, remains in the stomach for a very long time. It is not unusual to find food in a dog's stomach as long as 24 hours after a meal consisting largely of fat meat.

The osmolar concentration of the gastric contents has a profound effect upon the rate of gastric emptying. One of the earliest facts to be determined with respect to gastric emptying was that physiological saline leaves the stomach faster than salt solutions of either greater or lesser concentration. More recently Hunt (1956) has shown that in human subjects adding salt to water hastened emptying of the water from the stomach up to a concentration of about 100 m eq per liter. Above 150 m eq per liter the emptying was delayed. In this way he showed that making the gastric contents either hypertonic or

hypotonic with respect to the blood caused a delay in emptying. This is an important factor in the slow emptying of sugar solutions although, as will be pointed out later, sugar slows gastric emptying in another way.

The effect of acid on gastric emptying has been the subject of considerable study and extensive speculation. The fact that strongly acid solutions leave the stomach slowly and that the rate of emptying of such solutions can be accelerated by neutralizing the acid is well known. For example, in some experiments by Crider and Thomas (1937) 300 cc of physiological saline left the stomach of a dog in an average time of 17 minutes, whereas it took 42 minutes for the stomach to dispose of an equal amount of N/20 hydrochloric acid. However, it does not necessarily follow that hydrochloric acids plays an important part in regulating gastric emptying under ordinary circumstances. The acidity of the gastric and intestinal contents is usually not great enough during digestion to materially affect gastric emptying. For example, a pH of 3.0 in the duodenum is necessary in order to influence the rate of emptying of the stomach but the intestinal contents usually have a pH that is well above this level, pH values of 4.0 to 6.0 being most common. Nevertheless, the inhibitory effect of acid on gastric emptying has an important function in protecting the duodenal mucous membrane against excess acidity.

Regulation of Gastric Emptying

At least two mechanisms are available for regulating the rate at which the gastric contents pass into the duodenum. One is the powerful sphincter muscle that surrounds the pyloric orifice at the junction of the stomach and duodenum. Strong contraction of the pyloric sphincter could, if maintained, effectively prevent the passage of the gastric contents through the pyloric orifice. The other mechanism has to do with the control of gastric motor activities. In the early days of physiology it was taken for granted that gastric emptying was controlled entirely by the pyloric sphincter. This was the result of reasoning from structure to function; there was no other apparent use for the powerful sphincter muscle so strategically situated between the stomach and duodenum. However, a closer scrutiny of the function of the pyloric portion of the stomach reveals the fact that a sphincter muscle is necessary at this point to enable the pyloric muscle to carry out its function of comminution and maceration of the food

mass. It is important, too, to have a sphincter to serve as a valve to prevent excessive regurgitation of duodenal contents into the stomach.

Another fact which has contributed to the concept of pyloric control of gastric emptying is the existence of a powerful pyloric reflex. This reflex is elicited by mechanical or chemical stimulation of the duodenum and results in contraction of the pyloric sphincter muscle. One of the stimuli which is capable of eliciting a pyloric reflex is relatively strong hydrochloric acid in the duodenum. This fact, along with other observations made in connection with his classical studies of gastric motility, led Cannon (1907) to propose his theory of the acid control of the pyloric sphincter. He assumed that the pylorus remains closed and thus prevents emptying of the stomach until the gastric contents become acid in reaction. As soon as the secretion of hydrochloric acid in the stomach is sufficient to acidify the gastric contents in the pyloric portion, the pylorus opens and allows some of the chyme to escape into the duodenum. The acid chyme in the duodenum then elicits a pyloric reflex and causes the pylorus to close and to remain closed until such time as the duodenal contents are neutralized. This attractive theory failed to take into account the facts that gastric emptying proceeds normally in persons who secrete no hydrochloric acid; that there is no failure of regulation of gastric emptying when the pyloric sphincter area has been removed surgically, and that the acidity of the duodenal contents necessary to close the pylorus is far in excess of that which normally occurs in the duodenum. Thomas *et al* (1934) found that even when the pyloric sphincter does contract in response to duodenal irritation, the contraction is of brief duration and is followed by relaxation to below the previous tone level.

If the pyloric sphincter were to act as a regulator of gastric emptying, it would be necessary that the sphincter muscle and the muscle of the remainder of the stomach should be reciprocally innervated, that is, that the innervation would have to be so arranged that when the sphincter is contracting the stomach would relax, and vice versa. The true situation is quite the contrary; stimuli which cause contraction of the gastric muscle also increase the tone and activity of the pyloric sphincter, whereas those which cause relaxation of the sphincter also cause relaxation of the gastric musculature (Thomas and Wheelon, 1922).

It has been shown that the major factors

regulating gastric emptying are still effective even though the pyloric sphincter is mechanically prevented from contracting by placing an open tube in the pyloric orifice (Crider and Thomas, 1937). In these circumstances the differences in the rate of emptying of acid, saline, alcohol and olive oil are in no way modified by maintaining the pylorus in an open condition except that the emptying time for alcohol and fat are somewhat prolonged. This is evidently due to the fact that duodenal contents regurgitate freely into the stomach when these two substances are being emptied through an open pylorus.

THE ENTEROGASTRIC REFLEX. As soon as it became apparent that the characteristic response of the pyloric sphincter to acid in the duodenum was not contraction, although this sometimes occurs, but prolonged and persistent relaxation and that this is associated with loss of tone and relaxation of the remainder of the gastric muscle, it was evident that the acid control of the pyloric sphincter could not be a major factor in the regulation of gastric emptying. A more adequate explanation was found in the diminution of gastric peristalsis and gastric tone with the consequent decrease in intragastric pressure which follows duodenal stimulation. So long as the pressure in the stomach is below that in the duodenum, emptying cannot occur. Further study revealed that not only acid but many other constituents of the gastric chyme such as products of protein digestion (Thomas and Crider, 1939), products of starch digestion (Quigley and Phelps, 1934), fats and fatty acids, when present in the duodenum, all cause inhibition of the gastric muscle. None of these substances, with the exception of hydrochloric acid, causes even momentary contraction of the pyloric sphincter. Mechanical distention of the intestine by means of saline also has a moderate inhibitory effect on gastric motility. However, this particular method of stimulation also causes sustained contraction of the pyloric sphincter, hence, the inhibitory effect on the gastric muscle is probably of little consequence in regulating emptying in response to mechanical stimulation. Thomas, Crider and Mogan (1934) found that the inhibitory effect of many chemical substances disappears after the vagus nerves have been cut. They concluded that the inhibitory effect of these substances is caused by a reflex involving the vagus nerves and proposed that it be designated the *enterogastric reflex*.

Enterogastrone. The inhibitory effect of fat on gastric motility has been known for many years

and was recognized by Cannon who exempted the delayed emptying due to fat from his acid control theory. Fat exerts its effect in the absence of any available nerve supply (Farrell and Ivy, 1926). Kosaka and Lum (1930, 1933) and also Quigley, Zettleman and Ivy (1934) showed that fat inhibition is caused by a hormone which Lum (1933) called *enterogastrone*. This hormone is released from the intestinal mucous membrane by fat or fatty acids and by some other substances in the duodenum and, while circulating in the blood, it is carried to the stomach where it has an inhibitory effect on the gastric muscle. The fact that it also inhibits gastric secretion was mentioned in chapter 36. Quigley and Phelps (1934) were also able to demonstrate inhibition of the denervated stomach by carbohydrate substances when present in the intestine. It is assumed that carbohydrates also release enterogastrone or some closely related substance. In the experiments on vagotomized animals, Thomas and Crider (1934) noted that in dogs hydrochloric acid continued to exert some (although slight) influence on gastric motility after the vagus and splanchnic nerves were cut. They concluded that a hormonal as well as a nervous mechanism was probably involved in the action of hydrochloric acid. Schapiro and Woodward (1955) have found that acid in the intestine inhibits gastric motility in human subjects equally well whether or not the vagi are intact.

In summary, we can visualize the events following a meal approximately as follows: gastric emptying begins as soon as any part of the gastric contents become fluid enough to pass through the pylorus. Once started it proceeds rhythmically, a small amount being evacuated about every 20 seconds on average. Regulation of emptying begins as soon as the evacuated material has accumulated in the intestine to the point where any one of the numerous stimuli to the intestine associated with the chyme reaches threshold value. These stimuli are comprised in the chemical constituents of the chyme and to some extent in its volume. The chemical stimuli include the following, listed in the order of inhibitory potency in the concentrations usually encountered: fats, fatty acids, proteoses, peptones, amino acids, sugars and other products of starch digestion, and hydrogen ions, also effective are osmotically active substances and non-specific irritants. The effect of these stimuli is to decrease the tone and peristaltic activity of the stomach, thus reducing the pressure gradient which develops with each gastric cycle and which

is responsible for the passage of fluid through the pylorus. With the more powerful inhibitors, e.g., fat, the gradient may be reversed and duodenal contents will then regurgitate into the stomach. The inhibitory effect is exerted through a reflex involving the vagus nerves (*the enterogastric reflex*) or through a hormone (*enterogastrone*), released into the blood from the intestinal mucous membrane, or both. Products of protein digestion, acid and nonspecific irritants act mainly through the reflex mechanism, fats and carbohydrates act mainly through the hormone, enterogastrone. However, there may be a reflex element in the effect of the latter group and there is undoubtedly a hormonal component in the effect of hydrochloric acid. The pyloric sphincter plays a part by preventing regurgitation of the duodenal contents into the stomach, it also contracts rhythmically in such a way as apparently to limit the volume evacuated at each cycle but there is as yet no evidence that this function is utilized in regulating the over-all rate of gastric emptying.

VOMITING

Vomiting is a reflex which serves to relieve the upper gastrointestinal tract of its contents. This may occur either because the contents are irritating, or because the organs themselves, or the nerves that supply them, are more irritable than normal, in either case there is an unusual degree of stimulation of some part of the tract. The most sensitive area is the first portion of the duodenum (Luckhardt, Phillips and Carlson, 1919) but adequate stimulation of other parts of the intestine or of the stomach, can induce the reflex. Even mild mechanical stimulation of the pharynx or fauces is effective in most people. Inflammation, or mechanical disturbances in the intestine such as appendicitis, obstruction, or strangulation, may induce violent emesis. Vomiting may be induced by abnormal stimulation of sensory receptors in organs outside the gastrointestinal tract, for example, the uterus, kidneys, heart or semicircular canals. Effective stimuli may also enter by way of the eyes, nose or mouth in the form of nauseating sights, odors or tastes, these give rise to what is called psychic vomiting. It is not unusual for a soldier to vomit on going into battle, or at some time during the battle experience, some people vomit at the sight of blood.

Vomiting that is induced by irritation of organs other than those of the gastrointestinal tract is sometimes referred to as "reflex" vomit-

ing. This is an incorrect distinction however since nearly all vomiting is reflex in origin. Even psychic vomiting is probably the result of conditioned reflexes.

Vomiting may be induced by certain types of motion as, for example, in seasickness, air sickness, carsickness, and the nausea and vomiting that some people experience when in a swing. This is probably the result of unusual stimulation of the equilibratory sense organs of the labyrinth.

The Vomiting Center

The vomiting center lies in the dorsal part of the lateral reticular formation of the medulla oblongata close to (and to some extent including) the tractus solitarius. It lies in close relation to (but is quite distinct from) the respiratory centers. It is one of a constellation of visceral centers in this situation—salivatory nuclei, defecation and vasomotor centers, as well as the vestibular nuclei—a relationship consistent with the physiological reactions (salivation, vasomotor and respiratory, etc.) associated with the vomiting act. The efferent fibers are contained chiefly in the phrenics, the vagi and the sympathetics, but fibers are also conveyed by spinal nerves to the abdominal muscles and by cranial nerves to the muscles of the pharynx, palate, etc. The afferent impulses reach the center along a multitude of routes, the chief being the vagal and sympathetic fibers of the stomach and abdominal viscera.

"CENTRAL" VOMITING. Vomiting may occur as a result of direct stimulation of the vomiting center in the medulla. Certain substances such as apomorphine, ipecac (or emetine), picrotoxin, when administered intravenously cause vomiting through a specific action upon the center. These substances induce vomiting in animals when applied directly to the center. Typical vomiting efforts (retching) follow the injection of apomorphine after removal of the stomach and intestines. The experiments of Wang and Borison point to a chemoreceptor "trigger" mechanism in the area cinerea which, through its connection with the vomiting center itself, induces vomiting when stimulated by these emetics. Copper sulfate was found by these investigators to act as an emetic both peripherally, through the gastrointestinal tract, and centrally, a lesion in the area cinerea abolished the central action only.

Most important clinically is the central vomiting caused by traumatic stimulation of the center due to head injuries, increased intracranial pressure, brain tumor or meningeal irritation.

This type of vomiting is characterized by the great force with which the vomitus is ejected (projectile vomiting). There is also a minimum of nausea and a relative absence of participation of the voluntary muscles.

The persistence of pernicious vomiting of pregnancy is probably due to increased excitability of the center resulting from some metabolic disturbance. According to Harding the important factors in its production are carbohydrate starvation and dehydration with ketosis. Ordinary morning sickness is looked upon as a minor form of this condition and differing from pernicious vomiting only in degree. As a result of the demand of the fetus liver glycogen is low during pregnancy. After the fast of the night the reserves of carbohydrate are further reduced and mild ketosis results which leads to nausea and vomiting. The distaste for food by hindering the replenishment of the carbohydrate stores aggravates the ketosis. Thus morning sickness merges insensibly into the pernicious type of vomiting. A neurotic element is also frequently a potent influence in the development and persistence of the condition. The obvious corrective measures are high carbohydrate feeding, the free administration of fluids, injections of glucose if necessary, mild sedatives, rest and quiet.

The Vomiting Movements

Vomiting usually begins with nausea which is characterized by secretion of excessive quantities of saliva containing a large amount of mucus in addition to certain well known disagreeable sensations. In the dog in which it has been possible to analyze by graphic methods the sequence of events in vomiting the first muscular movement to occur is a strong sustained contraction of the upper small intestine. Next the pyloric sphincter contracts and then the pyloric portion of the stomach. These changes all take place during the period of nausea and result in emptying the contents of the upper jejunum, duodenum and pyloric portion of the stomach into the fundus and body of the stomach which are relaxed and dilated. After this has occurred the voluntary muscles come into play and at the same time the cardiac sphincter, esophagus and esophagopharyngeal sphincter relax. Following an inspiratory movement the glottis is closed and the abdominal muscles contract in a characteristic jerky manner (retching) compressing the stomach between the contracted diaphragm and the abdominal organs. The resulting pressure on the gastric contents

causes their evacuation through the relaxed esophagus.

The precise sequence described above is probably not always followed and the mechanism may differ somewhat in different animals. For example, Cannon (1911b) gives the following graphic account of the act of vomiting in a cat as observed by means of X rays.

The upper part of the stomach showed complete inhibition of its tone and appeared as a perfectly flaccid bag, the cardia relaxed. There then followed several deep peristaltic contractions which commencing about the middle of the body of the organ, swept downward toward the incisura angularis where they came to a standstill forming a sharp ring of constriction. From this point a weaker wave continued to the pylorus. Finally, a very deep strong contraction at the incisura appeared to almost divide the stomach in two, the upper part of the stomach and the cardia meanwhile remaining quite relaxed. A sharp contraction of the diaphragm and abdominal muscles then followed and ejected the gastric contents through the open cardia into the esophagus. The stomach played a more or less passive part in the process its evacuation being effected by the strong compression to which it was subjected by the sharp descent of the diaphragm and the contraction of the abdominal muscles. Antiperistalsis was observed only once and then the wave did not proceed beyond the antrum. The deep contraction at the incisura offered an effectual barrier to the passage of stomach contents in a downward direction. Similar movements have been described in man.

Definite antiperistaltic waves in the stomach are rarely seen although violent churning movements may occur.² In certain types of vomiting e.g. intestinal obstruction or in persistent vomiting from other causes antiperistalsis arises in the small intestine and sweeps material into the stomach or there may be a strong contraction of the duodenum which reverses the pressure gradient between the antrum and the duodenal bulb. Such movements of the duodenum occur

² In certain lower forms however e.g. the fish and the frog which of course have no diaphragm vomiting is carried out by the activity of the stomach alone antiperistaltic waves carrying the food through the cardia. Thus more primitive type of vomiting i.e. where reverse peristalsis and relaxation of the cardia are the prominent features occurs normally in infants. The excess fluid of an oversized meal is regurgitated without the assistance apparently of the abdominal muscles or diaphragm position, and external pressure upon the abdomen following the meal sometimes no doubt also play a part.

sometime prior to the actual vomiting or at the same time, it accounts for the fact that a short time after the stomach has been thoroughly washed out, bile-stained fluid or fecal material may be vomited. According to Alvarez, reverse peristalsis starting in the upper bowel is itself a potent cause of nausea and vomiting.

Relaxation of the cardia is an essential part of the vomiting act, for the stomach is subject to strong compression during coughing, defecation, etc., yet the gastric contents are not as a rule forced into the esophagus. The tone of the cardia is probably actually increased at these times. It has been mentioned that division of the vagi in animals causes the cardia to enter into a spastic state. Hatcher and Weiss found that if after such a procedure a vomiting reflex was initiated, mucus was expelled from the esophagus and the usual muscular movements were called into play, with the exception of relaxation of the cardia. That is, the animal retched but material was not expelled from the stomach. It is well known that with some persons vomiting is difficult whereas in others little distress is experienced. Differences in the degree of tone of the cardia are probably responsible for these individual peculiarities (table 42 1).

During the ejection of the vomitus the esophagus is relaxed throughout, the glottis is closed and the respirations are inhibited, the larynx and hyoid bone are drawn upward and forward and are held rigidly in this position. The throat is thus enlarged to allow free exit for the stomach contents which are prevented from entering the nasopharynx by the elevation of the soft palate.

ABNORMAL GASTRIC MOTILITY

Either hyper- or hypomotility of the stomach may be seen clinically. In the absence of specific diseases involving these conditions, such changes are most often psychogenic and result from acute or chronic emotional disturbances. Acute emotional upsets are usually associated with relaxation of the gastric muscle due to increased activity of the thoracolumbar sympathetic nerves and the adrenal medulla. Hypermotility is said to occur more frequently in prolonged or chronic emotional states involving resentment or prolonged anger. Hyperperistalsis is seen in pyloric obstruction, in this situation it is due in part to the absence of inhibitory reflexes from the duodenum (the enterogastric reflex) and probably also in part to continued stimulation by retained gastric contents. Excessive belching, heartburn (pyrosis), regurgitation of food, hiccups and

TABLE 41 1

Drugs	Afferent Autonomic Fibers Acted upon	Organs Containing Susceptible Fibers
Mercuric chloride	Sympathetic and vagus	Stomach
Tartar emetic	Vagus	Stomach duodenum and heart
Digitalis	Sympathetic and vagus	Heart
Pilocarpine	Sympathetic and vagus	Heart

other types of gastric distress are probably traceable to some abnormality in the movements of the stomach but the relationships have not been well defined.

Hypotonus or general loss of tonus in the gastric muscle is likely to be associated with the deterioration of all body function seen in asthenic states. Hypertonus is supposed to be associated with a condition called *vagotonia*. Vagotonia, if it exists, is a form of hyperactivity of the parasympathetic innervation of the viscera but the condition has never been well defined clinically. Cardiospasm and pylorospasm are conditions in which these sphincter muscles are supposed to be in a state of sustained contraction. Doubtless such abnormalities occur but probably much less frequently than they are diagnosed. Cardiospasm for example could be easily confused with loss of power in the esophageal muscle or absence of esophageal peristalsis, pylorospasm likewise is often diagnosed when the true condition is failure of the gastric peristaltic mechanism to develop adequate gastric pressures, e.g., following the operation of vagotomy. In such instances the pylorus is usually less contracted than normally the appearance of a closed pylorus being due to failure of the gastric muscle to develop sufficient power to force the gastric contents past even a relaxed pyloric sphincter. True pylorospasm occurs as a congenital condition in infants who suffer from hypertrophy of the pyloric muscle. It is also seen in adults, associated with irritative lesions in the region of the pylorus, either of the duodenum or pyloric portion of the stomach.

MOVEMENTS OF THE ALIMENTARY CANAL—Continued

SMALL AND LARGE INTESTINE. INNERVATION

Movements of the Small Intestine

The major part of the smooth muscle of the small intestine is distributed in a thick circular layer and a much thinner longitudinal layer. The circular layer is responsible for most of the visible intestinal movements. The longitudinal layer undoubtedly participates in the movements but the relation of its activity to that of the circular muscle has been described differently by different authors and is therefore somewhat uncertain. The outstanding characteristic of the muscle is its rhythmicity which is manifest under appropriate conditions by alternate contractions and relaxations at a remarkably regular frequency.

RHYTHMIC SEGMENTING CONTRACTIONS

The more common type of rhythmic contraction occurs at regularly spaced intervals along a section of the intestine dividing it into short segments, also, they may occur singly, in pairs, or in a variety of other arrangements. The area involved in each segment may be less than one centimeter or it may be several centimeters long. In the cat Cannon (1902) saw a certain type of rhythmic contraction in which a section of intestine was divided into short segments by rings of contractions occurring at regularly spaced intervals. When the contracted areas relaxed, the relaxed areas between contracted, dividing each segment into halves. The two halves of adjacent segments joined together to form a new segment (Fig. 42.1). Cannon described these contractions as *segmenting contractions* and that is the name that is most commonly applied to them at the present time.

The rhythmic nature of this activity reminded Ludwig (1861) of a pendulum, hence he applied the name 'pendulum' movements to these contractions. Ludwig used the pendulum as a symbol of rhythm only, but some authors have attempted to apply the simile in the sense of the to and fro motion of a pendulum. Swaying movements of

the intestinal coils are to be seen at times as well as a to and fro motion of opaque masses within the intestine as is seen with a fluoroscope. Alvarez (1940) described them as follows: "in the rabbit, and to a certain extent in other animals and in man, a local mixing of the intestinal contents with digestive juices, similar to that produced by the segmenting contractions is brought about by sway or 'pendular' movements. A segment of bowel is pulled first in one direction and then in the other. The wall apparently being drawn over its contents like a stocking over a foot. My impression from watching these movements in men and women who have taken a barium meal is that, in man, activity is more like a short pendular movement than a rhythmic segmentation." However to identify these movements and these only as pendular movements is confusing, since the term as originally used and commonly applied is synonymous merely with rhythmic movement without regard to the effect of the activity on the intestinal coils or their content. If we exclude the swaying movements described by Alvarez, then the rhythmic segmenting contraction and pendular movements are one and the same thing.

The frequency of the rhythmic contractions varies with the species of animal and with the region of the intestine in which they occur. For example, in the rabbit the contractions occur at a frequency of about 20 per minute in the duodenum and about 10 per minute in the lower ileum. In the dog they occur at a frequency of about 18 per minute in the duodenum and 8 to 9 per minute in the lower ileum. The frequency in other parts of the intestine is intermediate between these extremes, becoming less frequent the greater the distance from the pylorus. The frequency is surprisingly constant in any one area and is not affected by stimulation of the extrinsic nerves or by neurotropic drugs. In excised material the frequency varies with the temperature.

The variation in frequency at different levels

FIG 421 Diagram representing the process of rhythmic segmentation. Lines 1 2 3 4, indicate the sequence of appearances in a single loop. The dot lines represent the regions of division. The arrows show the relation of the particles (eg, a and b) to the segments they subsequently form (c). (After Cannon 1911)

FIG 422 Diagrammatic representation of the gradient of rhythmicity in the small intestine. The zig zag lines are stylized representations of kymographic records of the contractions and relaxations of segments taken from the indicated levels of the intestine. The sloping line suggests a linear distribution of the gradient, however, there is no evidence that this is so.

of the intestine suggested to Alvarez and his pupils the idea that there is a gradient in the various physiological properties of the intestine, the activity being highest at the duodenal end and lowest at the ileal end of the small intestine. Among the properties for which a gradient has been established are rhythmicity, irritability, shortness of latent period, susceptibility to drugs, and certain others of less obvious importance (Alvarez and Hosen, 1929). The most easily observed is the gradient of rhythmicity manifested by the variation in frequency of rhythmic contractions (fig 422).

An interesting question with respect to the rhythmic contractions of the intestine is whether they originate in nervous or muscular tissue. All the available evidence indicates that the rhythmic contractions are myogenic. The problem has been studied by Magnus (1904), Gunn and Underhill (1914), Alvarez and Mahoney (1922) and numerous others. Using various methods of eliminating the influence of nerves upon the smooth muscle,

each of these groups of investigators was able to demonstrate rhythmic activity in denervated intestinal muscle. Probably the most complete denervation was accomplished by Gasser (1926) and van Esveld (1923) who made serial sections of their preparations and found a considerable number in which no nerve cells could be found. Such preparations, however, still respond to cholinergic and adrenergic drugs. When excised preparation of intestine are treated with high concentrations of nicotine (1 mg per ml) the response of the muscle to stimulation of the mesenteric nerves and also the response to the autonomic drugs disappears, the autonomic receptors are apparently paralyzed by the nicotine. The smooth muscle, however, continues to contract rhythmically (Kuntz and Thomas, 1923). It should not be inferred from this that the rhythmic activity is uninfluenced by the intrinsic or extrinsic nerves. Although the frequency of the contractions is apparently not subject to nervous control they can be made to increase or decrease in amplitude or to disappear altogether by stimulation of appropriate extrinsic nerves or by the application of drugs which mimic the action of the autonomic nerves.

Although the frequency of the rhythmic contractions is not influenced by ordinary nervous stimuli, it may be modified or perhaps the contraction may even be initiated by stimuli of another sort. In 1929 Douglas reported that the frequency of rhythmic contractions in the dog's jejunum changed from about 18 per minute to 12 per minute if the jejunum was cut off from the duodenum. This observation suggests that the rhythm of the pendular contraction is not determined locally but by conducted impulses which are initiated at a higher level and which are conducted along the intestine in an aboral direction as a wave of excitation. The electrical studies of Ambache (1947), Bozler (1949) and of Milton and Smith (1956) lend support to this view. These authors have described the electrical activity of the intestine as consisting of slow waves which are frequently, but not necessarily, associated with local muscular contractions, and rapid, spikelike waves which appear only when the muscle contracts. The slow waves have the same frequency as the rhythmic contractions, whether or not these are present, and (according to Milton and Smith) they are regularly conducted along the intestine in an aboral direction. It is interesting in this connection to recall that Bayliss and Starling (1899) saw shallow waves which travelled aborally over the intestine.

at regular intervals and which seemed to them to initiate the rhythmic contractions in an area subject to local stimulation. These waves could have been caused by the regularly conducted impulses described by Milton and Smith.

The function of the rhythmic contractions is evidently to agitate the intestinal contents. Such agitation facilitates several processes: it tends to increase the degree of subdivision of food particles, to mix the food with the intestinal secretions and other digestive fluids, and constantly to change the layers of fluid in contact with the mucosa, thus facilitating absorption. Changes in pressure brought about by these contractions may also be a factor in intestinal absorption.

PERISTALSIS IN THE SMALL INTESTINE

Stimulation of the intestinal smooth muscle causes contractions which tend to travel from the stimulated point in both directions. However, under normal circumstances the progress of the contractions in an oral direction is quickly inhibited and the contractions disappear. The contractions which travel in an aboral direction tend to persist, so that the intestine may be said to be polarized in the sense that conducted contractions travel normally in only the aboral direction. Such aborally conducted contractions are commonly described as peristalsis. The term has been used to describe a variety of contractile phenomena which have only one thing in common, namely the direction of travel. The common conception of peristalsis as consisting of a wave of contraction progressing smoothly over otherwise relaxed intestine is erroneous. Usually the peristaltic movement is superimposed upon the rhythmic segmenting contractions in such a way that the two are present simultaneously. The peristaltic contraction makes itself manifest as a rise in the tone level of the intestinal muscle without any interruption in the rhythm of the segmenting contractions; indeed, these are usually increased in amplitude at the peak of the wave. This of course has the effect of narrowing the lumen of the intestine at the point at which the increase in tonus occurs and it may actually obliterate it. As this wave of contraction, or tonus, travels down the intestine it tends to sweep the contents forward, or toward the distal end of the intestine. In another type of propulsive movement rhythmic contractions, although retaining their rhythmic character, recur at successively more aboral levels and thus appear to travel along the intestine as a wave of peristalsis. Ordinarily, peristaltic waves appear in the small intestine at irregular intervals

and travel for varying distances (Bayliss and Starling), some travel only a few inches, others a few feet.

Under the influence of especially strong stimuli such as irritant cathartics, a peristaltic wave may sweep over the entire length of the small intestine without interruption, or several such waves may occur in succession. Peristaltic waves of this character were described by van Braam Houckgeest in 1872; he called them "rollbewegungen" but they are usually described in the modern literature as *rush waves* or as *peristaltic rush*, after the terminology proposed by Meltzer and Auer in 1907.

Whether the conditions that give rise to rhythmic contractions on the one hand or to peristaltic movements on the other, differ qualitatively or only quantitatively is not known. It is known that both mechanical and chemical stimuli are effective in promoting peristalsis and that mild stimulation favors rhythmic activity. Doubtless not only the nature and strength of the stimuli but also the irritability of the intestinal neuromuscular mechanism play a significant part in determining the nature and location of the activity. The latter may be influenced by local and central reflexes and by circulating hormones and metabolites, as well as by the previous history of the muscle (e.g., by refractoriness or fatigue following a period of activity).

THE LAW OF THE INTESTINE. The polarity of the intestine, that is the fact that peristaltic waves characteristically travel in one direction only, has been the subject of much interesting speculation but no satisfactory explanation has as yet been offered. Bayliss and Starling (1899, 1901) to whose classical studies we owe most of our basic knowledge of intestinal motility, observed that the response of the small intestine to local stimuli consists of a contraction of the smooth muscle above and relaxation below the stimulated area. "Thus," they said, "is the law of the intestine." Since the contraction wave and the preceding inhibition usually travel down the intestine in an aboral direction from the stimulated point, Bayliss and Starling thought that intestinal peristalsis might consist simply of a succession of responses to stimuli manifesting the law of the intestine. In their opinion, a particular mass might give rise to stimulation resulting in contraction above the stimulated point with relaxation below and this would cause the mass to move aborally, in its new position it would also act as a stimulus and again cause contraction of the muscle above and relaxation below, again being

FIG 42.5 X ray photograph showing Miller Abbott tube in the small intestine

and Abbott (1934) may save the patient's life (see fig 42.5)

The cause of postoperative ileus was investigated by Cannon and Murphy (1906) and found to be reflex inhibition of motility through reflexes from the irritated peritoneum in which the splanchnic nerves were an essential part of the reflex path. They found that cutting the splanchnic nerves prevented the ileus. There was one exception to this finding, if the intestine itself was subjected to severe trauma, ileus ensued even with the splanchnics cut. Apparently, in this instance, the local nerve plexus serves as a pathway for the inhibitory reflexes. It has since been shown that intestinal paresis from a variety of causes (e.g., peritonitis) is relieved by spinal anesthesia, which is neurologically equivalent to splanchnic section.

Acute Intestinal Obstruction

Symptoms of intense severity result when the lumen of the small bowel is completely obstructed as a result of constriction by an adhesive band, kinking, twisting or pressure by new growth, intussusception, strangulation by a hernial ring, etc. The condition is ushered in by severe cramplike abdominal pain, vomiting and shock. If the condition is not relieved by operation, reverse peristalsis arises above the point of obstruction, intestinal contents passing into the stomach and the vomiting becomes fecal in character. Later the bowel above the obstruction loses its tone, becoming dilated and filled with intestinal secretions and gas. The loss of fluid in the vomitus and the drainage of large quantities of fluid into the

dilated bowel leads to a fall in blood chloride, alkalosis and dehydration (p. 24). Other blood changes are a rise in the nonprotein nitrogen and an increase in the fibrinogen content. The former is the result of tissue destruction combined with impairment of renal function. Great prostration occurs, ending in death.

EXPERIMENTAL OBSTRUCTION When the intestine of an animal is tied across, the symptoms which follow are chiefly weakness, prostration and vomiting. The animal shows little or no evidence that it is suffering pain. The higher in the intestinal tract the obstruction is made, the more severe are the symptoms, and the shorter is the duration of life after the operation. Following obstruction of the colon the animal may survive for some weeks, whereas after obstruction of the jejunum or duodenum it dies as a rule within five or six days. Reduction in blood volume (anhydremia) fall in blood chloride (see below), increased alkali reserve and nonprotein nitrogen of the blood, and a rise in the percentage of fibrinogen occur.

Paralytic ileus may be produced in dogs by the injection of a solution of iodine into the peritoneal cavity. It was shown by Markowitz and Campbell that the intestinal inhibition produced in this way could be abolished by spinal anesthesia which apparently blocked inhibitory impulses reaching the bowel through the splanchnic nerves (p. 723-725).

A CONSIDERATION OF THE CAUSE OF DEATH IN MECHANICAL OBSTRUCTION

A number of theories have been advanced in recent years in attempts to give an explanation for the symptoms and death in acute mechanical obstruction of the bowel. We may, at the outset, dismiss the possibility that death is simply the result of blockage of the alimentary tract, and the prevention of the passage of food along its lumen. It was shown originally by Stone, Bernheim and Whipple that if a few inches of the bowel were excised, both ends of the segment closed and the continuity of the digestive tract then re-established by an anastomosis of the cut ends of the bowel, death occurred even more rapidly than if the bowel had been obstructed by ligation. The survival time after the closure of such an isolated segment or loop is rarely more than 3 or 4 days and may be only 24 hours.

Toxic Theories

A bacterial theory in one or other of its modifications has had its adherents. The toxin of the

Welch bacillus has been suspected by some, but little support has been given by recent work to the belief that this or any other bacterial toxin is responsible for the symptoms. Others have thought that a toxic agent derived from the bacterial decomposition of protein within the intestinal lumen was the lethal agent. It is impossible to consider seriously any bacterial theory of intestinal obstruction, for such theories ignore the fact that the symptoms diminish in intensity, and the survival time is lengthened, the lower in the intestinal tract that the obstruction is produced. Bacterial growth, protein decomposition and histamine concentration on the other hand, are all greater in the lower than in the higher reaches of the intestinal tract.

The Dechlorination and Dehydration Theory

It was first shown by Hartwell and Hoguet (1912) that obstructed animals which survived for some days showed marked dehydration. Vomiting it was claimed, was responsible for the reduction in body water, the symptoms of obstruction and death were believed to be the direct consequence of the dehydrated state. They showed and their observation was confirmed by Haden and Orr and others that the life of an animal with an obstructed intestine could be prolonged by the subcutaneous or intravenous administration of saline.

That the loss of chloride in the vomitus may cause a profound fall in blood chloride and dehydration is an established fact. Hastings, Murray and Murray found that in dogs obstruction at the pylorus caused a reduction in the blood chloride to 50 per cent of the normal within a few days after the operation. Gamble and Ross confirmed this observation and made a more extended study of the changes in blood chemistry which follow pyloric obstruction. They consider that loss of chloride, by leading to a reduction in the electrolytes of the body, is the primary cause of the dehydration. They state that a withdrawal of the electrolytes of the body fluids will be accompanied by a proportionate reduction in the volume of body water and that this change can only be repaired by replacing both the lost water and the lost electrolytes. These observers showed that the loss of chloride in the vomitus is repaired for a time by the retention of carbon dioxide and the consequent increase in bicarbonate. By this means the concentration of electrolytes is maintained. In other words, the sum of (Cl^-) and (HCO_3^-) remains constant for a time (30 hours or so) after the obstruction has been

FIG. 42.6. Diagram to show change in the total content and distribution of electrolytes in the body fluids following pyloric obstruction (After Gamble and Ross.)

established. A degree of alkalosis, however, results which is countered by a loss of base (Na^+) in the urine, a reduction in $(Cl^-) + (HCO_3^-)$ occurs. The reduction in ionic concentration of body fluids resulting from the depletion of base which unlike Cl^- cannot be substituted for, is accompanied by a proportionate loss of water (fig. 42.6). The value of sodium chloride injections in prolonging life in obstructed animals depends chiefly upon the fact that the replenishment of the stores of sodium permits the retention of water. Chlorides such as NH_4Cl or KCl are without any beneficial effect, nor will water alone or a solution of glucose prolong life.

The reduction in the blood chloride is not necessarily the result of vomiting. The accumulation of secretions above the point of obstruction will just as surely cause chloride depletion and dehydration. In the rabbit for example, which cannot vomit, obstruction causes the characteristic blood changes. A most powerful stimulant to secretion is distension of the bowel wall, the dilated bowel in the later stages of obstruction thus becomes a receptacle for large quantities of fluid. In the case of the rabbit, fluid amounting to thirteen per cent or so of the body weight may be found in the stomach and bowel after death. The fatal effect of distension has been shown by Herrin and Meek. They distended a loop of bowel by means of a balloon and allowed the continuous secretion which resulted to drain to the exterior. The animals died in from 6 to 14 days. A loop of bowel

opening to the exterior but not distended causes no injurious effect. Herrin and Meek concluded that the loss of chloride in the secretions was the essential factor leading to the death of their animals. Dragstedt and Ellis have also shown that the profound fall in blood chloride which follows the drainage of the gastric juice to the exterior is accompanied by grave symptoms and ultimately ends in death. The symptoms are rapidly relieved by the administration of saline. Fine and his associates have reported a pronounced reduction in the plasma volume of patients suffering from acute obstruction of the small intestine.

There is no doubt that chloride loss and dehydration are important factors in the later stages of obstruction. The administration of saline is one of the most valuable measures possessed by the clinician for combating the condition at this stage either before or following operation.

Nevertheless, although the blood changes at this time undoubtedly prejudice the animal's chance of survival it is unlikely that they play the primary role in causing death. For one thing, correction of the blood chemistry, although it prolongs life, does not permit survival. Moreover, death frequently occurs before any significant change in the blood chlorides takes place, whereas on the other hand, the blood chlorides may be maintained at a level considerably lower than that usually seen in obstruction without the animal becoming ill. The following experiments¹ indicate a nervous element as the primary cause of the train of symptoms seen in acute obstruction. A balloon was placed in the lower duodenum and distended to a pressure of about 100 mm. Hg. A large sized rubber tube attached to one side of the balloon and extending into the bowel below prevented any actual obstruction. X-ray examination showed that a barium mixture moved freely beyond the distended region. These animals had symptoms indistinguishable from acute obstruction yet little fluid was lost by vomiting and the blood chlorides showed practically no change. On the other hand, otherwise normal animals who had had the blood chloride depleted by means of histamine injections (to stimulate gastric secretion) and apomorphine (to induce vomiting) remained in apparent good health even though the blood chloride had been maintained at a level 50 per cent below the normal for three weeks.

It is evident that in the balloon experiments just mentioned, distention of the bowel caused death in some way other than by chloride deple-

tion. Another group of animals in which the bowel was distended by a balloon as described, but in which the segment of bowel had been first denervated survived for a much longer time than those in which a preliminary denervation had not been performed. This result indicates that afferent impulses arising from the distended segment of bowel are concerned in some way with the severe symptoms of obstruction. Herrin and Meek also observed that if a distended draining loop were denervated the animals survived indefinitely. They, however, offer an explanation of the benefit derived from denervation based upon the theory that dechlorination plays the essential role, namely that when the vomiting and loss of appetite produced reflexly from the distended loop are abolished by nerve section, chloride loss is reduced and chloride ingestion increased. The importance of afferent impulses from the intestine in the production of the symptoms of obstruction therefore must be admitted, that they may cause death quite independently of dechlorination is undoubted. It is well known that many reflex effects upon the cardiovascular system and upon several important functions can be initiated from the gastrointestinal tract. The severe pain and collapse which result from the distention of other hollow viscera, e.g., the gall bladder, stomach, kidney pelvis, etc., may also be recalled in this connection. Moreover, the severe symptoms and early death which result from the mere distention of the bowel by a balloon calls to mind the analogous clinical condition known as Richter's hernia. In this condition only a portion of the intestinal lumen is pinched off and isolated from the main passage. The bowel is not obstructed, yet all the symptoms of acute obstruction are present. It is quite conceivable that acute distention of the small isolated pocket by secretions and gas is responsible for the symptoms.

The importance of distention as a factor in acute obstruction of the intestine is now generally recognized and it has become the practice in suitable cases to decompress the bowel by suction drainage through a tube passed from the mouth to the duodenum (Wagenstein and Paine) or as in the method of Miller and Abbott to insert a long slender tube through the nose into the stomach and allow it to be carried to the level of the obstruction. The tube has a double lumen and is provided at its tip with a small balloon which can be moderately inflated after it has entered the duodenum. The balloon serves as a stimulus to peristalsis which carries it and the tubing along the bowel to the point of obstruction (fig. 43.5).

¹ Taylor, Weld and Harrison.

The Ileocecal Valve (Valvula Coli)

This structure permits the passage of the contents of the small intestine at intervals into the cecum, but when competent hinders the return of the material into the ileum. Its ability to do this depends, according to one view, not upon any mechanical valvelike device, but upon the contraction of the circular fibers of the gut which are thickened in this region to form a sphincter guard for the ileocecal orifice. But, although a sphincterlike thickening of the circular muscle fibers is found in this situation, most anatomists agree that the competency of the ileocecal valve is mainly, or at least partly due to a valvelike construction. The ileum enters the cecum obliquely and in doing so invaginates the cecal wall, this alone would tend toward a valvelike action. The valve proper is formed as follows. As the lower end of the ileum enters the cecum, the invaginated portion of the cecal wall forms two transverse folds or lips, one above the other on the cecal aspect of the ileocecal orifice. The lips fuse laterally to produce a fold on either side of the orifice (*the frenula coli*) which are continued around the interior of the cecum. As the cecum distends the frenula are stretched and pulling upon the lips from either side draw them firmly together. Thus the valve can withstand a high pressure in the cecum but yields to a low pressure from above. Materials introduced by enema may in some instances pass through the valve into the ileum. Such incompetence may permit the enema fluid to reach the duodenum. The ileocecal opening has been observed in man through a cecal fistula. It appears as an oval or round opening from 2 to 3 cm. in diameter situated in the center of a small papilla. When tightly closed the valve was found to offer considerable resistance to the passage of the finger. While digestion was in progress the papilla was observed to flush, its color altering from a pale pink to a vivid red. The orifice opened rhythmically at frequent intervals and allowed a jet of fluid to escape into the cecum. Emotional excitement or the swallowing of food increased the frequency of the ejections (*gastroileal reflex*). During fasting nothing passed through for long periods, but in from $\frac{1}{2}$ to 4 minutes after food was taken into the mouth, fluid appeared in gushes of about 15 cc. every half minute or so.

The functions of the ileocecal valve appear to be (a) to prevent the contents of the ileum from passing into the cecum before the digestive processes have been completed, (b) to serve as a barrier which prevents the bacteria laden contents of

the large bowel from contaminating the small intestine.

Movements of the Large Intestine

The colon receives the mixed residues remaining after completion of intestinal digestion and absorption. These consist of undigested or undigestible food residues, whatever remains of the digestive secretions including considerable quantities of water, and the fluid that has been swallowed or secreted and has escaped absorption in the small intestine. The colon extracts the water from this mixture and forms the indigestible residues into fecal masses which are later evacuated. The motor activities are appropriate to these functions, they may be divided into two classes, first, those that appear to be designed primarily to facilitate absorption, second those concerned principally with propulsion.

Movements of the first type have been studied principally in experimental animals since the human colon does not lend itself readily to experimental study. Barcroft and Steggerda (1932) studied the exteriorized cecum and proximal portion of the colon in dogs. In their experiments the organ to be studied was brought out through an incision in the skin and after healing had taken place observations were made without anesthesia. They observed what they called kneading movements, antiperistalsis and mass peristalsis. The kneading movements seemed to them to resemble segmenting contractions in the small intestine, except that they occurred at a slower rate and involved longer sections of the intestine, they appeared at intervals of about one half minute. Antiperistaltic waves appeared when the colon became distended and followed each other at a frequency of 5 to 7 per minute. The "mass peristalsis" belongs to the second class of contractions and will be considered a little later.

Cannon (1902) studied the movements of the colon in cats by means of X rays. He noted that the characteristic movement of the transverse and ascending portion was antiperistalsis. He described what he called mass contractions of the cecum and ascending colon which forced material into the transverse colon from which it was driven back by antiperistaltic waves. This is obviously a stirring and mixing function and is not concerned with the transport of material in the aboral direction.

Templeton and Lawson (1931) studied the movements of the colon in dogs, using multiple balloons and manometers. With these they were able to determine the extent of the contractions,

if any, and whether they progressed and in what direction. They described three types of contractions which they designated as type I, type II and type III respectively. Type I movements were simple, rapid contractions and relaxations, frequently simultaneous over the three balloons but often confined to one balloon. These they considered to be stationary, rhythmic contractions. They are evidently analogous to the segmenting contractions in the small intestine. Type II are slower contractions on which type I movements were superimposed. Analysis indicated that these either swept analward, oralward, or remained stationary. They might start in one direction, become stationary, then move in the other direction. Antiperistaltic waves would be of this type but some were obviously peristaltic. Type III contractions are suggestive of the kneading movements described by Barcroft and Steggerda. Type III contractions were tone changes on which were superimposed type II contractions. They were apt to be in opposite phase in the proximal and distal colon and to increase in one region while decreasing in the other. These movements would result in a to-and-fro motion of the intestinal contents and are suggestive of Cannon's alternate mass contractions and antiperistaltic movements. Elliot and Barclay Smith (1904) observed antiperistalsis in the colon of the dog, cat, rabbit and rat.

Todd (1930) observed slow peristaltic movements in the cecum of human subjects when it was being filled with barium from the ileum. He described these as follows: "As the ileal coils

empty themselves, slow peristalsis taking place meanwhile, the outlines become better defined and the cecal peristaltic movement is plainly seen. The shadow of the cecum becomes denser as more contents are poured into it and slow massive movements occur, involving its entire outline. How they can drive the contents onward is altogether obscure but the dense barium shadow does progress upward." He also observed a "concertina like" action of the transverse colon, which he attributed to contractions and relaxations of the tenae.

In the rabbit and probably in other animals there are contractions of the haustra (which are the bulgings of the wall of the colon between the tenae). Alvarez (1940) describes these contractions as resembling "those of the jointed curtains of two roll top desks facing one another. First one top is pulled down and then the other."

To summarize this rather confusing mass of data it appears that the colon agitates its contents by means of segmenting contractions similar to those seen in the small intestine, haustral contractions in which the colonic walls roll back and forth over the contents, kneading movements in which fairly large segments can contract while adjacent segments are relaxing to be followed by contraction and relaxation in reverse phase, and finally, by means of alternate peristalsis and antiperistalsis. It should be pointed out that these movements occur principally in the ascending and transverse colon where absorption of most of the water takes place. It is not to be inferred that each type of movement occurs in every species of animal. We can only be certain that they occur in those species in which they have been observed. For example, antiperistalsis has rarely been observed in the human colon. In spite of the variety of movements described it is common to find no activity whatever on X-ray examination of the human colon. Templeton and Lawson observed that in spite of the presence of balloons in their animals periods of activity in the colon alternated with periods of complete rest.

The second class of movement consists of those which propel the colonic contents analward and includes colonic peristalsis and mass movements. Peristalsis of the colon has been observed by a number of investigators, beginning with Bayliss and Starling in 1901. It does not differ materially from peristalsis in the small intestine, except perhaps in frequency of occurrence. It consists of a contraction wave preceded by relaxation (Iuer and Kreuger, 1947) and its forward progress is dependent upon the integrity of the myenteric

FIG. 427 X-ray photograph of normal large bowel completely filled. (After Barclay.)

plexus The movement proceeds with great power, particularly in the descending colon, due perhaps to the hard dry character of the material to be moved. Auer speaks of seeing a hemostat with which the intestine was clamped, twisted apart by a peristaltic movement in the descending colon of the cat. Peristalsis is relatively rare in the human colon except in association with mass movements or during the act of defecation (Todd, 1930).

Mass movements occur at relatively infrequent intervals and, generally, in the past, have been confused with peristalsis, however Code and his coworkers (1954) have pointed out that these movements, although their propulsive nature has not been questioned, are not true peristaltic waves since they involve simultaneous contractions of large segments of the colon. Holzkecht (1909) (Fig. 428) was the first to describe these contractions and they were later studied in detail by Hurst (1907) and by Hertz (Hurst) and Newton (1913). The latter authors noted that they occur usually after a meal or on any occasion when the stomach is being filled with food. They described the increase in colonic motor activity following a meal as the *gastrocolic reflex*. Hurst later observed that the terminal ileum also became hyperactive following meals and proposed to call this phenomenon 'the *gastro-ileac*' reflex. Douglas and Mann (1940) found that the entire small intestine manifests increased motility under these circumstances and that the excitation is transmitted along the intestine, and not by way of the central nervous system. In any case, not only mass movements but all motor activities of the colon are increased at this time, for example, in the experiment of Barcroft and Steggerda, kneading movements and antiperistalsis were increased in dogs after feeding. Hurst remarked that the taking of food is the most powerful of all stimuli to the motor activity of the colon in man. He found that the feces advanced considerably after each meal, much more progress having been made in one patient for example, during the hours in which dinner was taken than in the previous four hours.

The mass movements of the colon serve to empty the contents of the proximal colon rapidly into the more distal portions. Frequently such movements are followed by a desire to defecate and it is assumed that on these occasions the movement has been vigorous enough to carry fecal masses into the rectum. Since normally a desire to defecate does not follow every mass movement of the colon it must be assumed that on some occasions the forward movement of the

FIG. 428 Holzkecht's diagrams of the happenings during a mass movement of the large intestine: 1, distribution of the food before any change was noted; 2, the haustral segmentation in the transverse colon has disappeared; 3, the whole colon beyond the hepatic flexure passes on suddenly; 4, it is again a picture of "still life" a few seconds later and the haustral segmentation has returned. (After Barclay.)

colonic contents stops short of the rectum. People differ considerably with respect to their susceptibility to the gastrocolic or gastroileac reflex. Alvarez (1940) describes a patient in whom every mass movement resulted in defecation. He found that even the sight or smell or taste of food induced the gastrocolic reflex, so that in walking down the street it was necessary for him to avoid passing in front of restaurants if he wished to avoid trouble.

DEFECATION

As pointed out by Hurst (1909) the rectum is normally empty. The fecal masses driven forward by the mass movements of the colon are stored, not in the rectum, but in the sigmoid or pelvic colon. Fecal matter does not collect elsewhere if defecation is regular, if, however, defecation is long deferred the descending colon becomes filled when the pelvic colon can hold no more. The desire to defecate occurs when, as a result of a mass movement, some feces enter the rectum. While the usual stimulus is the taking of food, a glass of cold water or smoking a cigar may have the same effect. Many people find that a glass of cold

orange juice or lemon juice and water is an effective stimulus to the gastrocolic reflex. The desire to defecate may be induced by straining efforts which may raise the abdominal pressure to as much as 200 mm of mercury and force feces into the rectum.

The act of defecation is in the adult, preceded by a voluntary effort consisting of assumption of an appropriate posture, voluntary relaxation of the external anal sphincter, and usually compression of the abdominal contents by means of straining efforts. These movements in turn prob-

FIG. 429 Diagram of the innervation of the stomach, small intestine and proximal part of the colon. ably give rise to stimuli which augment the visceral reflexes although these originate primarily in the distended rectum. As a result of these reflexes peristaltic waves appear in the entire colon (Hurst, 1909) and the internal anal sphincter relaxes. Peristalsis in the descending colon carries its contents into the pelvic colon which in turn transfers them into the rectum eventually to be evacuated by way of the anus, hence, the entire distal colon from the splenic flexure to the anus may be emptied at one time. A prominent mechanical feature of the final act of evacuation is contraction of the longitudinal muscle of the distal colon which is most pronounced in the rectum itself. The shortening of the distal colon tends to elevate the pelvic colon and obliterate the angle which it normally makes with the rectum. This straightening of the passage doubtless facilitates evacuation. Shortening of the rectum itself is an important factor in expelling the feces through the anal orifice.

The act of defecation provides another instance of a reflex that is under some degree of voluntary control. The voluntary regulation consists of the ability to inhibit the reflex under normal circumstances and to initiate it voluntarily provided the necessary visceral stimulus (recent distention of the rectum) is present. Reflex centers for defecation have been located in the hypothalamus, in the lower lumbar and upper sacral segments of the spinal cord, and in the ganglionic plexus of the gut. The intrinsic intestinal plexus of the lower colon is able to take over the function of controlling defecation even in animals in which the spinal cord has been destroyed. For this reason, in severe spinal injury, the defecation reflex suffers less than does, for example, the reflex of micturition.

THE COMPOSITION OF THE FECES According to Cantarow and Schepartz (1954) adults on an average diet excrete from 75 to 170 grams of feces daily, about 25 to 30 per cent of which is made up of solids, the remainder is water. If the diet is rich in vegetables the quantity is greater, especially if the vegetables are eaten raw. Bacteria comprise about one-third of the dry weight of the feces under average conditions. The pH is 7.0 to 7.5. The feces contain those inorganic substances which are relatively insoluble at alkaline pH ranges such as calcium phosphate and oxalate, iron phosphate and similar compounds. The organic material is principally cellulose, protein and fats. About half the protein nitrogen of the feces is of bacterial origin, the remainder represents unabsorbed intestinal secretions and digestive

fluids, mucus, and desquamated epithelial cells from the mucosa. Only a small amount is actual food residue. Enzymes are also present but in very small quantities; these are pancreatic amylase and trypsin, nucleases, maltase, sucrase, lipase and lysozyme. Fats comprise from 5 to 25 per cent of the feces under normal circumstances, they are greatly increased in conditions in which there is interference with pancreatic or biliary function. In total absence of pancreatic juice from the intestine as much as 90 per cent of the ingested fat may be excreted in the stools. Much of the fecal fat has undergone digestion as indicated by the following average composition of fecal lipids: neutral fat, 7.3 per cent of dry weight of feces, free fatty acids, 5.6 per cent, and soaps, 4.6 per cent.

The color of the feces is due chiefly to bile pigments, *stercobilin* (*urobilin*), produced by reduction of bilirubin by the intestinal bacteria. The characteristic odor is due largely to indole and skatole, but is contributed to also by hydrogen sulfide and other odoriferous substances.

GAS IN THE INTESTINE A variable amount of gas is always to be found in the small and large intestine, principally the latter. This consists of the respiratory gases—oxygen and carbon dioxide, nitrogen, methane, hydrogen and small amounts of other gases including the rare atmospheric gases. The average composition according to Pogrand and Steggerds (1948) is as follows: carbon dioxide, 7.5 per cent, oxygen, 3.0 per cent, methane, hydrogen and other rare gases, 9.5 per cent, and nitrogen, 80 per cent. The source of the oxygen, nitrogen and carbon dioxide is swallowed air and diffusion from the blood. Bacterial fermentation and putrefaction of food residues in the intestine produce the methane and hydrogen. No matter what the composition of swallowed air may be it quickly comes into equilibrium with the venous blood with respect to oxygen and carbon dioxide, and more slowly with respect to nitrogen; hence, the relative constancy of composition of intestinal gas with respect to these gases. The amount of putrefactive gas is much more variable. It is the rapid expansion of these gases that gives rise to intestinal cramps on ascending to high altitudes in an unpresurized plane. Some of this gas is absorbed into the blood and some escapes from the rectum as flatus. The amount in the intestine can be reduced by giving the subject pure oxygen to breathe. This reduces the partial pressure of nitrogen in the blood and thus favors diffusion of nitrogen from the intestine toward the circulating blood. Since nitrogen dif-

fuses very slowly it is necessary to continue the treatment over a long period of time in order to obtain any beneficial results. The same result could be obtained by using oxygen diluted with helium or other inert gas, as long as nitrogen is not present.

ABNORMAL COLONIC MOTILITY—CONSTIPATION

Abnormal motor activity in the colon is one of the most common conditions for which the physician may be consulted. The causes may be local only or they may involve systemic disease. Psychic factors are important and it can be safely asserted that no other part of the gastrointestinal tract is so profoundly affected by emotional disturbances as is the large intestine. This statement is supported by lay observation as well as clinical experience and also by experimental observations on suitable human subjects. It has been possible to demonstrate changes in tone, motility, or vascularity of the large intestine in response to experimentally induced emotional reactions. For example, in three children, four, nine and ten years old studied by Friedman and Soape (1946), changes in color and motility were observed during emotional excitement, mild, painful stimuli or even the suggestion of pain or discussion of unpleasant experiences caused blanching of the mucous membrane, the sight or smell of appetizing food caused reddening. During eating the mucous membrane was engorged, but returned to normal after the meal. These changes of course indicate constriction (blanching) or dilation (reddening) of the blood vessels. In two adults studied by Grace, Wolf and Wolff (1948), experimentally induced anger or feelings of guilt or resentment or of hostility caused hyperfunctioning of the colon, there was increased motor activity, increased blood flow, increased lysozyme production and increased secretion of mucus, acute fear caused pallor and relaxation. Increased motor activity and blood flow were also observed in

these subjects while they were eating a meal. During psychometric examination subjects also showed by perfunction of the colon.

The most frequent manifestation of malfunction of the large intestine is constipation. For a discussion of the various causes and the treatment of this condition, appropriate clinical texts should be consulted. It may be mentioned here that one of the most frequent causes of chronic constipation is neglect of the call to stool. The desire to defecate is experienced whenever the pressure within the rectum is increased. An increase in the volume of the contents of the rectum of from 15 to 25 cc has been shown to be sufficient to produce an urge. If the rectum is not emptied at such a time, the sensory mechanism becomes adapted to the pressure and the urge is no longer felt, it then requires a further increase in volume with a corresponding increase in pressure to produce a sensation. This will also pass if neglected and a still further increase in volume is required to arouse a sensation, finally the irritability of the rectum is so reduced that an urge is no longer induced. Usually the subject will then take a cathartic which further injures the sensory mechanism. Frequent repetition of this cycle results ultimately in dependence on cathartics. An important factor in the prevention or treatment of such a condition is the establishment of a conditioned reflex. Taking advantage of the gastrocolic reflex which follows a meal the subject selects a convenient time of day for going to stool, usually after breakfast. He then makes an effort to defecate at this time each day whether or not he gets the urge. In the beginning mild laxatives may be necessary to facilitate the establishment of the reflex but once it is thoroughly established they can be omitted. Such a conditioned reflex can become so firmly established that one feels the desire to defecate at a particular time of day whether or not a meal has been eaten.

The formation of indican

Conversion of tyrosine to tyramine cresol and phenol

Intestinal Intoxication

THE LARGE INTESTINE Several substances some intensely toxic in character are formed in the large intestine as a result of the decomposition of protein by the normal bacterial flora (colon type of organism). Among such putrefactive products are histamine, phenol, cresol, indole, skatole, ethylamine, isobutylamine, tryamine, etc. Choline is also formed as a result of the decomposition of lecithin, and choline gives rise to traces of neurine. Some observers impressed by the powerful actions of these substances when injected into animals, have suggested that their absorption into the general blood stream is responsible for many ills, and particularly for the well known symptoms of constipation. Metchnikoff (1907) arraigned the colon as the body's greatest enemy. Arruthnot Lane, in more recent times (1918), inveighed against this cesspit and recommended its extirpation under certain circumstances. No reliable evidence can, however, be cited to connect any of the toxic products mentioned with the symptoms of disease. Many of them are produced only in mere traces and even though some, such as indole, are produced in relatively large amounts (60 mg, according to Herter (1907), may be present in 100 grams of

feces) toxic doses are prevented from entering the systemic circulation by the barrier offered by the bowel wall and through the detoxicating action of the liver. Indole, for example, when given to the human subject by mouth in an amount (1 gram), which is more than would ever be present in the bowel at one time, produces no symptoms, 2 grams causes only some dizziness and slight headache, whereas large amounts may be introduced into the colon without ill effect. The slight absorption of indole and skatole under ordinary circumstances is indicated by the fact that although the feces contain considerable amounts of both these substances, the detoxicated product indican may be absent from the urine. On the other hand the ability of the liver to protect the body against these substances is shown by the observation that large amounts of indican are constantly present in the urine of certain individuals, showing that considerable quantities of the putrefactive products are absorbed, yet such persons enjoy good health.

Choline may be given by mouth with impunity, even when relatively large amounts (15 to 20 mg per kg. in the cat) are given intravenously, no toxic effects are produced. Since this substance is

rapidly destroyed in the blood stream, large amounts may be injected slowly over a period of time without noticeable effect.

Histamine, another powerful depressor substance was found by Meakins and Harington in minute amounts in the cecum but only insignificant amounts, they conclude, pass through the intestinal wall. Even after the introduction of a large dose into the small bowel only slight absorption was evident. Koessler and Hanke (1924) gave the amine by mouth in doses of 100 mg. to guinea pigs, there were no ill effects, and upon analysis of the intestinal contents 24 hours after the administration of this amount, less than 2 mg. were recovered. The chief protection against the toxic effects of histamine is apparently in the bowel wall itself. It has also been found by Weiss and associates that in the case of the human subject 20 mg. of histamine may be injected per hour without causing a depressor effect. 500 mg. given orally were inert.

According to Alvarez the symptoms of constipation—headache, furred tongue, foul breath, malaise, etc., are of reflex rather than of toxic origin. Afferent impulses set up from the wall of the overloaded rectum appear to be responsible. Distention of the rectum by inert material such as absorbent cotton has been shown to produce almost all the symptoms of constipation. In the dog, packing the rectum in this way causes a rise of some 10 mm. Hg in blood pressure which is maintained until the foreign material is removed.

The manifestations of constipation referable to the alimentary tract, namely, the loss of appetite, coated tongue and offensive breath are, according to Alvarez, probably due to small waves of contraction originating in the wall of the loaded bowel and travelling in a reverse direction over the small intestine, stomach and esophagus (p. 691). A strong argument against the symptoms of constipation being due to toxic absorption is the almost immediate relief which follows evacuation of the bowels—it would certainly take some time for the blood to be cleared of a poisonous material. Furthermore, in constipation the feces are relatively dry and hard, conditions much less, rather than more favorable to the absorption of putrefactive products. One should expect, indeed, that the latter would occur more readily during diarrhea. Apart from all the indirect evidence against a toxic element being concerned in constipation, is the positive fact that many subjects of the disorder, even though this is of a severe grade, do not excrete indican in the urine and, as mentioned above, other individuals who for some

unknown reason excrete large quantities remain free from symptoms.

There seems little doubt that toxic products of the bacterial flora of the large intestine are prevented from entering the systemic circulation in amounts that are pathologically significant.

THE SMALL INTESTINE The immunity of the body to auto-intoxication applies only to the large intestine. The small intestine is not equipped in the same degree to resist the passage of toxic products into the blood stream. Normally, however, the bacterial flora of the small intestine are quite different from those of the large intestine. The microorganisms (e.g., *Bacillus bifidus*) in the former situation have a fermentative action not a putrefactive action. Through their action upon carbohydrate, organic acids—acetic, butyric and lactic—are produced. The acid reaction of the ileal contents is unfavorable to the growth of the proteolytic bacteria. As long as the supply of carbohydrate material is adequate the microorganisms of the acid producing type flourish and any of the bacteria of the large intestine which may have invaded the small intestine are unable to gain a foothold. Under certain circumstances however, especially in infants, this does occur. In young children, in whom the protective power of the small intestine is even less than that of adults, a severe type of toxemia results, characterized by vomiting, diarrhea, dehydration, acidosis, fever, emaciation and great prostration.

Some believe that guanidine is the toxic product concerned in certain types of intestinal intoxication in infants. In intestinal disorders associated with the extension into the small intestine of the flora of the large, measures are directed toward encouraging the normal acid producing type of organism in gaining the upper hand. Carbohydrate is supplied, usually in the form of lactose, which passes farther down the intestinal tract than other sugars before it is absorbed. It has also been common practice to administer cultures of the fermentative type of organism such as that of sour milk—*Bacillus bulgaricus* (so-called as the result of the writings of Metchnikoff (1907) who attributed the health and longevity of the Bulgarian peasant to his drinking large quantities of sour milk). Today cultures of *Bacillus acidophilus*, one of the normal inhabitants of the small intestine, are usually employed. Ordinary antiseptics given with the view of inhibiting bacterial growth exert no appreciable effect, although certain sulphonamides are valuable for their bacteriostatic action.

Nervous and Hormonal Regulation of the Gastrointestinal Smooth Muscle

The gastrointestinal tract receives an abundant nerve supply via the autonomic nerves. In addition, it contains within its walls an elaborate plexus of interconnected ganglia. This is usually described as consisting of two plexuses, the *myenteric plexus* situated between the circular and longitudinal layers of the smooth muscle and the *submucous plexus* situated in the submucosa. Kuntz (1953) considers that this is an artificial division and that actually the plexuses function as a unit. Langley (1921) suggested that the enteric plexuses should be regarded as a separate subdivision of the autonomic nervous system and proposed that they be designated the "enteric nervous system." He wrote as follows: "This classification is, I think, advisable for the central connection of the enteric nerve cells is still uncertain and evidence has been obtained that they have automatic and reflex functions which other peripheral nerve cells do not possess. Functional evidence for reflex activity in the enteric nervous system has been available since the work of Bayliss and Starling." In 1922 Kuntz presented anatomical evidence of the existence of reflex arcs in the enteric plexuses. Understanding of the fact that the enteric plexuses constitute a complex and highly coordinated reflex mechanism is essential to an intelligent interpretation of the effects of the extrinsic nerves on intestinal smooth muscle.

EXTRINSIC NERVES

The autonomic nerves are classified as sympathetic and parasympathetic but it is more in keeping with modern thought to consider them as cholinergic or adrenergic depending upon whether they liberate acetylcholine or an adrenalinlike substance at their final terminations on the muscles. In this sense most parasympathetics are cholinergic and sympathetics are adrenergic, but there is considerable mixing since cholinergic fibers have been demonstrated in considerable abundance in the sympathetics.

The parasympathetic nerve supply to the gastrointestinal smooth muscle comes mainly from the vagus, however, the pelvic nerves supply the distal portion of the colon. The parasympathetic fibers, whether vagus or pelvic in origin, do not end directly on the smooth muscle cells but end by making synapses with cells in the enteric plexuses. Therefore, as pointed out by Carlson (1922), they stand in relation to these plexuses

FIG. 42.10 Diagram of the innervation of the distal colon.

FIG. 42.11 Upper, shows the inhibitory effect of splanchnic stimulation upon the movements of the small intestine, the heavy white line indicates the time during which the stimulus was applied (after Starling). Lower, shows effect upon intestinal motility of stimulating vagus nerves (After Thomas and Kuntz).

as intercalated or internuncial fibers between reflex centers and not as ordinary motor nerve fibers. The function of such fibers in the central nervous system and presumably in this situation also, is to increase or decrease the excitability of the reflex centers and not directly to initiate muscular activity.

The sympathetic supply to the stomach and small intestine is by way of the splanchnic nerves. The cecum, appendix and ascending and transverse colon are supplied by nerves which arise from the superior mesenteric plexus. These nerves include both vagus and sympathetic fibers. The descending colon and upper part of the rectum are supplied by nerves which arise from the inferior mesenteric plexus. This plexus is a derivative of the aortic plexus through which it also receives vagus fibers from the celiac plexus. The lower part of the rectum is supplied by sympathetic fibers which arise from the upper and lower divisions of the hypogastric plexus (Kuntz, 1953). The preganglionic sympathetic fibers end in the celiac, superior or inferior mesenteric, or aortic ganglia. The fibers that reach the intestine, therefore, are postganglionic. They probably have no functional relation to the enteric plexuses even though they traverse the enteric ganglia and are distributed along with the postganglionic enteric plexus fibers. Most of them are concerned with the vasomotor supply of the numerous blood vessels in the intestine but some go to the intestinal smooth muscle.

THE FUNCTION OF THE EXTRINSIC NERVES The gastrointestinal tract is capable of carrying on its major functions after all the extrinsic nerves have been severed. This automaticity may be attributed partly to the local nervous mechanism and partly to the properties of the smooth muscle. Probably the essentially rhythmic functions, such as gastric peristalsis, segmentic contractions of the small and large intestine, and antiperistalsis in the colon are dependent upon the properties of the smooth muscle, whereas the more highly coordinated functions such as forward peristalsis in the small and large intestine are dependent upon the functional integrity of the myenteric plexus. Both the neurogenic and myogenic functions are regulated through central nervous system reflexes by way of the autonomic nerves.

The tone and peristaltic activity of the stomach is usually increased on stimulation of the vagus nerves. The statement that the vagus increases the activity of the muscle in the gastric wall while inhibiting the sphincters has been

proved to be an error, when motor effects are observed in the muscle of the pyloric portion, for example, the pyloric sphincter responds in the same sense, thus the idea of a reciprocal innervation of the sphincters and the other muscle of the stomach is not borne out by the experimental facts (Thomas and Wheelon, 1922). There may be somewhat more justification for such a concept in regard to the relation between the esophageal and cardiac sphincter but in order to demonstrate inhibition of the cardiac sphincter by vagus stimulation Langley found it necessary to first atropinize the animal so as to paralyze the motor fibers.

The effects on the stomach of stimulating the splanchnic nerves is usually described as inhibitory but it is far from being invariably so. In simply acute experiments on anesthetized animals increased motor activity is seen about as frequently as inhibition on stimulation of the splanchnic nerves, indeed only motor responses are seen unless care is taken to permit full recovery from the shock of the operation and to avoid undue handling of the viscera while making the preparation. The fact is as Carlson and his associates (1922) pointed out, that motor responses are more likely to be obtained when the muscle is in a state of relaxation, whereas inhibitory effects occur when the muscle is in a state of high tonus or vigorous activity. This rule applies to both vagus and sympathetic stimulation, nevertheless with the muscle in a medium state of tonus the vagi will more often produce excitatory effects and the splanchnics inhibitory effects. The reason for the preponderance of sympathetic motor effects in recently anesthetized, operated animals is that the stomach in such circumstances, is always in a state of very low tone.

In the small intestine the parasympathetic nerves are nearly always excitatory and the sympathetics nearly always inhibitory, however the excitatory vagus effect, as mentioned previously is usually preceded by a brief inhibition. In the upper portion of the small intestine motor effects from stimulation of the sympathetic nerves are by no means uncommon. The tonus rule holds here also, motor effects are more apt to be observed in the relaxed intestine.

In the large intestine, stimulation of the parasympathetic innervation is reported to cause mainly increased activity, whereas stimulation of the sympathetic nerves gives results that are even more confusing than those obtained in the stomach. Some investigators report only in

hibitory effects, others report only motor effects whereas still others report inhibition of the walls of the viscera with contraction of the sphincters. There seems to be somewhat more basis for this last concept in the large intestine than in the case of the stomach. The sympathetic tends to cause retention of contents, for example in the rectum, through contraction of the internal anal sphincter and relaxation of the rectal walls, the parasympathetics tend to promote evacuation of contents by causing relaxation of the sphincters and contraction and propulsive motility in the walls. Here also muscle in high tonus tends to respond to nerve stimulation with relaxation, whereas muscle in low tonus tends to respond with contractions.

The effects of stimulating the autonomic nerves is confusing if one attempts to classify them simply as excitatory or inhibitory to the smooth muscle. It is much more understandable if we bear in mind the fact that at least the parasympathetic nerves serve merely to increase or decrease the excitability of the local reflex mechanism. Although it is true that stimulation of either vagus nerve generally increases the activity of the gastric and intestinal smooth muscles, in inhibitory effects have been observed. Brief inhibition regularly precedes contraction in the small intestine following vagus stimulation (Bayliss and Starling, 1899), inhibitory effects are also seen occasionally in the stomach. The varying responses to parasympathetic stimulation may be interpreted as being due to the vagaries of the enteric reflex arcs which are subject to stimuli from many sources. The vagus impulses, being only one of these sources, could not be expected always to determine the response. The responses to sympathetic stimulation are undoubtedly influenced by changes in the blood supply brought about by the vasomotor fibers which always accompany the nerves to the intestinal smooth muscle, but mixed responses are obtained even in excised, bloodless preparations so we must assume the existence of fibers leading to both excitatory and inhibitory nerve endings.

Visceral Reflexes

While studying the effects of electrical stimulation of autonomic nerves it is well to bear in mind the fact that nerves were not developed for the purpose of being artificially stimulated. Under normal circumstances the autonomic nerves serve only reflex functions and when aroused normally through their reflex connections they may produce effects quite different from those seen on electrical

stimulation. Normal reflex stimulation is selective, exciting only those fibers which will promote the function subserved by the reflex, whereas ordinary electrical stimulation excites all the fibers without regard to their normal function.

Certain gastrointestinal reflexes involving the peripheral autonomic nerves have already been mentioned, among these are the receptive relaxation of the stomach, the enterogastric reflex, and the so called gastrocolic reflex. These reflexes chiefly involve the parasympathetic nerves and are concerned with regulation of the normal functioning of the gastrointestinal smooth muscle. Other reflexes have been described which occur only under unusual circumstances and generally involve the functioning of the sympathetic nerve supply. One of these is the *intestino-intestinal inhibitory reflex*. This consists of reflex inhibition of the whole intestinal tract as a result of distention of some one segment. The stomach may also be inhibited but in this case we are dealing with a mechanism different from the enterogastric reflex previously mentioned. The reflex is abolished or greatly diminished when the splanchnic nerves are cut, hence it involves discharge of impulses over the sympathetic nerves. It probably belongs in the category of responses to noxious stimuli which, generally throughout the body, tend to cause increased activity of the sympathetic nervous system and to inhibit gastrointestinal motility. Other examples of reflex responses to noxious stimuli are inhibition of the intestine due to irritation of the peritoneum, distention of the gall bladder and bile ducts, overfilling of the bladder, or forcible stretching of the anal sphincters. All of these stimuli produce inhibition of the gastrointestinal smooth muscle through activation of adrenergic mechanisms, mainly the sympathetic nerves.

VISCERAL SENSATIONS

True and Referred Pain

The abdominal and thoracic viscera are insensitive to the several types of stimuli which readily arouse sensations in the skin and more superficial tissues of the body. The effects of the different varieties of stimulus—*thermal, chemical, tactile and pain*—have been investigated by a large number of observers.

Sensations of pain cannot be elicited from the viscera by the *usual means*. The intestine or the liver, the stomach or the heart may be cut, burned or pinched without arousing any immediate sensation. In the second stage of a colostomy operation, for example, the colon can be opened without pain being experienced by the patient. Harvey remarked upon the absence of sensation in the exposed heart of Viscount Montgomery.¹

☛ The insensibility of the alimentary tract to ordinary forms of stimulation commences in the lower or middle third of the esophagus and extends as far as the commencement of the anal canal. How can these observations be reconciled with the well known fact that pain is one of the commonest manifestations of visceral disease?

The whole subject of pain arising in or referred from the viscera is still highly controversial. No final answer can be given. The most that can be attempted is a summary of some of the more significant experimental results and clinical observations, the opinions of those who have especially interested themselves in the subject.

☛ Lennander considered that abdominal pain was always due to the stimulation of somatic nerve terminals in the parietal peritoneum or root of the mesentery, the bowel itself was supposed to be quite devoid of pain fibers. According to this view

¹ Harvey records "I carried the young man to the King (Charles I) that His Majesty might with his own eyes behold this wonderful case, that, in a man alive and well, he might, without detriment to the individual, observe the movement of the heart, and with his proper hand even touch the ventricles as they contracted. And His Most Excellent Majesty, as well as myself, acknowledged that the heart was without the sense of touch, for the youth never knew when we touched his heart."

therefore, pain localized within the organ itself—*true visceral pain*—was an impossibility. ✓

Ross's theory postulated that pain from the abdominal viscera was of two types (a) *referred (somatic) pain*, and (b) *true visceral or splanchnic pain*, which was diffuse, poorly localized but felt in the viscus itself.

Mackenzie, as a result of his clinical observations, strongly supported Ross's idea of referred pain, but maintained that *all* visceral pain was of this nature, the viscera being quite insensitive to all forms of stimulation. In agreement with Lennander, he did not believe that the viscera contained pain fibers, true visceral pain, i.e., pain in the organ itself, was therefore never experienced.

CONCEPTION OF REFERRED PAIN ACCORDING TO ROSS AND MACKENZIE

When a viscus is diseased, pain or tenderness is frequently felt in the tissues overlying it approximately (abdominal or chest wall) or in some part quite remote from it. For example, pain is felt in the neck or shoulder (fig. 43 1) in conditions affecting the diaphragm, between the scapulas in gastric disease, in the region of the umbilicus in appendicitis, in the testis in renal colic and in the sternal region or down the left arm in angina pectoris (ch. 28). When traction is made upon a coronary artery of a dog, the animal whines and indicates the location of the pain by limping on the left forepaw. In dextrocardia anginal pain is felt in the right arm. Other examples are, the pain in the perineum and tip of the penis caused by a stone in the region of the neck of the bladder, and the pain in the groin due to a stone in the ureter.

It will be recalled (ch. 65) that a given spinal segment supplies a visceral area with autonomic nerve fibers (afferent and efferent) and also a well delimited area of the skin (dermatome) with somatic nerves. The two types of structure linked in this way through the afferent nerves and the central nervous system may be some distance apart (e.g., diaphragm and shoulder) or be more closely related (e.g., area of abdominal wall and

FIG 43.1 Location of maximum points of referred neck pain from irritation of the diaphragm. The figures refer to the number of stimulations in each instance. They are all situated in the region supplied by the third and fourth spinal segments (After Capps)

an underlying abdominal viscus) Mackenzie believed that afferent autonomic impulses arising in a diseased organ although of themselves in capable of arousing any sensation would upon entering the spinal cord set up an irritable focus with the result that cells accustomed to receive impulses from the corresponding somatic area were excited. Thus the impulses from the viscera spread or irradiated on to cells of the corresponding somatic center. New impulses originating in these cells travelled along the usual paths to higher perceptive centers (thalamus) which projected or referred the sensation to the somatic area e.g. skin or muscle from which it was accustomed to receive impulses. In this way, *spontaneous pain* in superficial structures remote from the diseased site was accounted for. Mackenzie spoke of these reactions as *viscero-sensory reflexes*.² Tenderness to touch, pressure or light pinching of the skin (hyperesthesia and hyperalgesia) was ascribed to the impulses which ordinarily would be below the threshold for pain arriving in the segment rendered hyperexcitable as a result of impulses received from the diseased organ. In the case of the abdominal viscera Mackenzie claimed that the area of tenderness in the abdominal wall remained fixed although the position of the diseased organ changed thus indicating the referred nature of the pain. He explained the rigidity (hypertonus) of muscles overlying a diseased organ, the right rectus abdominis

² This is obviously a most unsuitable term for it is not a reflex in the ordinary accepted sense of that word.

FIG 43.2 Diagram to illustrate Mackenzie's theory of referred pain. A, representing normal conditions a visceral reflex is shown. B illustrates a visceromotor and a viscerosensory reflex. Impulses from a viscus are conceived as setting up an irritable focus in the cord which through the involvement of neighboring neurons increases the tone of muscles innervated by the same segment and causes a discharge of impulses over the pathway for pain. The sensation is then projected in consciousness to the periphery as indicated by the dotted line.

in acute appendicitis for example upon a similar basis. Afferent impulses of normal intensity arising in the muscle proprioceptors upon arriving at the spinal centers which had been rendered hyperexcitable by the receipt of abnormal visceral impulses resulted in a reflex increase in tonus of the corresponding muscles. The referred motor reaction he spoke of as a *visceromotor reflex* (see fig. 43.2).

The conception of referred pain was supported by the work of Head who mapped out the segmental distribution of the cutaneous nerves responsible for hyperalgesia in diseased states and showed that they came from the same segments as received autonomic fibers from the diseased organ.

In table 43.1 are given the segmental areas to which pain is referred in disease of various viscera (Head).

TRUE VISCERAL (SPLANCHNIC) PAIN

True visceral pain although denied by Mackenzie exists. The pains of dysmenorrhea or childbirth for example or the pain of intestinal colic or of an overdistended bladder or the substernal pain of coronary occlusion although diffuse seems to arise in the organ itself even when referred as well to a somatic structure such

TABLE 43 1*

Viscus	Spinal Segments
Lungs	1-7 dorsal mostly 2-5 dorsal
Heart	3-5 cervical, 1-8 dorsal, predominantly on left side, sometimes bilateral
Esophagus	Mainly 5 dorsal, also 6, 7 and 8 dorsal
Breast	4 and 5 dorsal
Stomach	7, 8 and 9 dorsal, usually bilateral
Intestine	9-12 dorsal, bilateral or on left side only
Liver	8-10 dorsal on right side
Gall Bladder	Mostly 8 and 9 dorsal, also 5-7

Ovary	10 dorsal
Fallopian tubes	11 and 12 dorsal
Uterine cervix	11 and 12 dorsal and 1-4 sacral
Uterine body	10 dorsal to 1 lumbar

* From W. R. Brain, Diseases of the Nervous System, after Head

as muscle or skin. Kinsella observed that, in conscious patients, pressure with the fingers upon an inflamed appendix caused pain centered in the viscus; a healthy appendix is insensitive. He and others have also shown that a chronic duodenal ulcer is also tender to direct contact. In transection of the cord at the third thoracic vertebra in a patient (reported upon by Kinsella) in whom there was complete paralysis and anesthesia of the abdominal wall, intestinal pain was experienced, which obviously could not be caused by reference to somatic nerves. Impulses in such cases must reach the central nervous system along intact visceral afferents. They travel apparently by sympathetic fibers which enter the cord above the level of the transection. It is unlikely that they are transmitted by the vagus.

Pain in a normal viscus may also result from disease in a distant organ through a visceromotor reflex. Painful pylorospasm, for example, may accompany disease of the appendix. A distinction should be drawn between pain of this nature and referred pain.

The Adequate Stimulus for True Visceral Pain

The existence of true visceral pain is not incompatible with the statement made above that the viscera are insensitive to the ordinary types of stimulus. From his investigations Hurst concluded that the only adequate stimulus for visceral pain fibers is tension. Distention of a hollow viscus, e.g., stomach, intestine, gall-bladder, etc., gives rise to pain as a result of the stretch stimulus applied to the nerve terminals in its wall. The pain is roughly localized to the viscus itself, or referred. Under certain circumstances chemical substances produced in an ischemic organ, as in angina pectoris or intermittent claudication, may stimulate nerve fibers subserving pain.

Although the question is by no means settled, it appears that contraction of the muscular wall of a hollow viscus, such as the intestine, does not cause pain unless the movement of the bowel makes traction upon the mesentery. Pain arises, however, if the contraction causes distention of a neighboring portion of the wall as may result when the contraction wave approaches a mechanical obstruction, a length of bowel in spasm or a sphincter which fails to relax (achalasia). Poulton, for example, found that when a balloon was inserted into the lower part of the human esophagus, the approach of a peristaltic wave toward the obstruction caused pain, but during its passage over the esophageal wall in contact with the balloon no sensation was felt. Poulton ascribes the absence of pain during the passage of the contraction wave to the reduction in the diameter of the tube and the consequent release from stretch of the nerve endings lying between the muscle fibers. Pain was also relieved if the esophageal muscle relaxed to accommodate the balloon, that is, adjusted the length of its fibers to the distending force (see p. 695). As further evidence for the effectiveness of distention in causing pain the following observations may be cited. In animals, when an intestinal loop exposed under local anesthesia is stimulated to powerful contraction, there is no evidence of pain, whereas even moderate distention of the loop (as by inflating it with a balloon) is manifestly painful. Distention of the gall bladder of the cat is accompanied by reactions indicative of intense pain. Distention of the human appendix by the injection of fluids through an appendicostomy opening causes severe pain in the epigastrium or in the region of the umbilicus, and when the duodenum is distended by the injection of material through a duodenal tube, pain is felt on the

right side. The pain impulses undoubtedly reach the central nervous system through the splanchnic nerves. Bentley and Smithwick distended the duodenum of patients whose splanchnics had been divided on one or on both sides. After unilateral denervation, distention caused pain on the unoperated side only, no pain whatever was felt after bilateral splanchnic section.

MORLEY'S THEORY OF THE PARIETAL ORIGIN OF REFERRED ABDOMINAL PAIN

Morley contends that the referred pain of abdominal disease does not involve visceral afferents (as postulated by Mackenzie) but is due to the stimulation of somatic pain fibers in the parietal peritoneum or mesentery, the sensation being referred to the superficial area innervated from the same spinal segment. He expresses what he terms the *law of referred pain* in the following words: *Referred pain only arises from irritation of nerves which are sensitive to those stimuli that produce pain when applied to the surface of the body*, that is by the stimulation of somatic sensory nerves. He believes that the somatic innervation of the peritoneum extends along the mesentery to within a short distance of its attachment to the bowel and does not terminate as has been generally supposed near the root of the mesentery. The mesentery or peritoneum is therefore sensitive to tearing, cutting, etc., whereas the organ itself which contains only visceral afferents is insensitive to these types of stimulus. In support of his views Morley cites the pain in the shoulder associated with irritation of the peritoneal covering of the diaphragm. He points out that the diaphragm is innervated (through the phrenic) chiefly by the fourth cervical spinal segment and to a less extent by the third and fifth. None of these segments gives rise to autonomic fibers but the third and fourth cervical nerves furnish somatic afferent fibers to the shoulder area in which the referred pain of diaphragmatic disease is located. Morley explains muscular rigidity in a similar manner—the radiation of impulses over the motor nerves. He replaces

*Sheehan has made a study of the nerves of the mesentery and finds the following types of fiber: (a) Fibers ending in Pacinian corpuscles scattered throughout the mesentery. These are afferent sympathetic fibers which travel in the splanchnic nerves. (b) Free nonmyelinated fibers. These are afferent and efferent sympathetic fibers; their terminals are distributed to the serous covering of the bowel. They provide a medium for the transmission of true visceral pain. (c) Free myelinated fibers derived presumably from somatic nerves. These apparently do not extend as far as the serous covering of the bowel itself.

FIG 43.3 Diagram to illustrate Morley's theory of peritoneocutaneous radiation and peritoneomuscular reflex. M muscle, P peritoneum, S skin. After Morley, redrawn.

Mackenzie's terms, viscerosensory and visceromotor reflexes by *peritoneocutaneous radiation* and *peritoneomuscular reflex* respectively. Morley also recognizes spontaneous true (unreferred) visceral pain resulting from an adequate stimulus—namely tension. The pain and tenderness that result from pressure upon an inflamed viscus (e.g., ulcer of the duodenum) through the abdominal wall, and that seems to arise in the organ itself, he ascribes however to the parietal peritoneum being brought into contact with the roughened surface of the lesion. As evidence that the sensation is not, in such instances, referred to the skin from the diseased structure, but is due to the stimulation of nerves in the parietal peritoneum, he states that (a) the area of tenderness shifted with the movement of the viscus and (b) direct pressure upon the inflamed organ when exposed by operation in a conscious patient (i.e., under local anesthesia) did not give rise to any sensation (see fig. 43.3).

Morley has made out a case for the production of pain in some instances through a peritoneocutaneous reaction, and for pain and tenderness upon pressure being the result of the stimulation of somatic nerves in the parietal peritoneum. But his views cannot be accepted in their entirety. Others have reported that a duodenal ulcer is tender to direct touch and there is no doubt that referred pain can be brought about through the mediation of either visceral or somatic nerves. Woollard and Carmichael, for example, have obtained evidence for the latter from experiments upon the human testis which, since it has migrated from the abdominal cavity and is enveloped by peritoneum, may be looked upon as an abdominal organ, in so far as the question

of referred pain is concerned. These observers found that after all the nerves to the testis had been blocked by means of novocaine, except the autonomic fibers passing along the spermatic artery, no sensation was felt within the organ when it was compressed, but pain referred to the tenth dorsal segment—lower abdomen and back—was experienced. The observation of Bentley and Smithwick, mentioned above, point in the same direction.

THE VIEWS OF LEWIS AND KELGREN

Lewis and Kelgren postulate a common system of afferent nerves supplying deep somatic structures as well as the viscera. They maintain with good reason that since referred pain can follow the irritation of either visceral or somatic afferent nerves, there is no physiological justification for making a distinction between pain referred from a viscus and that referred from the parietes, nor between the motor reactions (e.g., muscular rigidity) resulting from stimulation in either situation. Although in the first instance visceral afferent fibers are stimulated, and in the second it is somatic sensory nerves, the impulses in either case enter the spinal cord by the posterior nerve roots, and the nerve fibers which transmit them have their cell stations in the posterior root ganglia. There is no indication that they do not follow identical paths in the central nervous system. Thus impulses from a viscus or a deep somatic structure cause a sensation which in either case is projected to a part remote from that stimulated but innervated by the same spinal segment. The pains whether referred from a viscus or from part of the soma, have common characteristics, being diffuse and poorly localized.

Lewis and Kelgren carried out experiments on a number of human subjects, their results are highly significant to the question of referred pain. Pain closely resembling in character the referred pain of visceral disease was induced by the injection of a small quantity (0.3 cc.) of hypertonic saline into an interspinous ligament at various spinous levels. Injection into the first lumbar interspinous ligament caused pain distributed in a manner strikingly similar to the pain of renal colic, namely, in the loin and in the inguinal and scrotal regions. The pain was accompanied by retraction of the testis. Injection into the ninth thoracic interspinous ligament caused pain in the back in the region of the first lumbar spine and over an area in front extending from the ninth costal cartilage on the affected side to the umbilicus. Rigidity of the abdominal muscles and deep tenderness were associated with the pain. Stimulation of the eighth

cervical ligament was followed by pain in the interscapular region, over the pectoralis major muscle and down the inner side of the elbow and fore arm, together with a sensation of constriction in the upper part of the chest on the stimulated side. Several subjects of angina pectoris were chosen for experiment and were asked to compare the pain which they experienced in an attack with that caused by the stimulation of the seventh cervical or the first thoracic interspinous ligament. In all instances the patients described the experimentally induced pain as being identical in character with that caused by the disease, although it showed some minor differences in distribution.

Lewis and Kelgren also found that in cats mechanical stimulation (pinching) of the pancreas or of the mesentery in the duodenal loop caused motor reflexes from the abdominal muscles which resembled closely those caused by stimulation of the back muscles.

AN EXPLANATION OF REFERRED PAIN ON THE BASIS OF REFLEX VASOMOTOR CHANGES (VISCEROSOMATIC REFLEX) OR THE LIBERATION OF A CHEMICAL SUBSTANCE AT SOMATIC NERVE ENDINGS

Pollock and Davis stimulated the peritoneal surface of the diaphragm in dogs. The animals showed every sign of suffering pain, which was abolished by any one of the following procedures: Section of the phrenic nerve; removal of the cervical sympathetic chains, severing the eighth cervical and the first, second and third thoracic anterior roots; transection of the cord at the seventh cervical segment, destroying the cord at the first and second dorsal segments; or section of the cervical posterior roots. Pollock and Davis conclude from these results that the pain impulses following stimulation of the diaphragm travel over the phrenic, enter the cord by the posterior cervical roots, descend the cord to the level of the eighth cervical and first, second and third thoracic segments. Connections are then made with cells in the lateral horn of gray matter (intermediate lateral column) from where impulses pass by sympathetic preganglionic fibers to the cervical sympathetic chain and then by postganglionic fibers—effectors in the skin, blood vessels, meninges and other structures where by some vasomotor (?) or hormonal (?) process the sensory endings of the cerebrospinal system are stimulated and a sensory impulse travels over the ordinary cerebrospinal system, enters the spinal cord by the posterior roots and ascends to consciousness. The pain and cutaneous lesions of herpes zoster come to mind in this connection.

The diffuse character of deep pain in contrast to the accurate localization of cutaneous stimulation can be accounted for by (a) the existence of

relatively few afferent fibers in deep structures, (b) the lack of experience and training in the localization of sensations from the viscera since such are normally felt very infrequently and (c) when impressions from the internal organs do occur their localization is not aided by sight as in the case of more superficial sensations. However, in experiments with intelligent subjects having some knowledge of anatomy, and in whom pain was evoked by inflating balloons inserted into hollow viscera the subjects' sense of localization was much improved above the ordinary

The Sensibility of the Alimentary Tract to Tactile, Thermal and Chemical Stimulation

Touch The sensation of touch disappears at the lower end of the pharynx. This was shown by Hurst by means of an esophageal tube with a slit on one side through which the mucosa of the esophagus could be stimulated. Carlson by means of a test tube brushed passed into the stomach was unable to elicit the sensation of touch from the gastric mucosa. The rectum possesses no tactile sensibility but the anal canal is sensitive.

Thermal sensibility The esophagus is sensitive to extremes of heat and cold. The sensations of temperature that are felt when hot or cold materials enter the stomach have been thought by some to originate in the lower end of the esophagus by others to arise in the skin of the epigastrium either through thermal conduction or by reflex changes in the cutaneous blood vessels. Carlson has shown however that the gastric mucosa is sensitive to extreme temperature changes (i.e. protopathic thermal sensibility (below 13°C or above 45°C)). It is the lower end of the esophagus however which is responsible for the greater part of the thermal sensation that is experienced when excessively hot or cold materials are swallowed. This is due to the greater sensitivity of the esophageal mucosa as well as to the fact that the material is retained for an appreciable length of time above the cardia. The colon is insensitive to temperature changes but even comparatively slight differences in temperature can be detected in the anal canal.

Chemicals with the exception of alcohol cause no sensation whatever when introduced into the stomach or intestinal canal. The mucosa is completely insensitive to acids; the introduction into the healthy stomach of a solution of 0.5 per cent hydrochloric acid causes no pain or sensation of any kind. Alcohol stimulates the mucosa of the esophagus and stomach and causes a sensation of warmth. Peppermint and various condiments free from alcohol arouse no sensation. The pelvic colon and rectum show a similar sensitivity to alcohol but are insensitive to other chemicals. The anal

canal is extremely sensitive especially to alcohol and glycerine. Both cause a burning sensation.

Nausea

Nausea usually precedes the act of vomiting (p. 701) but may occur alone. On the other hand vomiting may occur without nausea, as in certain cerebral conditions. The sensation is felt in the back of the throat or pit of the stomach, and in its milder degrees is merely a sinking sensation in the epigastrium. It is frequently associated with vasomotor disturbances and sweating. Increased tension upon the walls of the stomach or duodenum is a potent cause of the sensation and Poulton has shown that it is also induced by distention of the lower part of the esophagus. During the passage of a peristaltic wave which relieves the tension upon the nerve fibers in the esophageal walls the sensation is relieved. Barclay showed by radioscopy in the human subject that nauseous odors caused the lower border of the stomach to descend an inch or two evidently as a result of sudden relaxation of the abdominal muscles. This movement would tend to stretch the esophagus and gastric walls and so exert tension upon the nerve endings. The stimulus which induces nausea is, therefore, the same apparently as that which causes visceral pain but of lower intensity. It is likely that the sensations experienced during changes in speed of an elevator are also the result of tension exerted upon the esophagus and gastric walls. This element is also probably a contributory factor in the production of seasickness being brought into play by the pitch and roll of the ship.

The relief of nausea and vomiting by the application of counter irritants to the epigastrium or over the sternum is probably due to either a reflex change in the tone of the gastric walls or to the reflex initiation of peristaltic contractions. The tension upon the nerve endings in the latter instance is taken up by the muscle fibers. Poulton observed for example that the sensations caused by a balloon in the esophagus were relieved by vigorous friction of the skin over the sternum. Contraction of the esophagus in some cases or adjustment of the postural tone of the esophageal wall in others were observed to accompany the disappearance of the sensation.

Regulation of Food And Water Intake

The energy requirements of the body are met by the food that is consumed and absorbed. If an excess of food were consumed continually and there were no change in the energy expenditure there would be a consistent gain in weight. A

shortage in the energy value of the food assimilated would result in a steady loss of weight. The fact that the average adult maintains a constant weight or gains or loses weight very slowly is sufficient evidence that a balance is usually maintained between the energy expended by the body and the energy content of the food that is assimilated. The precision of this adjustment can be appreciated when we realize that the addition of 500 mg. of dry food (less than one soda cracker) to each meal would cause an increase in weight over a 10-year-period of more than 10 pounds if there were no compensatory increase in energy expenditure. Of course some people do gain weight but it is believed that this is usually the result of some abnormality affecting the regulation of food intake.

The balance between food intake and energy output is maintained by regulating both the food intake and the output of energy. There is an immediate effect of the excess food through its specific dynamic action, which results in an increase in energy output. Thus however, is rarely sufficient to account for all the energy contained in the excess food eaten. If it were, there would never be a gain in weight. If an individual consumes a certain measured excess of food at each meal over a period of time he will gain weight steadily but the gain in weight will result in an increase in his basal metabolic rate which, if the excess food intake is not too great, will ultimately increase the metabolism to a point where the energy output will again equal the energy of the food, including the excess. In this way a new balance is established at a higher weight level. In addition, there is apparently another mechanism less well understood which, in some cases at least, balances the energy output against the food intake even when this is in excess. In experiments on dogs at the University of Illinois it was found that dogs that were maintaining a constant weight on the amount of food which they ate voluntarily could be given an excess over this amount through a gastric fistula amounting to 23 per cent of their voluntary food intake without either diminishing their voluntary food intake or causing a gain in weight (Share *et al.*, 1952). Evidently the animals had some means of metabolizing the excess food without increasing their total body mass. This suggests that there is some mechanism for adjusting the total body metabolism to the energy content of the food consumed, even though that is in excess of the need, however, we are here concerned with the other aspect

of the adjustment of food consumption to energy output, that is, the regulation of food intake.

There are several methods of demonstrating the fact that food intake is regulated in some manner so as to equal the energy requirements of the animal. Healthy animals when allowed all the food that they will eat will consume only as much as is necessary to meet their energy requirements and to maintain their weight, or their normal growth if they have not already attained their adult weight. If the caloric value of the food is increased, the amount consumed will be diminished so as to maintain a normal intake of food calories. If, on the other hand, the caloric value of the food is decreased by dilution with inert material ordinarily the animal will consume more food, up to the limit of its capacity, in order to maintain an adequate caloric intake. This mechanism may be tricked by human devices into permitting an excess food intake as in the experiments of Share and his coworkers, described above, but usually it works very well. Adjustment of food intake to energy expenditure is illustrated in figure 43-4.

HUNGER AND APPETITE

Since eating is a voluntary act, regulation of food intake must be accomplished through conscious sensations which indicate either that food is needed or that enough food has been consumed. The sensations that cause food to be eaten are described as hunger and appetite. These terms have never been precisely defined in the scientific sense but in a general way we recognize that hunger is the sum of the sensations aroused by the physical need for food. Appetite on the other hand is a psychic or emotional desire to eat, and may or may not be associated with the need for food. Cessation of eating is also a voluntary act and is induced by a conscious sensation called satiety when a sufficiency of food has been eaten. The mechanisms of hunger and satiety are probably inborn and dependent on the inherent organization of the nervous system. Appetite, on the other hand is acquired and is probably dependent upon pleasurable past experiences associated with eating. For example an individual who is hungry will eat almost any wholesome food so long as it is reasonably palatable. When he has reached a state of satiety, however, he will eat only those foods which are particularly pleasing to him and with which he has had pleasant experiences in the past. Thus, because of hunger, one may eat a wholesome meal which is fully adequate for his needs and then because of ap-

FIG 43.4 Illustrating the effect of exercise of various durations on caloric intake and body weight of exercised rats. Three ranges can be distinguished: sedentary, normal activity and exhaustion. (From Mayer, 1955. Courtesy of New York Academy of Science.)

petite add to it a dessert which is entirely unnecessary so far as caloric requirements are concerned.

THE NEURAL REGULATION OF FOOD INTAKE

It has long been known that persons suffering from tumors of the hypophysis have a tendency to become obese, the condition is known as Frolich's syndrome. In 1940 Hetherington and Ranson showed that a similar condition could be produced in animals by injury to the hypothalamus in the vicinity of the hypophysis. Later, Brobeck and others (1943), showed that the obesity was caused by injury to the ventromedial hypothalamic nucleus situated in the tuber cinereum. If this area is destroyed in rats, cats or monkeys, instead of being satisfied with an amount of food appropriate to its caloric requirements, the animal continues to eat as long as it is able to swallow food or as long as food is available, with the result that it becomes excessively obese. A little later, Anand and Brobeck (1951) found that injuries to the lateral hypothalamic nuclei, just lateral to those involved in obesity would cause the animal to stop eating altogether. Animals with such injuries absolutely refused food even though they starved to death. If an animal with a medial hypothalamic injury and consequent hyperphagia (habitual overeating) was subjected to an injury to the lateral hypothalamus,

such an animal not only recovered from its hyperphagia but refused absolutely to eat anything. From these observations it was concluded that the nuclei in the lateral area of the hypothalamus contain a 'feeding center' and the medial hypothalamic nuclei contain a "satiety center." Since injury to the medial nuclei was effective only if the lateral nuclei were intact it was concluded that the medial satiety center acted by inhibiting the lateral feeding center.

It is interesting to note that the areas of the hypothalamus involved in the control of food intake have a much higher concentration of high energy phosphate compounds (adenosine triphosphate, creatine phosphate) in fasted animals than in animals recently fed, the increase in these compounds implies increased activity of these areas in hungry animals (Larsson, 1954). The medial hypothalamic areas, which are believed to inhibit the feeding centers in the lateral hypothalamus, exhibit increased electrical activity when drugs which reduce or abolish appetite, such as amphetamine, are given. It is believed that the increased electrical activity indicates stimulation of the medial nuclei and that these then inhibit the action of the feeding centers. It has been shown that electrical stimulation of the lateral hypothalamic nuclei by means of implanted electrodes produces hyperphagia (Brobeck *et al*,

TABLE 43 2*

Classification of feeding reflexes on a basis of initial sensory stimulus (left side) or behavior pattern induced (right side)

Sensory Basis	Behavior Basis
Visual reflexes	Reflexes of attention
Olfactory reflexes	Reflexes of approach
Auditory reflexes	Reflexes of examination
Tactile reflexes	Reflexes of incorporation
Gustatory reflexes	Reflexes of rejection
Enteroceptive reflexes	

* From Brobeck, 1957

1956) in rats, cats, mice, monkeys, goats and sheep. During period of stimulation the animals exhibit a compulsive desire to eat and if food is available will eat as much as it is possible for them to swallow (Larson, 1954).

Brobeck (1957) has suggested that the areas of the hypothalamus that control food intake do so either by facilitating or inhibiting the reflex mechanisms involved in the acquisition and consumption of food, he calls these feeding reflexes. These he classifies in two ways: (a) according to the sensory mechanism arousing the reflex and (b) according to the nature of the response. The reflexes are listed in table 43 2. Probably the list could be extended if the mechanisms involved were better understood. The important point is that the hypothalamic centers do not control food intake directly but do so by making more or less responsive to stimuli the lower brain centers which control the reflexes governing the acquisition, consumption and assimilation of food.

Peripheral Mechanisms

Consumption of food brings about consequences which induce satiety and stimulate the mechanisms that are inhibitory to the feeding reflexes. Starvation or the absence of food brings about consequences which excite hunger and stimulate the feeding centers. In spite of extensive study and even more widespread speculation the peripheral mechanisms which contribute to hunger and satiety are still not fully understood. Among the possible operating devices we can recognize gastrointestinal mechanisms and metabolic mechanisms. The gastrointestinal mechanisms are mainly of a physical nature whereas the metabolic mechanisms are chemical. The physical mechanisms are presumed to act through stimulation of sensory nerve endings, whereas, the chemical

mechanisms are supposed to act on some hypothetical sensory device within the central nervous system or connected with it through afferent nerves, although this is by no means certain.

Among the gastrointestinal stimuli which tend to increase food intake and to cause a sensation of hunger, are the so-called hunger contractions of the stomach and intestine (see Quigley, 1955). These have been described in detail in chapter 41. The fact that hunger contractions cause a sensation of hunger helps us little in the solution of our problem for we still do not know what causes the hunger contractions. Probably besides mere emptiness of the stomach and intestine they are excited by something in the metabolic category. Emptiness is not the whole answer because although the stomach may be completely empty a few hours after a meal, hunger contractions become more intense and more distressing the longer the fast is continued. However, they cease at once when food is taken and before any metabolic changes have taken place, therefore, whatever their cause, they can be completely inhibited by the presence of food in the stomach and intestine.

It is known that hunger contractions can be induced or made more intense if already present by inducing a state of hypoglycemia through administration of insulin (Quigley *et al.*, 1929, 1930). This brings about stimulation of medullary centers in which increased activity of the vagus centers is a prominent feature. If the vagus nerves are cut, insulin hypoglycemia does not stimulate hunger contractions (Quigley and Templeton 1930), indeed it tends to inhibit them if they are already present. The hunger contractions induced by insulin evidently are due directly to an action of low blood sugar on the central nervous system. They can be inhibited by administration of glucose intravenously but the normally occurring changes in blood sugar level are in no way related to the presence or absence of gastric or intestinal hunger contractions (Quigley, 1955; Scott *et al.*, 1933). Hyperglycemia may or may not inhibit hunger contractions, it obviously does not in diabetic subjects. In a majority of experiments on normal animals hyperglycemia induced by injecting glucose intravenously does not inhibit gastric hunger motility. It has been shown by Stunkard and Wolff (1956) that in those instances in which the hunger contractions were not inhibited by intravenous glucose that the injection of glucose did not cause a great rise in the arterial as compared to the venous glucose concentration. The arteriovenous glucose concentration difference is

taken as an index of the rate of utilization of glucose by the tissues. On the other hand in those instances in which there was inhibition of hunger contractions there was an increase in arteriovenous glucose difference. Reference will be made to this fact a little later under the head of "Metabolic Factors."

Undoubtedly gastric hunger contractions contribute to the hunger state but they are by no means solely responsible for it. Enough human cases have been studied in which both splanchnic nerves were severed to establish the fact that this operation abolishes all sensation produced by contraction of the stomach during hunger. The contractions persist but they are no longer felt. However, individuals so operated upon do not experience any decrease in their desire for food and they have periods of hunger just as intense as before the splanchnic nerves were severed (Grossman and Stein, 1948). Cutting the vagus nerves abolishes the hunger contractions altogether for a time but by no means abolishes the sensation of hunger. On the contrary, as judged by the amount of food consumed, the hunger sensation is intensified by vagotomy (Vollmann, 1844). We may conclude that the hunger sensation arises not only in the stomach and intestine but elsewhere in the body also and that the gastrointestinal component is dispensable.

Sensations arising in the gastrointestinal tract which diminish or abolish food intake are somewhat better understood. The act of eating in itself diminishes hunger and appetite. For example, if an animal is prepared with an esophagostomy so that food that is eaten passes through the mouth and pharynx and upper esophagus but does not enter the stomach the animal will eat more food than would a normal animal, but feeding ceases eventually. If an animal is given a measured amount of food before its regular mealtime it will reduce the amount of its voluntary food intake proportionately. If the prefeeding is carried out through a gastric fistula instead of by mouth the reduction in voluntary food intake is much less pronounced, indicating that the decrease in food intake was not all due to distention of the stomach but partly to the oropharyngeal stimulation of eating.

Distention of the stomach alone inhibits hunger and appetite. For example, if an animal is given a portion of its food a few minutes before regular feeding time through a gastric fistula and this practice is continued over a period of time, eventually the animal will come to reduce the size of its subsequent meal by an amount equal to an

amount given through the gastric fistula, in other words the total size of the meal will be maintained constant (Janowitz and Hollander, 1955). This adjustment does not occur immediately and is never very precise, but it does show that gastric distention with food tends to reduce hunger and appetite. Similarly, if the stomach is partly filled with inert materials the size of the subsequent meal will be reduced. Inflation of a balloon in the stomach has the same effect (Janowitz and Grossman, 1949). That these effects are mechanical and not metabolic in nature is shown by the fact that if the artificial feeding, instead of being given immediately before the regular meal is given some 4 hours after and time allowed for it to be disposed of, the animal will eat a normal amount at the next regular meal, provided the artificial feeding was not too large. As much as one-third of the animal's regular food consumption can be given in this manner over a period of time without affecting his voluntary intake (Share *et al.*, 1952). The fact has already been referred to that animals so fed, although receiving 30 per cent or more in excess of their regular food intake do not necessarily gain weight. The effect of gastric distention on hunger and appetite is doubtless due to the presence in the stomach of stretch receptors (Paintal, 1954) situated in the muscular walls and connected to afferent fibers of the vagus nerves; section of the vagi does away with the effects of gastric distention on appetite. Indeed vagotomy produces a condition of hyperphagia comparable to that caused by lesions of the medial hypothalamic nuclei.

The effects of the gastrointestinal stimuli are largely confined to determining the size of an individual meal. They do not serve to regulate the over-all balance between energy intake as represented by the food and the energy output as represented by the total metabolism of the body. Presumably metabolic factors are responsible for this type of regulation but any discussion of such factors at the present time would be in the nature of speculation. We know certainly only that some metabolic consequences of the assimilation of food are not effective as regulatory factors. It has been shown, for example, that changes in blood sugar, at least those that are not associated with changes in arteriovenous glucose difference have no effect on voluntary food intake nor do they influence hunger contractions except those induced by insulin (Quigley and Halloran, 1932). An increase in the amino acid concentration of the blood caused by intravenous injection of the amino acids has no effect upon voluntary food intake in dogs.

FIG 43.5 Outline of mechanisms taking part in transition from appetite to satiety (From Brobeck, 1957)

However the slight increase in temperature which results from the presence of pyrogens in some intravenous solutions does definitely influence appetite, even though the rise in temperature is too small to be recognized clinically as a fever. This, and the fact that taking food causes a slight increase in temperature due to the specific dynamic action of the food has suggested to Brobeck (1957) the possibility that the increase in body temperature caused by the specific dynamic action of the food may be a factor limiting food intake (figure 43.5).

Mayer (1955) has suggested that food intake is controlled in some way through the metabolism of glucose, the so-called glucostatic hypothesis. Recognizing the fact that hunger and appetite are not related to changes in blood sugar level Mayer contends that they are governed by the utilization of carbohydrate food by the tissues. To quote from a recent article (1955) 'According to the glucostatic theory the mechanism postulated for the short term regulation of energy intake rests on the concept that somewhere, possibly in the hypothalamic centers shown to be implicated in the regulation of food intake, perhaps peripherally as well, there are glucoreceptors sensitive to blood glucose in the measure that they can utilize it.' In other words, when the tissues are rapidly utilizing glucose, thus establishing a high arteriovenous glucose difference, the glucoreceptors are stimulated and through their central connections suppress hunger and appetite and inhibit food intake. On the other hand, when glucose is not available for tissue utilization and the arteriovenous glucose difference tends toward zero, a state corresponding to tissue hunger exists and this is in some way sensed by the hypothalamic centers which then facilitate the feeding reflexes.]

Another theory suggests that the total energy stores of the body are maintained at a certain predetermined level by the balance between hunger and satiety. Whatever the mechanism may

be, it is evident that metabolic factors are important and quite possibly play a determining role in the regulation of the balance between food intake and energy output in the body.

THIRST

The sensation of thirst is referred to the pharynx and is due to the stimulation of sensory nerve endings in this situation. Two theories have been advanced to explain the mechanism by which the sensation is aroused.

According to one view, thirst is due simply to the drying of the pharyngeal mucous membrane, the salivary glands being given a role in the regulation of the water balance of the body. When the water content of the body falls below a certain level salivary secretion is depressed the consequent drying of the mucous membrane of the throat then elicits the characteristic sensation. If such a view is correct, drying of the pharyngeal mucosa from whatever cause should cause thirst. Cannon, who provided the principal support for this theory, found in studies upon himself that after abstinence from fluids for a time the depression of salivary secretion which resulted was definitely associated with thirst. Atropine, which inhibits salivary secretion, also produced the typical sensation and thirst aroused by the deprivation of water was relieved by the application of cocaine to the mucosa. Pilocarpine or acid substances which stimulate the flow of saliva also relieve thirst. In dogs, however, atropine and pilocarpine are without effect upon the water intake.

According to the other view, thirst is a sensation resulting from changes in blood composition probably due to a rise in its osmotic pressure which stimulates the afferent nerve endings or acts perhaps upon central nervous structures. Rowntree and his associates, for example, found that the thirst of diabetes insipidus was relieved neither by cocainization of the mucous membrane nor when salivation was induced by pilocarpine. The experiments of Gilman suggest that cellular dehydration rather than a rise in osmotic pressure is the prime factor in arousing thirst. Elevation of the osmotic pressure of the blood of dogs by the injection of a hypertonic salt solution, and the imbalance thus caused in the osmotic relationship between intra and extracellular fluids, caused a much greater intake of water than an equivalent rise in osmotic pressure resulting from the administration of urea. After the injection of salt, sufficient water was drunk to quickly reduce the osmotic pressure of the blood, whereas after urea

to which the cells are readily permeable, and which therefore, did not disturb the osmotic relationships the water intake was but little increased and the osmotic pressure of the blood remained elevated. In support of the view that a lowered water content of the cells is the true thirst stimulus Gilman cites an experiment in which anhydremia was induced by the withdrawal of large quantities of extracellular electrolytes (e.g., NaCl) without the withdrawal of water. In such anhydremic animals dehydration of the tissue cells does not occur and although the oral mucous membranes are quite dry there is no evidence of thirst—water is refused.

That the two theories are not incompatible is indicated by the work of Holmes and Gregerson (1947) who found that in human subjects following the intravenous injection of 300 ml of 5 per cent sodium chloride although there was an increase in plasma volume there was a considerable decrease in salivary secretion associated with the sensation of thirst. This proves that the decrease in salivary secretion leading to a sensation of thirst may be caused by an increase in the osmotic pressure of the blood and suggests that tissue dehydration may induce the sensation of thirst through the reduction in the flow of saliva.

The neural mechanisms for the regulation of water intake are similar to those for regulation of food intake. Indeed they are closely associated and have not as yet been clearly separated. Certain types of injuries to the lateral hypothalamus induce not only a cessation of food intake but also cessation of water intake. The animals die of dehydration unless given water by stomach tube (Greer 1955, Morrison and Mayer 1957). Greer found that stimulation of the dorsomedial nucleus in the cat caused violent drinking activity; thus there are probably centers for the regulation of water intake in the hypothalamus comparable to the feeding centers but these have not been so precisely localized; apparently they are very near to the feeding centers. Like the intake of food the intake of water is influenced by gastric distention. Animals made thirsty by intravenous injection of hypertonic salt solution will usually drink an amount of water over a short period of time approximately equal to the amount necessary to dilute the injected salt to an isotonic concentration. If the stomach is distended by means of a water-filled balloon the amount of water that is voluntarily drunk will be diminished and the replacement of the water deficit delayed. The vagi play a part in the regulation of water intake. Vagotomized animals not only eat more food

but also drink more water than normal animals. The food intake and the water intake are increased proportionately by vagotomy; they are decreased by sympathectomy (Towbin 1955).

Excessive thirst also occurs in lesions of the anterior hypophysis leading to diabetes insipidus. In this disease there is failure of production of the antidiuretic hormone of the anterior hypophysis resulting in an excessive loss of water through the kidneys. In this case thirst is probably secondary to dehydration.

SECTION SIX

Nutrition and Metabolism

44

COMPOSITION AND ENERGY CONTENT OF FOODS: GENERAL METABOLISM

General Outline of the Function and Composition of Foods

Nutrition deals with the needs of the organism for sustenance. Nutrition concerns a complex aspect of living things (both plants and animals) that consists of the taking in and assimilation through chemical changes (metabolism) of material, whereby tissue is built up and energy liberated. There are three successive stages in the process, known as absorption, assimilation and excretion. In all animals, and certain plants, a stage known as digestion precedes the three stages named. In the more highly developed animals, digestion is preceded by mastication and deglutition, and excretion is effected by four routes, the processes being referred to as expiration, perspiration, urination and defecation. The essential feature in nutrition is the *intake* of the raw materials needed for the maintenance of life, but it overlaps *virtual*ling, food preparation and metabolism. The modern science of nutrition deals mainly with the requirements of the body, both in kind and amount, and the choice of foods to meet these needs.

The three chief functions of food are (1) to supply energy, (2) to form (or maintain) body tissue, and (3) to preserve a suitable internal environment so that the enzymes bringing about the metabolic reactions and the hormones regulating the processes may function properly.

Chemical methods for the analysis of foodstuffs as they developed over the years, revealed that natural foods contain (besides water and the ash constituents) cellulose, lignins, galactosans, pentosans, starches, sugars, fats, waxes, sterols, carotenoids and other pigments, proteins, purines,

pyrimidines, acids (such as oxalic, lactic, tartaric, citric, malic, benzoic, salicylic, quinic and uric) and many other minor components such as tannins, alkaloids and simpler bases, glucosides and essential oils. Mesurier (1783-1855) first tested the effects (in dogs) of feeding gelatin, sugar and butter alone and noted that animals cannot survive for long on such individual foodstuffs. Prout (1785-1850) in his notable book *Chemistry, Meteorology and the Function of Digestion* (1834) developed the modern view that of the many components of natural foods, three kinds are essential in the diet, each possessing characteristic nutritive properties. Prout referred to them as the albuminous group (gelatin, cooked egg white, cooked flesh being examples), the saccharine group (sugars and starches) and the oleaginous group; these are known today of course, as the proteins, carbohydrates and the fats.

For many years (about 1860 to 1910) interest was focussed on the energy content of foods and the energy requirement of the body. The nitrogen (protein) requirement continued to receive much attention. Although chemists recognized that the methods for the analysis of foods were only approximate, and that carbohydrates were usually estimated by difference, so that the values always added to 100 per cent, the conclusion had been reached that minerals, proteins, carbohydrates and fats were the only nutrients required by man and animals. There seemed to be no room in the make up of foods for any other ingredient of nutritive importance.

Besides the seven principal ash components (calcium, magnesium, sodium, potassium, phosphorus, sulfur and chlorine) at least seven other

minerals, the so-called "trace elements" are today known to be essential for animals and man iron, copper, manganese, zinc, cobalt, iodine and

fluorine The possible essentiality of aluminum, silicon, arsenic, boron, selenium and other elements has been suggested but not established

Energy Content of Foodstuffs

There have been many tabulations showing the average chemical composition and energy values of the edible portion of common food materials The values in these tables are based upon a number of assumptions that are commonly made by food chemists A brief review of the techniques used and errors involved will illustrate the uncertainties inherent in many tabulations In spite of these limitations, certain valuable generalizations about the nutritive worth of the commoner food materials have been reached

The energy value of foods is measured in kilogram-calories or large Calories (spelled with a capital C) This is the amount of heat required to raise the temperature of a kilogram of water 1° (from 15 to 16°C) The potential energy of a foodstuff can be estimated in three ways (1) It may be determined directly by measuring the amount of heat generated when a weighed sample of the material is burned in a bomb calorimeter (see p 751) (2) Indirect calorimetry involves measurement of the oxygen required to burn completely a sample of the foodstuff in the oxy-calorimeter (see p 753) and calculation of the energy content from the oxygen used (3) As will be shown later, an approximation to the number of calories that a foodstuff will provide may be calculated from the chemical estimates of protein, fat and carbohydrate in it "Physiological corrections" are then applied to allow for incomplete combustion and losses in the urine and feces

Antoine Laurent Lavoisier (1743-1794), the founder of modern chemistry first used the thermometer and balance in the study of metabolism¹

¹ Graham Lusk has given an account of the scientific descent of the leading chemists who have devoted their lives to the nutritional aspects of physiology Berthollet (1748-1822), who established the composition of ammonia and of hydrogen sulfide, and who showed (in 1786) that nitrogen is a constant constituent of animal tissues, (a colleague of Lavoisier and instructor of Napoleon I in chemistry), bequeathed his sword to his favorite student, Gay Lussac, originator of volumetric methods and formulator of the gas laws Gay Lussac (1778-1850) was the teacher of Liebig (1803-1873), the father of modern methods of organic analysis Liebig, author of the first chemical text to deal extensively with agricultural matters and the composition of foods, tissues and excreta (*Animal Chemistry*, 1846) taught Carl von Voit (1831-1908) Under Voit's energetic leader

His careful experiments and clear deductions explained the nature of oxidation, of combustion and of respiration and showed their similarities He recognized that fuels and foods are composed of carbon, hydrogen and oxygen Lavoisier showed that oxidation of these organic substances to carbon dioxide and water led to the production of characteristic amounts of heat² Simultaneously, in Britain, Crawford was making similar experiments on "animal heat" and combustion

In 1842, half a century later, the English physicist James Prescott Joule (1818-1889) determined the mechanical equivalent of heat³ In the same year, the German physician physicist Julius Robert von Mayer (1814-1878) published his revolutionary theory of heat together with his views on the conservation of energy Mayer stated that the sum total of the energy in the universe remains constant but that any one form (mechanical, potential thermal, chemical electrical) may be converted into another Several years later (1845) another German scientist von Helmholtz (1821-1894) extended the application of the Law of Conservation of Energy and formulated it mathematically It is interesting to know that at the time the contributions of both men were rejected by the leading German scientific journal⁴

Through the work of Voit Pottenger and Rubner the Law of Conservation of Energy was shown to hold true in the animal body Rubner established the heat value of carbohydrates, fat and protein when burned outside the body in a calorimeter (for operational details see p 751)

ship the Munich School became the outstanding centre of research in nutrition and metabolism (about 1860-1910) The conversion of carbohydrate to fat, and of part of the food protein to carbohydrate was demonstrated at Munich Voit taught Rubner (1854-1932) Atwater (1814-1907) E P Cathart (1877-1951) of Glasgow University Graham Lusk (1866-1932) of Cornell University Medical College, New York, and others who were the authorities 30 to 50 years ago They in turn taught and inspired many of the present leaders in nutrition

² Lavoisier believed that the heat was produced through the oxidation of carbon and hydrogen in the lungs Not until some years later was it shown that heat production was the result of the combustion of foodstuffs in the various tissues of the body

³ The unit of work, the erg = a force of 1 dyne acting through 1 cm The joule is 10⁷ ergs The mechanical equivalent of heat is the quantity of energy which, when transformed into heat, is equivalent to unit quantity of heat 1 calorie = 4.18 joules = 4.18 × 10⁷ ergs

TABLE 41.1

*Energy content (by bomb calorimetry) of some fuels, foods and metabolic products
(kilocalories per gram)*

H ₂ hydrogen	31.2	Ethanol	7.13	Castor oil	8.85
Carbon		Glycerol	4.32	Cod liver oil	9.40
charcoal	8.09	Arabinose	3.74	Citric acid	2.47
diamond	7.87	Glucose	3.73	Malic acid	2.42
graphite	7.85	Fructose	3.76	Glycine	3.14
Methane (CH ₄)	13.2	Galactose	3.73	Alanine	4.35
Ethane (C ₂ H ₆)	12.3	Sucrose	3.95	Leucine	6.55
Ethylene (C ₂ H ₄)	11.8	Lactose	3.96	Casein	5.85
Acetylene (C ₂ H ₂)	12.0	Starch	4.12	Gelatin	5.30
Benzene (C ₆ H ₆)	10.0	Acetaldehyde	6.34	Albumin	5.80
Petroleum	10.3	Acetic acid (C ₂)	3.49	Dried muscle	5.40
Coal gas	10.7	n Butyric acid (C ₄)	5.96	Edestin	5.64
Anthracite coal	7.0-8.7	Palmitic acid (C ₁₆)	9.36	Gliadin	5.74
Wood		Stearic acid (C ₁₈)	9.54	Legumin	5.62
Pine	4.4	Oleic acid (C ₁₈)	9.41	Uric acid	2.74
Beech	4.2	Butter fat	9.30	Urea	2.53
Oak	4.0	Cottonseed oil	9.40	Creatinine	4.98
Methanol	5.33	Linseed oil	9.41		

He then fed the three types of foodstuffs separately to a dog in a calorimeter. Carbohydrate and fat produced the same amount of heat, within the limit of experimental error, whether combustion occurred within the body or outside it. The physiological heat value of protein, however, was found to be distinctly less than the bomb value. Carbohydrates and fats, after absorption, are fully oxidized to carbon dioxide and water in the body as well as in the bomb, but this is not so for protein. In the bomb calorimeter, proteins are burned completely to carbon dioxide, water and sulfuric acid, part of the nitrogen is converted to oxides of nitrogen and part occurs as free nitrogen. The body excretes in the urine urea and other nitrogenous compounds. These carry out some of the carbon, hydrogen and nitrogen before they are fully oxidized and thus some of the potential energy of the protein is lost. Only about three-quarters of the calories obtained from protein in the bomb are physiologically available because of the less complete oxidation in the body.

The caloric values (bomb) of different carbohydrates, fats and proteins are not identical, as may be seen in table 44.1. Animal proteins are often said to liberate slightly less energy per gram than do plant proteins but this is an unsafe generalization (cf. table 44.1).

Rubner found the heats of combustion (Calories per gram) for glucose, lactose, sucrose and starch to be 3.69, 3.88, 3.96 and 4.12, respectively. He suggested 4.1 as the factor for the mixture of sugars plus starch in a mixed diet. Rubner

adopted 9.3 as the mean factor for fat and 4.1 for the physiologically available energy from proteins. Atwater and Bryant proposed 4.0, 8.9 and 4.0 respectively. For practical purposes the simple factors 4, 9 and 4 are adequate.

UNCERTAINTIES IN ENERGY VALUES OF FOODS ESTIMATES FROM COMPOSITION. The main reasons for uncertainty about the correct energy value to assign to natural foodstuffs are (1) the difficulty of choosing a representative sample, (2) difficulties connected with accurate chemical analyses, (3) inconstancy of the moisture content of the samples, and (4) the difficulty of choosing appropriate factors (a) for conversion of nitrogen to protein and (b) for the energy available to the body from different foodstuffs. This latter point includes the uncertainties introduced by variations in digestibility. Each type of foodstuff raises special problems. These will be dealt with separately.⁴

CARBOHYDRATE. In the early days of food chemistry (and often today) carbohydrate was determined by difference, i.e., $100 - (\text{moisture} + \text{ash} + \text{protein} (N \times 6.25) + \text{fat})$. All the errors in the previous determinations, plus the undetermined matters in the food, are thus included with the carbohydrates. Only in recent years

⁴Specific dynamic action of foodstuffs, which will be discussed in the following section, is concerned with alterations in the basal metabolic rate induced by ingestion of foodstuffs and not with the intrinsic potential energy of the foods.

have efforts been made to determine individual carbohydrates

The energy content of individual carbohydrates varies from 3.7 to almost 4.2 (table 44.1). The physiological availability varies from almost 100 per cent to zero. The energy of celluloses, although somewhat available to ruminants, is unavailable in man. Substances such as galactans, pentosans and hemicelluloses are poorly (if at all) utilized by man. The edible portions of most foods do not contain excessive amounts of indigestible carbohydrate but it is erroneous to conclude that all of the "carbohydrate" (as determined by difference) provides energy. Estimates of "crude fiber" are not given in older food tables. Sometimes no mention is made of whether a correction has been applied for indigestible carbohydrate. In a few cases, e.g., soyabean flour, only about 40 per cent of the carbohydrate is utilized by rats, and this probably represents the digestibility of these carbohydrates in man. The "average availability" figure of 97 per cent may be too high for mixed foods but is probably correct for mixed sugars and starches.

Organic acids occur in many foods, especially fruits, ovals, male and citric are the most widely found. Ovalic and tartaric are not utilized, male and citric are completely oxidized in the body, giving 2.42 and 2.47 Calories per gram, respectively. In a few cases a large percentage of the total calories comes from acids, e.g., in lemon juice 62, grapefruit and squash 12, oranges and tomatoes 6, pineapple and cucumber 4, cabbage and carrot 2 to 3.

In general, the value 4.0 Calories per gram of carbohydrate is essentially correct if adjustment for crude fiber has been made. When pure sugars are added to a ration, then exact values can, of course, be used although it is questionable whether one gains much in precision thereby. The reason for this pessimistic statement is that recent careful studies have shown that indigestible residues can interfere with the absorption of carbohydrates that would be completely utilized if fed separately. Thus other materials in the ration can play unpredictable roles in altering availability.

FATS The fat content of foods is usually determined by extraction of the dried and powdered material with ether. Evaporation of the solvent leaves the "crude fat" which is conventionally weighed as such. It is sometimes grossly contaminated with nonlipid materials that have been taken out by the ether, e.g., pepper corns contain 6.5 per cent of ether soluble matter but only about

2 per cent of glycerides, ground ginger contains 3.3 per cent of "crude fat," only one eighth of which is glyceride. For this reason the saponification procedure (Liebermann, 1898) and estimation of fatty acids has sometimes been used as a control. More often after extraction gives low values, in some cases much too low, fat values found by ether extraction (Sohxlet) and by Liebermann's method on Horlick's malted milk are 1.2 and 8.6 grams per 100 gram, respectively, corresponding data for Kellogg's All Bran are 1.0 and 4.5 for Grape Nuts 0.4 and 3.0 and for whole wheat flour 0.6 and 2.1, respectively.

The energy value of most edible oils and fats lies in the range 9.2 to 9.4 Calories per gram. The availability in the 3 adult male subjects studied by Atwater and Bryant (1900) varied from 90 to 95 per cent, but it is unsafe to accept their mean value of 92 as being of universal applicability.

The main difficulty in deciding about energy values from dietary fat data in food tables concerns the decision as to what constitutes a representative sample of the food, especially of meat cuts. Because fat has a controlling influence on the energy content, small differences between the character of the sample eaten and that analyzed may introduce gross errors in the computation. One large lean steak (200-gram portion, raw weight) of the following percentage composition: water 71, ash 1, protein 20 and fat 8 may be estimated to supply about 300 Calories, another steak of equal weight analyzing water 65, ash 1, protein 18 and fat 16 would supply more than 100 extra Calories (about 430), whereas a similar portion of a moderately fatty sirloin steak (28 to 32 per cent fat) would provide nearly 800 Calories if all the fat were consumed. Much is rendered out, however, some or all of which is left in the pan.

PROTEINS Proteins differ in many ways from the other two foodstuffs. Proteins typically contain (besides carbon, hydrogen and oxygen) nitrogen, almost always sulfur and sometimes phosphorus. Heterogeneous substances varying in nitrogen content from about 12 per cent (in tendomucoid) to about 19 per cent (in silk fibroin), in molecular weight from about 12,000 to about 60,000,000 and in digestibility from 0 to 100 per cent are covered by the same name. Their nutritional value, which can be determined only by biological testing, varies just as greatly. Casein (15.8 per cent N) and egg albumin (15.5 per cent N) are high quality proteins, being well supplied with essential amino acids and readily digested. Zein and gelatin contain more nitrogen (16.1 and 18.0 per cent, respectively) but are incomplete,

TABLE 412
Composition and energy content of common foodstuffs

Foodstuff	Usual Serving	Food Energy	Composition of Foods 100 Grams Edible Portion

lacking certain essential amino acids, and although they are readily digested have low sustenance value when fed by themselves. Thus knowledge of protein content is of limited value in assessing foods until some biological tests have established the nutritional usefulness of the protein. Proteins that are useless for supporting growth may still be utilized (oxidized) to supply energy. It is wrong to think of proteins only as fuel, but it is equally wrong to think that they are not oxidizable if not used efficiently by the body for other purposes. Many proteins contain about 16 per cent of nitrogen. Food chemists therefore adopted the convention of using the factor 6.25 (i.e., $100/16$) to convert nitrogen found in food to protein content. This factor has been used in preparing most food tables, although Rubner used 6.45 and Plummer (1921) used 5.68 for nitrogen in plant products, 6.38 for dairy products and 6.25 for meats.

Use of the factor 6.25 is based on two assumptions. The first is that all proteins contain 16 per cent of nitrogen, but this is far from true. The second assumption, that all the nitrogen in food is present as protein, is also untrue. The amount of nitrogen present in simpler natural bases (choline, betaine, atachydine, trimethylamine, creatine, etc.), purines, pyrimidines and other nitrogenous

compounds is usually small, but in a few cases it is far from negligible.

For flesh, the factor 6.25 is reasonably correct. For milk proteins a factor of 6.38 is appropriate. The factor 5.83 is more correct for calculating the protein content of barley, oats, rye and whole wheat. For refined wheat flour the factor 5.70×1.1 is recommended. The factor believed most appropriate for rice proteins is 5.95 for soybeans is 5.71, peanuts and Brazil nuts 5.46, almonds 5.18, and other nuts and oil seeds 5.30. The factor 6.25 may still be applied to the nitrogen in foods where specific information is not available.

Besides uncertainty as to the actual protein content of foods, it must be remembered that different purified proteins on combustion release different amounts of energy. Further, there is considerable difference between proteins in their digestibility. Attempts to evaluate the biological availability of the energy of food proteins require two corrections: (1) for loss in unabsorbed protein and (2) for further loss (from the portion digested and absorbed) in the urine of some potential energy in incompletely oxidized compounds such as urea.

Rubner determined the heat of combustion of urea and found it to be 5.52 Calories per gram or 5.4 Calories per gram of urea nitrogen. He pointed out that the urine contains also creati-

nine, uric acid and other nitrogenous end products capable of further oxidation. Attempts to estimate the physiologically available calories per gram of protein ingested were complicated by the finding that the heats of combustion of the organic substances excreted in the urine did not have a constant caloric value per gram of nitrogen. For example, the urine passed by a man eating a meat diet at one time and a potato diet at another gave 7.69 and 7.85 Calories per gram N, respectively, whereas the urine of a

baby living on breast milk gave 12.1 Calories per gram N. Rubner also analyzed the feces of the man who acted as his experimental subject. The loss of energy in the nitrogenous substance amounted to 6.9 per cent of that of the ingested protein. Adding this value to that of 16.3 per cent lost in the urine he obtained a total caloric loss of about 23 per cent. Rubner therefore deducted 23 per cent from the bomb value for the heat of combustion of proteins.

A summary of our current knowledge of the composition and energy content of certain food stuffs that are widely used is given in table 44 2. Most of the data were taken from Agriculture Handbook No. 8 (Composition of Foods) issued by the U. S. Department of Agriculture (1950). The mineral content of certain foods is given in table 44 3.

Main Food Groups

1 *Meats, fish, poultry, eggs* Protein rich foods, also rich sources of certain vitamins of the B group. Eggs sometimes classed separately because of richness in vitamin A.

2 *Legumes (dried peas and beans) and nuts* Protein rich, but less costly. The proteins of these foods are of somewhat lower quality and vitamins in these products are less abundant.

3 *Milk and milk products (other than butter)* Economical sources of proteins of high quality, rich in calcium and riboflavin.

4 *Grain products* Inexpensive sources of energy and of protein, although the latter are present in smaller amounts than in meats and milk products. If not too highly processed, good sources of iron and vitamins of the B group.

5 *Green and yellow vegetables* Sources of vitamin A, minerals and certain other vitamins.

6 *Tomatoes and citrus fruits* Rich sources of vitamin C.

7 *Other vegetables and fruits* Sources of vitamins and minerals.

General Metabolism

The word metabolism has a broad meaning. It is the term employed to describe the chemical changes that occur within the tissues. The integration of these reactions leads (1) to growth, (2) to the production of the heat required to maintain body temperature, and (3) to supply the energy for other vital processes. It is convenient for teaching purposes to consider *energy metabolism*, which is concerned with the gross

energy changes (heat production, muscular activity and energy for maintenance of vital functions), separately from *intermediary metabolism* which is concerned with specific chemical reactions occurring in the body. Thus customary differentiation is, however, not a real one since energy changes are essential components of chemical reactions. Many metabolic reactions, especially those concerned with the breakdown

of large molecules into simpler units, release energy, other reactions, especially those involving synthesis, absorb energy. The assimilative processes involved in the formation of new tissue are referred to as *anabolism*, the reactions concerned with tissue breakdown are referred to as *catabolism*.

Energy is required to maintain the body temperature, to support the automatic muscular movements of the heart, respiratory organs and gut and for the synthetic reactions that occur in the tissues (formation of protein, hormones and other complex metabolites). These activities, called *basal metabolism*, in an adult require about 500 Calories during an average 8-hour period of sleep or rest in bed. A similar energy expenditure continues during the waking hours (another 1000 Calories) giving a total basal expenditure of about 1500 Calories. A portion must be added for nonlabor activities (feeding, clothing, washing and amusing oneself), the energy required for these will vary considerably but probably averages about 500 Calories. The quota for the day's work varies from as low as 600 Calories (more frequently 800) for a sedentary student or clerk to possibly as much as 3600 Calories in a miner, woodcutter or athlete. Thus the total daily expenditure of energy of an average sedentary person weighing about 65 kg. would be about $1500 + 500 + 800 = 2800$ Calories. Total daily expenditures above 4400 Calories are uncommon.

Energy metabolism may be studied from several aspects: (a) the energy content (caloric value) of foods, (b) direct calorimetry, (c) the significance of the respiratory quotient (R.Q.), i.e., volume of carbon dioxide expired divided by the volume of oxygen consumed in the same period of time (CO_2/O_2), (d) indirect calorimetry, (e) basal metabolism, (f) energy cost (caloric requirement) of various types of activity, (g) the specific dynamic action (S.D.A.) of foods, i.e., the increased production of heat by the body as a result of a stimulus to metabolic activity caused by taking food.

HISTORICAL SURVEY

The first gas to be mentioned in the history of chemistry is one of great physiological importance, carbon dioxide. Van Helmont (1577-1644) corked up limestone with acid in a bottle and found that the pressure created by the substance being formed burst the bottle. He coined the word *gas*, derived from the Greek word *chaos*, to describe the wild motion of the particles responsible for the bursting force so generated. He called the product *gas sylvestre*. Joseph Black rediscovered

and investigated carbon dioxide in 1754 and called it *fixed air*, Van Helmont's name *gas* having not yet been generally accepted.

In 1669 John Mayow (1611-1679) put a large glass globe over a mouse on a platform in a shallow dish of water. A perceptible contraction of the air occurred slowly and caused the level of the water to rise in the globe. A burning candle produced the same effect. A mouse introduced into a vessel with a burning lamp lived only about half as long as a mouse in the same vessel without a lamp. From these observations Mayow concluded that air is composed of two gases: one concerned in combustion and respiration (which he called *nitro-aerial spirit*, because it was apparently the same substance that is "fixed" in saltpeter, i.e., niter and freed from it by heat), and a second gas incapable of supporting either combustion or respiration. Joseph Priestley (1733-1804) discovered several new gases (at that time called "airs") and established the existence of different airs, each with definite properties. In 1772 he made oxygen by heating niter (potassium nitrate) strongly and observed that a mouse lived twice as long in the 'new air' as in the same volume of common air. Priestley breathed the new air himself and fancied his 'breast felt peculiarly light and easy for some time afterwards', he therefore recommended its use in medicine. Priestley wrote, 'Who can tell but that, in time, this pure air may become a fashionable article in luxury. Hitherto only two mice and myself have had the privilege of breathing it.' Today it is a common privilege.

A generation later Crawford placed a guinea pig in a water calorimeter and demonstrated a parallelism between the oxygen consumed and the heat generated by the animal. Approximately the same quantity of heat was produced by the animal as when the same amount of oxygen was used to burn carbon outside the body.

A few years later two French scientists, the chemist, Lavoisier (1743-1794), and the physicist, Laplace (1749-1827), performed a similar experiment but measured the carbon dioxide produced rather than the oxygen used. They placed a guinea pig in a closed chamber and showed that the same product of oxidation of carbon is formed in the body and eliminated from the lungs as is produced by the burning of a candle. They determined the quantity of carbon dioxide eliminated by the animal in a 10 hour period and found that it was the same (12.1 grams) as that produced when 3.3 grams of pure carbon were burned in air. The guinea pig was next placed in a closed space surrounded by ice (fig. 44-1) and the heat given out by the animal's body was calculated from the quantity of ice that was melted. A comparable amount of heat was generated when 3.3 grams of carbon were burned in the ice calorimeter. Lavoisier and Laplace concluded that the heat generated by the animal was

FIG. 44.1 Ice calorimeter of Lavoisier and Laplace (After Luciani). A, chamber for animal, B, two concentric chambers filled with ice

produced by the combustion of 33 grams of the body's carbon. With this demonstration that animal heat is the result of the oxidation of carbon in the body, and establishment of a *parallelism between the amount of heat generated in the animal's body and the quantity of carbon dioxide eliminated*, the science of metabolism was begun.

Lavoisier believed that the oxidation of carbon and hydrogen occurs in the lungs. Heat production is now known to result from combustion of foodstuffs in the various tissues of the body.

J. von Liebig (1803-1873) established that it is not carbon and hydrogen that are burned by the tissues but *carbohydrate and fat*. Liebig (1842) believed that oxygen is used in the metabolic combustion of these two foodstuffs but he thought that the breakdown of protein is of a different nature, being caused by muscular work. This belief, although unsupported by any experimental evidence, was generally accepted until Carl von Voit (1831-1908) showed conclusively in 1860 by experiments on dogs and man that the metabolism of protein is not affected by muscular work.

Metabolic balance studies originated with J. B. Boussingault (1802-1887). He compared the carbon, hydrogen, nitrogen and oxygen ingested by a dairy cow in its feed with the amounts of these elements excreted in the milk, urine and feces. The portions unaccounted for were considered to have been used in respiration. Bidder and Carl Schmidt (1852) measured the protein intake and nitrogen excretion of adult dogs and cats and found that nearly all of the ingested nitrogen was eliminated in the urine and feces. Their findings were doubted until Voit (1857) measured the protein intake and nitrogen output of a dog for 53 days and recovered 99.7 per cent of the nitrogen in the excreta.

Regnault and Reiset in 1849 devised the first

closed circuit apparatus for respiration experiments (to be described later) and in it measured the metabolism of poultry, swine, sheep and calves. They showed that the respiratory quotient (volume of carbon dioxide expired divided by the volume of oxygen consumed in the same time period) is controlled by the nature of the food stuffs being oxidized and does not depend on the species of animal used in the experiment. Pettenkofer (1818-1901) constructed the first respiration chamber in which a man could live without discomfort for several days. He and Voit conducted many studies in it and established the fundamentals of energy metabolism. This aspect of metabolism received exhaustive study in the closing years of the last century by Rubner and his colleagues in Germany. Atwater, (1844-1907), the outstanding American authority in this field spent some time with Rubner, later, with the physicist, Rosa. He constructed the first human respiration calorimeter to be made on this side of the Atlantic and with F. G. Benedict and others perfected the study of energy metabolism.

ENERGY CONTENT OF SUBSTANCES

As explained in the previous section, the *physiologically* available energy of the three major foodstuffs is generally taken as 9, 4 and 4 Calories per gram for fat, carbohydrate and protein, respectively.

The potential energy of a chemical compound or foodstuff is determined by measuring the amount of heat generated when the material is burned. The *bomb calorimeter* (fig. 44.2) employed for this purpose consists of a small, strong, platinum-lined steel vessel immersed in a can containing a known weight of water. This in turn is enclosed in an insulating outer container. A known weight of the dried foodstuff is placed in the bomb which is then filled with pure oxygen under pressure. The bomb is immersed in the water and the mixture is ignited electrically. A thermometer graduated in very small units, capable of being read to the nearest 0.001°C, is used. The amount of heat produced is calculated from the rise in temperature of the water, with appropriate corrections being made for the "water equivalent" of the bomb and calorimeter parts. The rise in temperature multiplied by the sum of the weight of the water (in kilograms) plus the "water equivalent" of the apparatus divided by the dry weight of the substance (in grams) gives in Calories the heat value of the material per gram.

THERMAL EQUIVALENTS The heat production per liter of oxygen consumed varies from compound to compound (table 44.4) but the varia-

tion within groups of related compounds (e.g., carbohydrates) is smaller than between different groups of compounds (e.g., carbohydrates, fats and proteins). The thermal equivalent of the foodstuff is the number of calories liberated per liter of oxygen consumed or of carbon dioxide eliminated. The thermal equivalent of CO_2 varies much more than does that of O_2 (table 44.4). It is more usual, therefore, to estimate heat production from oxygen consumption rather than from carbon dioxide output. The thermal equivalent of oxygen when carbohydrate (mainly starch) is being burned is generally given as 5.04 and the corresponding value for fat is about 4.68. The thermal equivalent for protein varies; it has been given by Loewy as 4.683 and by Benedict and Fox as 4.60. For practical purposes an average value of about 4.5 Calories per liter of oxygen may be used for protein.

OXYCALORIMETER. Another type of apparatus used to determine the energy value of foodstuffs is the *oxycalorimeter* (fig. 44.3) devised by F. G. Benedict. Although less accurate than the bomb method, this procedure is useful for determining the energy value of actual meals. The sample is burned in a combustion chamber connected to a gas holder containing oxygen. The carbon dioxide is absorbed, permitting measurement of the volume of oxygen used. From the thermal equivalent of a liter of oxygen when used to burn the three primary foodstuffs (table 44.5), a value may be calculated for the heat available from the particular sample of food. This is an adaptation of the method of *indirect calorimetry* used in the clinic (see p. 780).

Since the Calories liberated per liter of oxygen used in the combustion of foodstuffs in the oxycalorimeter vary only between 4.5 and 5.0, the use of a mean figure of 4.8 will result in values with an error no greater than 5 per cent of the true (bomb) value. If the foodstuff is predominantly of one type, choice of a more appropriate factor (e.g., 5.0 for a starchy food, or 4.5 for a protein rich one) gives a value very close to the true one.

In the body the caloric value of oxygen varies similarly between 4.5 and 5.0, depending upon the type and proportion of foodstuffs being oxidized. Because the respiratory quotient gives an indication of this ratio, it will be discussed next.

The Respiratory Quotient

The ratio, vol CO_2 expired / vol O_2 used, is called the respiratory quotient or, briefly, the R.Q. Different relative amounts of carbon, hy-

FIG. 44.2 The bomb calorimeter consists of three vessels (1, 2, 3) one inside the other. The outer vessels (1 and 2) are usually of a plastic composition and serve merely to provide insulating dead air spaces. The innermost vessel (3) is of highly polished metal and contains a known weight of water in which the bomb (4) is immersed while the foodstuff is being burned. The top (5) of the bomb screws off to permit a known weight of dried foodstuff to be placed in the crucible (6). The top is replaced and through a valve oxygen under pressure of about 300 pounds per square inch is introduced. The foodstuff is ignited by means of electrical leads (7, 8). The water is mixed (stirrer, 9) and its rise in temperature is measured by the thermometer (10).

drogen and oxygen are contained in the molecules of carbohydrates, fats and proteins. Therefore, different characteristic amounts of oxygen are required to oxidize the constituent carbon and hydrogen to carbon dioxide and water. In the case of proteins, part of the sulfur may be oxidized to sulfate, thus using up slightly more oxygen without any concomitant production of CO_2 .

CARBOHYDRATE. The complete oxidation of glucose may be represented by the equation

TABLE 44.4

Data required to calculate the R Q and thermal equivalents of typical food components

Muscle protein ^c			4.23	0.981 ^d	0.774 ^e	0.79	4.32	5.43

* Fucose is an example of a desoxyhexose, C₆H₁₂O₅.^b Leucine—energy content (bomb)—855.6 Cal./mole—physiological oxidation: $2\text{C}_6\text{H}_{13}\text{O}_5\text{N} + 15\text{O}_2 \rightarrow \text{CO}(\text{NH}_2)_2 + 11\text{CO}_2 + 11\text{H}_2\text{O}$ —energy content (physiol.)/mole = $\frac{(2 \times 855.6) - 151.6}{2} = \frac{1559.6}{2} = 779.8$ ^c Physiological value calculated according to Loewy (as modified in text)^d It is customary to determine urinary N as a measure of protein metabolism. As shown in table 44.6, 1.00 gram of urinary N in the case of this particular protein arose from the catabolism of 100/16.28 = 6.14 grams protein requiring $6.14 \times 0.981 = 6.02$ liters of O₂ (STP) for its metabolism.^e Similarly CO₂ produced per gram of urinary N = $6.14 \times 0.774 = 4.75$ liters (STP)

Since 1 gram molecular weight of any gas occupies 1 gram molecular volume (22.4 liters at standard temperature and pressure (S.T.P.)) it will be apparent that 180 grams of glucose require 134.4 liters of O₂ and that 1.00 gram would, therefore, require 0.746 liter, or approximately 0.75 liter. Similarly it may be calculated that 0.75 liter of CO₂ would be produced. Thus the R Q is 0.75/0.75 = 1.00. One may use the ratios of the number of Gram Molecular Volumes (G.M.V.) directly, as a chemist would do, R Q = 6/6 = 1.00.

For starches, the equation would be

$$\text{R Q} = \frac{6n \text{ G.M.V. CO}_2}{6n \text{ G.M.V. O}_2} = 1.00$$

FAT The fats, being more highly reduced compounds than the carbohydrates, have a higher energy content. Because of their lower oxygen content, they require more oxygen per gram for their combustion. Equations for the complete oxidation of several fats are as follows:

$$\text{tributyrin R Q} = 30/37 = 0.881$$

$$\text{tristearin R Q} = 114/163 = 0.699$$

$$\text{trolein R Q} = 57/80 = 0.713$$

The mixed fats of the food, when burned in the body, are generally taken to have an R Q of 0.71.

PROTEIN Amino acids are not oxidized completely in the body, as mentioned earlier. Approximate values for O₂ consumed and CO₂ produced may be calculated as follows. Assuming complete oxidation, glycine would react thus:

Such a reaction does not occur in the body, however, 40 per cent of this substance is excreted as urea. Assuming excretion of all the nitrogen of glycine in the form of urea, the equation for the partial oxidation would be

One mole of urea, on combustion, liberates 151.6 Calories

This energy does not become available to the organism because the urea is not oxidized in the body. Therefore the energy liberated in the physiological (partial) oxidation of glycine shown in the second equation is $(938.0 - 303.2) = 634.8$ Calories per 4 moles of glycine, or 158.7 Calories per mole (2.12 Calories per gram). Because of its relatively large oxygen content, glycine is an atypical amino acid. Corresponding calculations for leucine give the data shown in table 44.4.

A typical meat protein (according to Loewy) analyzed as shown in table 44.6, and the constituents contained in the urine and feces per 100 grams of ingested protein are shown in the third column.

The carbon and hydrogen unaccounted for in the excreta were presumably completely oxidized

^b Depends on the fatty acid. For short chain fatty acids this value is greater, e.g. for trihydroxyrins 2.41.

TABLE 44.6

Data used in calculation of R.Q. for oxidation of protein

(After Loewy.)

All values are expressed in grams per 100 grams meat protein

Constituent	Constituent Ingested	Excreted in Urine and Feces	Portion Not Excreted
C	52.38	10.88	41.50
H	7.27	2.87	4.40
O	22.68	15.00	7.68
N	16.65	16.65 ^a	
S	1.02 ^b	1.02 ^c	

^a The bulk of this nitrogen (16.28 grams) was in the urine. Therefore 100 gram urinary N represents 6.14 grams meat protein.

^b Present as sulfide (methionine) and disulfide (cysteine).

^c Present mainly as ethereal sulfate.

because none of the nitrogen was retained and therefore probably all the protein was completely burned in the body. The 7.68 grams of oxygen not excreted may be assumed to have oxidized an equivalent amount of hydrogen $(2/16 \times 7.68 = 0.96 \text{ grams})$ to form what is sometimes called "intramolecular water," i.e., H₂O formed from H and O in the parent molecule. This would leave $4.40 - 0.96 = 3.44$ grams hydrogen and 41.50 grams carbon to be oxidized.

41.50 grams C require 110.6 grams O₂ and produce 152.2 grams CO₂.

3.44 grams H require 27.5 grams O₂.

Total CO₂ produced 152.2 grams = 77.4 liters at S.T.P.

Total O_2 required 138.1 grams = 96.7 liters at STP

Loewy's estimated RQ for this protein = 77.4/96.7 = 0.80

Loewy made no allowance for oxygen used in the oxidation of sulfur. The chemistry of cystine was not well understood at that time and methionine was unknown, but it is odd that the conversion of organic sulfur to SO_2 was not considered. For simplicity we may use H_2S for writing the equation because the sulfur atoms of methionine and of cysteine are both at the same oxidation level as that in H_2S .

32 grams S require 64 grams O_2 (= 44.8 liters at STP)

1.02 grams S require 2.04 grams O_2 (= 1.43 liters)

Total O_2 used for this protein = 138.1 + 2.04 = 140.14 grams = 96.7 + 1.4 = 98.1 liters. Revised estimate for RQ of this protein

$$77.4/98.1 = 0.79$$

The portion used for the oxidation of protein sulfur is small, probably always less than 1.5 per cent of the total oxygen requirement for protein, for practical purposes it may be neglected. Different proteins have different RQ's, as do different fats and carbohydrates, but the values remain close to the commonly used figure of 0.80.

Because alcohol sometimes provides energy for man it may be of interest to note that the RQ of ethanol is 0.67.

The value of the respiratory quotient is taken as an indication of the type of food being metabolized. It gives no quantitative estimation of the metabolism. An RQ around unity is taken to indicate that the material being used is chiefly carbohydrate, one around 0.70 indicates that it is mainly fat.*

On an ordinary mixed diet the RQ is about 0.85 and in the postabsorptive state (p. 764) about 0.82. In the formation of fat from carbohydrate, as in the fattening of farm animals, an oxygen-rich substance is being converted into one poor in oxygen. Oxygen is "liberated" in the conversion and less, in consequence, is taken in from the outside for general oxidative processes. The RQ may therefore rise above unity (up to 1.4). A very low quotient, as is seen in the hibernating animals, is supposed by some to indicate the reverse process, i.e., the conversion of fat to carbohydrate. In the hibernating marmot the RQ is between 0.6 and 0.7.

* Catheart and Markowitz point out, however, that probably too much reliance has been placed upon the value of the RQ as an unequivocal criterion of the type of foodstuff undergoing metabolism. The RQ in a given instance is undoubtedly a resultant of several different metabolic processes, syntheses and interconversions as well as combustion.

CALORIMETRIC MEASUREMENTS IN ANIMALS AND MAN

An animal's energy is derived from the food, which is to the body what fuel is to a furnace or machine.* We have seen that the law of conservation of energy holds true for the animal body in a healthy animal which is maintaining a constant weight the intake and output of energy are equal. The food undergoes combustion in the tissues, its carbon being oxidized to carbon dioxide, its hydrogen to water and its potential energy being converted into other forms of energy (mechanical, electrical, chemical and thermal). In a growing animal or in an animal during fattening the energy of the food is in part stored as newly formed tissue.

In the resting body all the energy liberated from the food ultimately appears as heat. It was for this reason that a heat unit was chosen as the most convenient one for measuring and expressing the energy exchanges of the body. This unit, the *large calorie* (Calorie or Cal) is 1000 times the *small calorie* (calorie or cal) used in physical measurements.

Calorimetry in man and animals involves two main types of procedure: (a) *direct*, the same in principle as that described above for the bomb calorimeter, and (b) *indirect*, in which the heat production is calculated from the respiratory exchanges. The latter is commonly used, the former rarely.

DIRECT CALORIMETRY. Respiration calorimeters permit measurement of the gaseous exchange and simultaneous heat production. The apparatus (fig. 44.4) designed by Atwater and Rosa (1897) was of such technical perfection that when a known quantity of alcohol was burned in it the resulting carbon dioxide was recovered with an accuracy of 99.8 per cent and the heat to 99.9 per cent of the theoretical value.

The elaborate nature of the apparatus required for this method precludes its use, especially for

* It may be well to remember that the analogy between *fuel for machines* and *food for men* (or animals) must not be pushed too far. Nutrition involves more than chemistry and physics. The available energy of a single foodstuff cannot be estimated without considering the adequacy of other factors in the diet, the effect of other factors on absorption (availability) and the level at which the nutrient is being fed.

FIG 414 The Atwater Rosa Benedict respiration calorimeter has two functional parts one for measuring the heat production of the subject the other for measuring the gaseous exchange. An air tight copper box or small room (1) which is essentially a constant temperature water cooled calorimeter is surrounded by a second copper box (2) and the whole is insulated by an outer layer of cork (3). This construction results in two insulating dead air spaces (4, 5). Rosa placed thermocouples (6) in series between the two copper walls on the tops, sides and bottom to detect differences in temperature. When the inner and outer copper walls have the same temperature there can be no heat exchange between them. If the temperature of the outer wall increases it is quickly restored to that of the inner wall by a cooling current of water run through pipes (not shown) between the outer copper wall and the insulating wall. A fall in temperature of the outer wall is corrected by electrical warming of this interspace. The heat produced by the subject would cause the temperature of the chamber to rise unless the heat could be removed in some way. This is accomplished by allowing a current of cold water to flow through the copper tubes (7) suspended from the ceiling at such a rate as to maintain a constant temperature in the chamber. Thermometers on the water intake (8) and outlet (9) give the temperature change. The volume of water which has passed through the cooling system is collected in a vessel (10) and weighed. The weight of water (in kilograms) multiplied by the temperature change in degrees Centigrade gives heat lost by radiation and conduction. To this must be added the latent heat present in the water vapor of the insensible perspiration and exhaled air (about one quarter of the total heat produced by a man). The amount of this water is determined by weighing the first sulfuric acid absorber (11) before and after the experiment. The heat so carried out is calculated knowing the latent heat of vaporization of water at 20°C to be 0.585 Calories per gram.

The same apparatus can be used to determine the gaseous exchange of the subject. In principle the procedure is as follows: air from the chamber is passed through the first sulfuric acid absorber to remove the water vapor, then through a moist soda lime absorber to remove carbon dioxide. A second sulfuric acid absorber takes up the moisture liberated from the soda lime. The gain in weight of the last pair of absorbers equals the carbon dioxide produced by the subject. The oxygen used is determined by adding sufficient oxygen to a spirometer (12) to maintain a constant pressure in the system and by weighing the oxygen cylinder before and after the experiment. The circulation of the air in the system is maintained by a fan (13). A window (14) permits observation of the subject. Thermometers (not shown) record the temperature of the room and of the subject.

the human subject in any ordinary laboratory or clinic. There are indeed only a very few in existence.

The calorimeter consists of an insulated chamber large enough to accommodate an animal or a man. The heat conducted and radiated from the

body is absorbed by water circulating in coils of copper pipes. The temperature of this water as it enters and leaves the chamber being known and also its quantity, the heat production in Calories can be determined. To this must be added the energy carried out by the water vapor

given off by the lungs and skin. This amounts to about one-quarter of the total heat production. (Further details about the apparatus and the calculations are given in the legend, fig 444.) A calorimeter of this type is usually combined with apparatus for determining the heat production by indirect calorimetry as described below, the instrument being then referred to as a respiration calorimeter.

INDIRECT CALORIMETRY The heat production of the body during a given period can be estimated using the thermal equivalents if one knows the quantity of oxygen consumed or of carbon dioxide produced during that time. As mentioned above, the estimate is more reliable when based upon oxygen consumption. Even so, the

* This table has been further modified by Cathart and Cuthbertson, see *J. Physiol.*, 1931, 72, 349.

food mixture undergoing combustion, as indicated by the R.Q., must be taken into account. The heat or caloric values (thermal equivalent) of a liter of oxygen at different respiratory quotients is given in table 447 compiled by Zuntz and Schumberg (as modified by Lusk).

In table 447 the percentages of fat and carbohydrate undergoing combustion have been calculated for respiratory quotients ranging from 0.707 to 1.00. These so-called *nonprotein respiratory quotients* were obtained by determining the total oxygen consumption and carbon dioxide produced and then subtracting the volumes of these gases exchanged in the catabolism of protein. The quantity of protein undergoing catabolism is obtained from the urinary nitrogen, each gram of the latter being considered, by convention, equivalent to 6.25 grams of protein. In precise experiments upon heat production, the calories produced from the catabolism of protein as well as those derived from fat and carbohydrate would require to be determined. For example, a subject may be found to produce per hour 13.50 liters of carbon dioxide, consume 16.00 liters of oxygen and excrete 0.50 gram of nitrogen in the urine. According to Loewy's data, each gram of urinary nitrogen represents the production of 4.75 liters of carbon dioxide and the consumption of 6.02 liters of oxygen (table 444, footnote).

Therefore

CO₂ produced by the subject in the catabolism of protein is $0.50 \times 4.75 = 2.38$ liters

O₂ consumed in the catabolism of protein is $0.50 \times 6.02 = 3.01$ liters

Then

non protein CO₂ production is $13.50 - 2.38 = 11.12$ liters

non protein O₂ consumption is $16.00 - 3.01 = 12.99$ liters

the nonprotein respiratory quotient is

$$11.12/12.99 = 0.86$$

It will be seen from table 447 that at this R.Q. the caloric equivalent of a liter of oxygen is 4.875. The heat produced by the combustion of non protein materials is therefore $12.99 \times 4.875 = 63.3$ Calories of which 54.1 per cent is derived from carbohydrate and 45.9 per cent from fat.

The heat production due to protein is $3.01 \times 4.59 = 13.5$ Calories. As will be shown in the section on *Energy Balance* this may be estimated in another way, the caloric equivalent of each gram of urinary N is 26.4, so the heat production

due to protein may also be obtained approximately by multiplying the figure for the urinary nitrogen (0.50) by 264 = 132. The average value may be taken as 134 Calories.

The total heat production per hour is therefore $633 + 134 = 767$ Calories. Of this 342 Calories or 45 per cent are derived from carbohydrate, 291 Calories or 38 per cent from fat and 17 per cent from protein.

In ordinary determinations of the basal metabolic rate (p. 765) urinary nitrogen is not measured and the foregoing calculations are not undertaken, only a slight error is involved if the R.Q. is assumed to be 0.82 and the heat production taken directly from table 44.7.

THE ISODYNAMIC LAW It was demonstrated by Rubner that just as the production of heat by a stove may be maintained at a constant level by burning different types of fuel, so in the generation of animal heat the different foodstuffs may replace one another in the diet in accordance with their heat producing values. The amounts shown of the following substances are isodynamic:

100 grams of fat	$\times 9$	= 900 Calories
225 grams of starch	$\times 4$	= 900 Calories
225 grams of protein	$\times 4$	= 900 Calories
128 grams of ethanol	$\times 7$	= 900 Calories

HEAT PRODUCTION IN RELATION TO SURFACE AREA The heat produced by an individual at rest is proportional to the surface area of his body. Thus a fasting adult man and a starving dog, although the surface area of each and the total heat production were widely different, were shown by Rubner to give out in 24 hours closely similar amounts of heat per square meter of body surface, namely, 1134 and 1112 Calories respectively. A small animal, e.g., a mouse, therefore, since its surface area is greater in proportion to its mass, and since it generates the same amount of heat per unit of body surface, must obviously generate more heat per unit of body weight than a larger animal. The heat is produced in the tissues (muscles, liver, etc.), consequently these, in the case of the smaller animal, must be the seat of a much more active metabolism (see table 44.8).

The shape of an object controls its surface area per unit weight. A sphere has the least surface area per unit of mass. The area of a cube is also relatively small, that of a thin sheet reaches the maximum. A few examples will illustrate the variation. A sphere (of material with density = 1) weighing 1000 gm. would have a radius of 6.20

TABLE 44.8

Showing relation of heat production per kilogram and per square meter of body surface in animals of different sizes

	Weight kg	Calories	
		Per kilogram	Per square meter surface
Ox	391	19.1	1567
Pig	128.0	19.1	1078
Man	64.3	32.1	1042

Mouse	0.018	654.0	1188

* The relatively low figures for the heat production of birds shown in the last column is due to their bodies containing a high proportion of osseous tissue which has an extremely low metabolism.

cm and a surface area of 484 sq. cm. A cube of the same weight would have an area of 600 sq. cm. An elongated cylinder (31.9 cm. by 6.32 cm. in diameter) would have a surface area of 694 sq. cm., the same amount of material in the form of a squat cylinder (20 cm. diameter by 3.18 cm.) would have an area of 828. A rectangular block of the same weight (5 by 10 by 20 cm.) would have an area of 700 sq. cm., a thick sheet (0.2 by 10 by 500) would have 10,204 and a thin sheet (0.01 by 200 by 500) would have approximately 200,000 sq. cm. Elliptical bodies with cylindrical appendages have a surface area per unit of weight intermediate between that of a sphere and an elongated cylinder.

PHYSIOLOGICAL CONDITIONS WHICH STIMULATE METABOLISM The heat production of the body is increased by (a) muscular work, (b) food, (c) a fall in environmental temperature, or (d) a rise in body temperature (fever). These influences will be considered later.

Indirect Calorimetry Determination of the Heat Production from the Respiratory Exchanges

The results of indirect calorimetry agree within less than 1 per cent with those obtained by the direct method. Two forms of apparatus—the closed-circuit and the open-circuit or air-current types—are employed for indirect calorimetry. In the closed-circuit method the subject breathes the air contained in a closed system, the carbon dioxide eliminated by the subject is re-

moved by soda-lime and weighed, a measured volume of oxygen is supplied to replenish that which has been absorbed. In the *open-circuit* type, the subject inspires room air and expires into some form of container the entire volume of expired air is measured and a sample analyzed for its carbon dioxide and oxygen percentages. Among the closed-circuit types of

apparatus are those of Regnault and Reiset, and of Benedict and associates. The Douglas bag and Tissot methods are of the open-circuit type. In Haldane's method for small animals, although it is of the open-circuit or air-current type, the carbon dioxide is absorbed and weighed.

CLOSED-CIRCUIT METHODS In the Regnault-Reiset type of apparatus, the air is circulated through a closed system of which a chamber, large enough to accommodate the subject, forms a part. Only a few institutions on this continent, such as the Russell Sage Institute in New York and the Nutrition Laboratory at Washington, possess an apparatus of this type (Atwater-Rosa) suitable for metabolic studies upon man. It is usually combined with an apparatus of the direct type. The construction of a closed-circuit type of apparatus for laboratory animals is not, however, such a difficult matter (fig. 44.5). The air in the system is rebreathed repeatedly, carbon dioxide and water vapor being removed and oxygen supplied to replace that consumed. The quantity of carbon dioxide eliminated by the animal is given by the difference between the weights of the soda-lime container at the beginning and end of the experiment. Oxygen is run into the system from a cylinder and meas-

FIG. 44.5 Schematic outline of respiration apparatus for small animals. The air leaves the chamber at A and after passing through the rotary blower B, which keeps the ventilating current in motion, is forced through the glass vessel C, which serves as a safety trap. The air then passes through the bottles D and E containing sulphuric acid to remove the moisture. The air, now water free, but containing the CO_2 produced by the animal and lacking the O_2 which the animal has consumed, passes into the 2 way valve V_1 , where it may be deflected into the bottle F containing soda lime for the absorption of CO_2 . The moisture gained from the soda lime is absorbed by sulphuric acid in bottle G. The air then passes through a second 2 way tap V_2 , to H containing dry sodium bicarbonate which removes the traces of acid vapor taken up by the air in passing through bottle G. J is a glass vessel containing water which supplies sufficient moisture to the air for the comfort of the animal. K is a 3 way valve. The chamber is constructed of copper and has a cover with a water seal M. N is a glass plate through which the animal can be observed. O is a spirometer attached to the system on the intake side of the rotary blower B. (From F. G. Benedict.)

FIG 446 Benedict Roth apparatus (courtesy of Warren E. Collins, Inc., Boston)

ured by means of a gas meter or by weighing the cylinder at the beginning and end of the experiment. The air in the chamber is analyzed at the end of the observation in order to ensure that no change in its composition has occurred.

In other closed-circuit methods, such as the one described below, the subject is not enclosed within a chamber, he simply breathes in and out of the apparatus through a connecting tube.

Clinical types of closed-circuit apparatus In the earlier clinical types the subject was connected by means of a mouthpiece and flexible tubing to the closed system and both carbon dioxide elimination and oxygen usage were determined. In the type most commonly used today—the Benedict-Roth apparatus (figs 446 and 447)—the heat production is calculated from the oxygen consumption alone. In order to purify the air the carbon dioxide is absorbed by soda-lime but the amount of this gas eliminated is not measured. In determining the basal metabolism (p 764) the subject lies upon a couch and breathes in and out of the instrument through a mouthpiece and two wide-bore tubes (inspiratory and expiratory) provided with valves. The nose is clipped. The main part of the instrument consists of a bell type spirometer. This is a hollow double-walled cylindrical vessel. In the narrow space between the two walls fits a second inverted hollow cylindrical vessel or bell. The bell is counterpoised so that it rides easily up or down in the annular space between the two walls. This space contains water which acts as a seal.

At the commencement of the experiment, sufficient oxygen is admitted from an oxygen cylinder to raise a pointer on the spirometer bell to the zero mark upon an adjoined scale which has been calibrated to oxygen volumes. The breathing of the subject through the inspiratory and expiratory tubes keeps the air circulating freely through the system. As oxygen is consumed the spirometer falls and from the difference in the levels of the pointer at the beginning and end of the experiment the oxygen usage is calculated. The volume of oxygen used, dry and reduced to standard temperature and pressure (see p 457) is then calculated. The heat production is found by reference to the table of respiratory quotients given on page 756.

The RQ of the subject is not determined. The average RQ in the postabsorptive state (see p 764) (0.82) is assumed. It will be seen from table 447 that at this RQ the caloric equivalent of 1 liter of oxygen is 4.825.

OPEN-CIRCUIT OR AIR CURRENT METHODS In the *Haldane* type of calorimeter (which is suitable only for small animals, mice, rats or rabbits)

FIG 447 Sectional view of Benedict Roth closed circuit respiration apparatus

FIG 44 8 Haldane's respiration apparatus 1 and 4, soda lime, 2, 3 and 5 pumice stone soaked in sulphuric acid, Ch, animal chamber, M, meter J is an inverted bell jar standing in a trough of water it serves to prevent sudden excess of negative pressure and to indicate the pressure actually employed P, pump (After Haldane)

a current of air is drawn through the system (fig 44 8) Carbon dioxide and water are removed from the air before it enters the chamber and again after its exit therefrom. The carbon dioxide absorber on the outgoing current of air is weighed at the commencement and end of the experiment as in the Regnault-Reiset method, in order to obtain the quantity of carbon dioxide eliminated. The system with the exception of the first pair of absorbers and including the animal is then weighed. Since only oxygen has entered this part of the system (the air being CO-free and dry) the gain in weight during the

experiment gives the quantity of oxygen consumed by the animal.

The Douglas bag and Tissot methods (gasometric methods) In these methods the subject inspires atmospheric air and expires into a bag (Douglas method) or into a large bell-type spirometer (Tissot method). At the end of the experiment the total volume of expired air is measured and samples are analyzed for carbon dioxide and oxygen (figs 44 9 and 44 10).

Gas analysis The sample of expired air is drawn into the graduated burette of a Haldane gas analysis apparatus, saturated with water vapor and its volume measured (fig 44 11). It

FIG 44 10 Diagram of Tissot spirometer

It is sometimes useful to be able to estimate the energy obtained from dietary protein using the so-called calorie equivalent of each gram of urinary nitrogen. In Rubner's experiment 15.16 grams of urinary N were excreted when 400 Calories were liberated from the ingested protein. Thus each gram of urinary N corresponds to about 26.4 Calories retained by the body.

Atwater and his colleagues in America analyzed urines from 46 persons and measured the heat of combustion of the organic residue. For every gram of nitrogen in the urine they found unoxidized material sufficient to yield 7.9 Calories. This value is close to Rubner's estimate of 7.5. It represents about 1.25 Calories per gram of protein absorbed, if the person is in nitrogen equilibrium.

The Basal Metabolic Rate (B.M.R.)

This is the term applied to the heat production of a subject who though awake is as nearly as possible at complete muscular and mental rest, and is in the *postabsorptive* state (i.e., from 12 to 14 hours after a light meal when, it is assumed, the digestive processes are quiescent). The room temperature should be 20°C. For example, the prospective subject of a basal rate determination is directed to refrain from undue muscular exertion or fatiguing effort of any kind for 24 hours previously. A light meal with the minimum amount of protein is taken not later than 7 o'clock the night before the test which is undertaken at about 9 o'clock in the morning. For a period of 30 minutes or so before, as well as during the test the subject should be lying down comfortably in a room with subdued lighting.

The apparatus most commonly employed for the determination of the basal metabolic rate in the clinic is the instrument of Benedict and Roth (p. 760). Tissot's method or the bag method of Douglas is also sometimes used.

BASAL METABOLIC RATE STANDARDS

We have seen that the metabolism is proportional to the body's surface area rather than to its weight (p. 757). Of two men of the same weight, one tall and lean and the other short and stout, the former will have a greater heat production. It is possible that this explains, in part at least, why a man of thin build often eats more than a stouter man of about the same weight. Since normal adults do not differ very greatly in size and shape, it may be stated as an

approximation that the heat production of the human body is one Calorie per kilogram per hour. But for the reasons just given it is much more accurate to express the basal metabolism in terms of body surface. Thus, the average basal rate of normal men between the ages of 25 and 50 years is from 40 to 37 Calories per square meter of body surface per hour. This value is constant for all normal men whether they are tall, short, thin or stout, large or small. Knowing a subject's height and weight his surface area can be determined at a glance from the chart (fig. 44.12), or from table 44.12, or it may be calculated from the height-weight formula.⁷ The average surface area for adults in Canada and the United States is about 1.6 square meters for women and 1.8 for men, the total basal heat production of the majority of normal adults ranges from 1400 to 1800 Calories per day.

The heat production per square meter of body surface is arrived at by dividing the value for the total heat production per hour of the subject, as determined by one or other of the methods already described, by the figure for the surface area. For example, a man 175 cm tall weighing 75 kg has a surface area of 1.91 sq meters. His total heat production is, say, 7620 Calories per hour. His heat production per square meter per hour is therefore

$$\frac{7620}{1.91} = 3984 \text{ Calories}$$

⁷ The formula introduced by Meeh and modified by Du Bois and Du Bois is as follows:

$A = W^{.725} \times H^{.725} \times 71.84$ (a constant)
where A = surface area in square centimeters
W = weight in kilogram and H = height in centimeters

TABLE 44 13

Basal and total metabolic rates of males and females

40	38.0	35.0	1641	1344	3000	2400

tuations do occur which have contributed to the difficulty of drawing conclusions

3 **HABITS** Owing to the greater development of their muscular tissues athletes and laborers have in general a higher B.M.R. than persons leading a sedentary life

4 **PREGNANCY** The basal metabolic rate of the pregnant woman shows little change until the sixth or seventh month when the fetus causes an appreciable increase in the weight of the mother. The metabolism of the mother from this time to term is the sum of her own metabolism in the nonpregnant state and that of the fetus. It was found by Murlin and Carpenter, for example, that the metabolism of the new born infant and the postpartum metabolism of the mother added together practically equaled the metabolism of the pregnant state near the end of term. Boothby and Sandiford estimated the surface area of the fetus throughout gestation and concluded that the excess heat production of the pregnant state was derived from the fetus and the increased mass of the maternal structures, the energy production per unit of mass of the maternal organism remaining constant. Normal pregnancy, then, exerts little or no specific effect upon the basal metabolic rate

5 **DIET** The nature of the diet seems to have little influence upon the B.M.R., although in

strict vegetarians it is said to be some 11 per cent lower than that of meat eaters

6 **VARIATIONS IN BAROMETRIC PRESSURES** A moderate reduction in oxygen pressure does not affect the metabolic rate, but a reduction in the latter occurs which varies by from 5 to 20 per cent in different subjects when the barometric pressure falls to half an atmosphere (O_2 pressure 75 mm Hg). This is around the barometric pressure at which mountain sickness usually appears (ch 33). Breathing excessively high tensions of oxygen does not raise the B.M.R. above the normal level. That is, the oxygen consumption cannot be raised simply by increasing the oxygen supply

7 **CHEMICAL SUBSTANCES** Caffeine, adrenaline, thyroid extract or thyroxine, benzedrine, and dimetophenol raise the basal metabolic rate. Smoking a cigarette especially if the smoke is inhaled increases the metabolism of most subjects, the average increase being around 9 per cent

B Pathological

1 The B.M.R. is below normal in the following conditions

- Starvation and undernutrition (ch 50)
- Obesity due to pituitary or hypothalamic disorders (chs 50 and 56)
- Hypothyroidism (myxedema ch 57)
- Addison's disease
- Lipoid nephrosis
- 2 Conditions with a high B.M.R.
- Hyperthyroidism (exophthalmic goiter ch 57)
- Fever (ch 52) The basal rate is raised about 7 per cent for each degree (Fahrenheit) rise in temperature
- Diabetes insipidus (ch 56)
- Cardio renal disease with dyspnea (+25 to +50 per cent)
- Leukemia (+21 to +80 per cent)
- Polycythemia (+10 to +40 per cent)

INFLUENCES WHICH RAISE THE METABOLISM OF A NORMAL INDIVIDUAL ABOVE THE BASAL LEVEL

We have already seen that the basal metabolism is defined as the heat production of a subject as nearly as possible at complete physical and mental rest some hours after food and with the room temperature at about 20°C. These three factors—muscular exercise, the ingestion of food and environmental temperature—have a powerfully stimulating influence upon metabolism

Muscular and mental effort Even light muscular exertion, e.g., sitting, standing, dressing and

TABLE 44 14

Extra Calories of metabolism per hour attributable to occupation

Typist, 50 words per minute	21
Seamstress, using sewing machine	57
Bookbinder	63
Housemaid (moderate work)	81
Laundress (moderate work)	124
Housemaid (hard work)	157
Laundress (hard work)	214

undressing, sewing, etc., raises the metabolism by from 25 to 60 per cent above the basal level. Moderate exercise, such as walking, swimming, housework, light carpentry, etc., raises it from 100 to 200 per cent, and very hard work may increase it from 10 to 15 times over the basal level. Henderson and Haggard found that in three members of the Yale University boat crew, the total heat production during rest amounted to 1.65, 1.42 and 2.4 Calories per minute respectively. The corresponding values during strenuous exercise on a rowing machine were 18.90, 21.83 and 29.37 Calories per minute. The extra energy expenditure caused by various occupations is shown in table 44 14. Mental effort, on the other hand, causes an almost negligible increase in metabolism. Benedict, for instance, after a series of experiments in which intense mental effort was expended in solving mathematical problems found an increase of only 3 or 4 per cent. He states, "The clustered scholar at his books may be surprised to learn that the extra Calories needed for one hour of intense mental effort would be completely met by the eating of one oyster cracker or one half of a salted peanut." The basal oxygen consumption of the brain however, is high (p 1134), amounting to about 10 per cent of that of the entire body. Strong emotion may raise the metabolism from 5 to 10 per cent above the basal level.

During sleep, when the muscles are more completely relaxed than is possible during the waking day the metabolism falls below the basal level. The reduction amounts to from 10 to 13 per cent (Strictly speaking, the metabolism during restful sleep, since it is the physiological minimum, is the true basal level.) If sleep is disturbed and associated with muscular activity the metabolism may be as high as or even higher than the "resting level" conventionally referred to as the basal level.

The influence of food and of environmental temperature (pp 787 and 891) upon metabolism are dealt with elsewhere.

PROTEIN METABOLISM

General Description and Classification of Proteins

Protein is a fundamental component of protoplasm and consequently forms a proportion of all living tissues—animal or vegetable, it is the predominant solid component of some tissues, e.g., muscle. It differs from the other foodstuffs—carbohydrates and fats—in containing (in addition to carbon, hydrogen and oxygen) nitrogen, sulfur and sometimes phosphorus. The molecules of certain proteins contain a prosthetic group, e.g., hemoglobin, glycoproteins, leucithoproteins, nucleoproteins, etc.

A classification and brief description of the various types of protein are given in table 45 1

The Protein Molecule

The protein molecule is constructed of a number of units linked together. These units or 'building stones' are called amino acids. They are separated when the protein molecule is hydrolyzed by boiling with acid or alkali, or by the action of the digestive enzymes (proteases). Some 25 different amino acids have been definitely identified as constituents of the protein molecule (see table 45 2). Some proteins contain nearly all of these in varying proportions, in others such as gelatin there are only 14 or 15 different kinds, some essential amino acids being missing, whereas such simple proteins as the protamines, sturine and salmine, contain only 3 and 4, respectively. The single amino acids have molecular weights ranging from 75 for glycine to over 200 for tyrosine and nearly 800 for thyroxine. The molecular weights of those proteins composed of large aggregations of amino acids are correspondingly great and extend over a very wide range. The molecular weight of egg albumin, for example, is 45,000, that of hemocyanin, over 6,000,000 and of tobacco mosaic virus, 40,000,000. Some basic proteins, protamines and histones, on the other hand, have molecular weights of about 2000 only.

Protein molecules also vary in shape. Studies of protein structure by means of X ray diffraction photographs reveal that the molecules of some proteins, such as keratin, collagen and myosin—the so-called *fibrous proteins*—have an elongated fiberlike form, resulting, it is believed, from the extended arrangement of the polypeptide linkages of which the molecule is constructed (see below). When stretched such molecules become elongated still further but return to their previous length when released from the stretching force. The changes in length are described as being due to folding and unfolding of the polypeptide chains in a concertinlike fashion. Other proteins—the *globular proteins*—such as egg albumin and the serum proteins, are composed of molecules which are folded or arranged into a lattice pattern to form a compact structure of a more or less globular shape. Unfolding and the assumption of a permanent extended form is associated with denaturation. Proteins of approximately the same molecular weight may differ considerably in their molecular structure and for this reason may show differences in such physical properties as elasticity, osmotic pressure and viscosity. The fundamental structure of all proteins is believed by Astbury to be fibrous, but the intermolecular arrangement of the polypeptide chains varies widely between different types and in the same protein under different conditions. Thus a variety of patterns is produced.

The average elementary composition of the molecule of a protein such as albumin or globulin is as follows: C, 54 per cent; H, 7 per cent; N, 16 per cent; S, 1 per cent; O, 22 per cent.

THE AMINO ACIDS

The amino acids may be regarded as derivatives of the saturated fatty acid series in which the α hydrogen atom has been replaced by an amino (NH_2) group, in the case of proline and hydroxyproline, the substitution is by an imino

(NH) group The simplest amino acid is amino-acetic (glycine or glycocoll)

and the structure of the other amino acids, with the exception of proline and oxyproline, may be represented by the following type formula

Amino acids therefore contain a basic (NH_2) group and an acid (COOH) group R represents a chemical group which varies greatly in size and structure. In the synthesis of the protein molecule chains of amino acids are formed by the linkage of the basic group of one amino acid with the acid group of another and the liberation of a molecule of water. Thus

The junction, CO—NH whereby amino acids become grouped together, is called the *peptide link* age. The reverse process, namely the separation of amino acids from one another is also effected at this link in the chain, a molecule of water first being taken up. This process is called *hydrolysis*.

Upon hydrolysis by heating with acid the ring is broken, and in the case of glycine anhydride the dipeptide glycyl glycine is formed

Glycyl glycine

Terminal amino acids of peptide chains always have a free polar group. At one end a carboxyl group is found (e.g., in the glycine moiety of alanylglycine or of glutathione), at the other end

Besides the chainlike combination of the amino acids in the protein molecule, a smaller proportion are believed to be united to form closed ring compounds—*diketopiperazines* (amino acid anhydrides). The amino acids undergo dehydration and unite by their free amino and carboxyl groups to form the diketopiperazine ring. In the example shown below two glycine molecules join to produce glycine anhydride

as a weak base or as a weak acid. In acid solution it acts as a base yielding cations to form protein chloride, sulfate, etc. When a current passes through the solution the amino acid cation migrates to the cathode or positive pole.¹ In alkaline solution it behaves as an acid, forming anions to produce a proteinate of sodium, potassium, etc. In an electric field the amino acid anion migrates to the anode. On account of these opposite reactions, depending upon the acidity or alkalinity of the solution, amino acids and the proteins which they compose are called *amphoteric electrolytes* or *ampholytes* (Gk. *amphō*, both). At a certain hydrogen ion concentration, which varies rather widely

¹ This migration in an electric field of cation and anions to the respective poles is called *electrophoresis* or *iontophoresis*.

TABLE 45 1

Class of Protein	Characteristics	Examples
<i>A Simple proteins</i>		
(1) <i>Albumins</i>	Soluble in water and coagulable by heat Present in both animal and plant tissues	<i>Serum albumin, egg albumin, lactalbumin</i> and various vegetable albumins such as <i>leucosin</i> (in wheat, rye and barley), <i>legumelin</i> in lentils, soy beans, beans and peas and <i>phaseolin</i> in kidney beans
(2) <i>Globulins</i>	Soluble in dilute saline solutions, insoluble in water Animal globulins are coagulated by heat Vegetable globulins imperfectly or not coagulated by heat	<i>Serum globulin, fibrinogen</i> (and fibrin) <i>vitellin</i> of egg yolk and vegetable globulins such as <i>exzelatin</i> (Brazil nuts), <i>edestin</i> (hemp), <i>phaseolin</i> (kidney beans), <i>legumin</i> (peas and lentils) and <i>tuberin</i> (potatoes) A number of other vegetable globulins have been isolated and named
(3) <i>Glutelins</i>	Found only in plants Insoluble in water, saline or alcohol, but soluble in very dilute alkali	<i>Glutenin</i> of wheat, <i>oryzenin</i> of rice and <i>glutelin</i> of maize
(4) <i>Prolamines or gliadins</i>	Found in cereals (except rice) Soluble in 70 to 90 per cent alcohol, insoluble in water They contain a large proportion of proline and compounds giving rise to ammonia nitrogen	<i>Gliadin</i> of wheat <i>hordein</i> of barley and <i>zein</i> of maize
(5) <i>Albuminoids or scleroproteins</i>	Especially resistant to the usual reagents They enter into the construction of protective and connective tissues e.g., skin, tendons ligments and bones	<i>Keratin</i> of hair, skin, bone, feathers, tortoise shell and eggshell <i>elastin</i> <i>collagen</i> <i>ossein</i> and <i>gelatin</i> of tendons, ligaments bone, etc
(6) <i>Histones</i>	Soluble in water and precipitated by ammonia solution and by alkaloids They contain a large percentage of diamino acids (p. 774)	<i>Globin</i> of hemoglobin, <i>thymus histone</i> , <i>scombron</i> and <i>gadus histone</i> in spermatozoa of mackerel and codfish respectively
(7) <i>Protamines</i>	Found in combination with nucleic acid in heads of fish spermatozoa Constructed predominantly of diamino acids	<i>Salmine</i> and <i>sturine</i> in spermatozoa of salmon and sturgeon respectively

B Conjugated proteins Proteins whose molecule is combined with another nonprotein group

(1) <i>Nucleoproteins</i>	Nucleic acid in combination with a protein belonging usually to the class of histones or protamines Found in cell nuclei	See ch. 47
(2) <i>Chromoproteins</i>	Protein in combination with a pigment (e.g., hematin) containing iron, copper or other metal	Hemoglobin, hemocyanin, etc
(3) <i>Glycoproteins</i>	Proteins other than nucleoproteins in combination with a carbohydrate group	<i>Mucin</i> in salivary gastric and intestinal secretions, <i>ovomucoid</i> of egg white and <i>chondromucoid</i> of cartilage
(4) <i>Lipoproteins</i>	Proteins in combination with lipid	Present in plasma, milk, cell nuclei
(5) <i>Phosphoproteins</i>	Proteins other than nucleoproteins and leucithoproteins in combination with a phosphorus containing group	<i>Caseinogen</i> (and casein), <i>vitellin</i> of egg yolk

TABLE 45 I—Continued

Class of Protein	Characteristics	Examples
<i>C Derivatives of proteins—derived proteins</i> These are produced by the action of acids alkalis or proteolytic enzymes upon certain of the proteins listed above		
(a) <i>Primary derivatives</i>		
(1) <i>Proteans</i>	Insoluble products formed in the early stage of the action upon proteins of water dilute acids and enzymes	
(2) <i>Metaproteins</i>	Formed in a later stage of the action of acid or alkali	Acid metaprotein alkali metaprotein
(3) <i>Coagulated proteins</i>	Formed by the action of heat or of alcohol upon solutions of proteins	
(b) <i>Secondary derivatives</i>		
(1) <i>Proteoses</i>	Formed by the action of pepsin or trypsin upon proteins They are soluble in water from which they are precipitated by saturation with ammonium sulfate They are incoagulable by heat	Albumose from albumen globulose from globulin caseose from casein
(2) <i>Peptones</i>	These represent a further stage in action of proteolytic enzymes They are soluble in water but are not precipitated from an aqueous solution by ammonium sulfate They are not coagulated by heat	
(3) <i>Peptides dipeptides tripeptides and polypeptides</i>	Products formed in the final stages of proteolytic digestion	Glycyl alanine leucyl glutamic acid etc

between different proteins the amino acids are electrically neutral and protein behaves neither as an acid nor as a base. In an electric field no migration either to anode or cathode occurs. The pH at which this occurs is known as the *isoelectric point* though the effect rather than being restricted to a point extends over a pH range which with some proteins is considerable. *Isoelectric zone* is therefore a better term (table 45.3). Within the isoelectric zone the solubility of the protein is least, here it is readily precipitated by alcohol, neutral salts and other reagents. Some proteins are quite insoluble at the isoelectric point and precipitate spontaneously. According to the classical conception the electrical neutrality of protein at the isoelectric point was due to ionization of the amino acids being at a minimum or absent as represented below in formula I. This view has

given place to the *Zwittersion theory* which more readily explains the experimental findings.

The Zwittersion theory This postulates that the amino acids at the isoelectric point carry equal numbers of positive and negative charges and this accounts for their electrical neutrality. They are called *zwittersions* (Ger *Zwitter* hemaphrodite) or *dipolar ions* (see formula II above). Much experimental support has been gained for this theory since it was first proposed.

The behavior of an amino acid (glycine) in acid and in alkaline solution according to the two conceptions is illustrated below (on p. 773). It will be seen that the end result on either side of the isoelectric point is the same according to either view. According however to the *Zwittersion hypothesis* the ampholyte molecule gives off at the isoelectric point equal numbers of basic and acid ions thus leaving ions—the so called *zwittersions*—holding equal numbers of negative and positive charges (formula II). Many proteins e.g. metaproteins, caseins etc. are almost insoluble at the isoelectric point—*isoelectric precipitation*.

The Absorption of Protein

Under ordinary circumstances only negligible amounts of unchanged protein, or even such of its derivatives as proteoses, peptones and polypeptides, are absorbed into the blood from the alimentary tract. Generally speaking the protein molecule must first be hydrolyzed into its constituent amino acids. These are absorbed from the small intestine but not from the stomach to any significant extent. They enter the circulation mainly through the portal blood, much smaller amounts pass into the lymph (chyle) and hence into the thoracic duct.

Small quantities of certain proteins, e.g., raw egg white and blood serum are sometimes absorbed from the intestine into the blood stream. They are excreted in the urine to a large extent unchanged. Such absorption which occurs more readily in young animals and children, should be regarded as a defect rather than as a physiological process. Nevertheless, experiments have shown that small quantities of protein introduced parenterally may be utilized by the tissues, and may even be capable of maintaining nitrogen equilibrium. It is, however, only for a short period and to a very limited extent that the body can utilize injected protein, for proteins are species specific and after a number of injections immunity is established to the foreign protein, an antibody known as a *precipitin* is formed which causes its precipitation. Furthermore, if a subsequent injection is given two weeks or so after a single injection or after the last of a series of such injections, a most serious toxic state—anaphylaxis—may ensue and

prove fatal. In the human subject such anaphylactic (or anaphylactoid) reactions may follow the second injection of a foreign protein e.g. diphtheria antitoxin (horse serum) or antitetanic serum. Skin rashes such as urticaria, erythema, eczema, giant edema, etc., or pain and swelling of the joints may occur. Collapse and death occasionally result. The sensitivity of some persons to certain proteins is also sometimes responsible for dietary idiosyncrasies. Certain foods such as shellfish, milk, strawberries, celery, etc., when ingested by persons sensitive to the proteins contained in these substances, result in cutaneous eruptions and sometimes localized edema. Minute amounts of the protein apparently enter the blood stream in an unchanged or partially digested state. Asthma, hay fever and other allergic conditions have been traced to foreign proteins (pollen cat or horse hair, feathers, etc.) entering the body through the respiratory passages.

Homologous plasma protein, on the contrary, does not cause these effects and Whipple and his associates found that dogs could be maintained in nitrogen equilibrium (p. 785) by the intravenous injection of plasma from other dogs as the sole source of protein.

A suitable assortment of amino acids, such as an hydrolysate of casein supplemented by cystine and tryptophane, injected intravenously, is capable of maintaining an animal in nitrogenous equilibrium. Animal gelatin or isinglass (fish gelatin) which differs from complete proteins in being nonantigenic, might be used for this purpose if supplemented by the missing amino acids.

The Fate of Amino Acids after Absorption

DEAMINATION This term means the removal of amino groups from the amino acids. Less than 20 per cent of the amino acids absorbed into the

portal blood pass through the liver unchanged into the general circulation. A very small proportion of these are excreted intact in the urine, some are deaminated by the kidney and the

TABLE 45 2

Classification of the amino acids

I ALIPHATIC AMINO ACIDS

A Monoamino monocarboxylic acids

- (1) Glycine (or glycocoll) $C_2H_5NO_2$, or amino acetic acid

- (2) Alanine, $C_3H_7NO_2$, or α amino propionic acid

- (3) Serine $C_3H_7NO_2$, or α amino β hydroxy propionic acid

- (4) Threonine $C_4H_9NO_2$ or α amino β hydroxy n butyric acid

- (5) Valine, $C_5H_{11}NO_2$, or α amino isovaleric acid

- (6) Norleucine, $C_6H_{13}NO_2$, or α amino n caproic acid

- (7) Leucine, $C_6H_{13}NO_2$, or α amino isocaproic acid

- (8) Isoleucine, $C_6H_{13}NO_2$, or α amino β ethyl β methyl propionic acid

Sulfur containing monoamino monocarboxylic acids

- (9) Cystine, $C_6H_{12}N_2S_2O_4$ (or di-cysteine) or di (β thio- α amino propionic) acid

- (10) Methionine $C_5H_{11}NO_2$ or α amino γ methyl thiol n butyric acid

B Monoamino dicarboxylic acids

- (11) Aspartic acid, $C_4H_7NO_4$, or α amino succinic acid

- (12) Glutamic acid $C_5H_9NO_4$, or α amino glutaric acid

- (13) Hydroxyglutamic acid, $C_5H_9NO_5$, or α amino- β hydroxy glutaric acid

C Diamino-monocarboxylic acids

- (14) Arginine, $C_6H_{13}N_4O_2$, or α amino- β guanidine n valeric acid

- (15) Lysine, $C_6H_{13}N_2O_2$, or α ϵ diamino caproic acid

II AROMATIC AMINO ACIDS

- (16) Phenylalanine,
- $C_9H_9NO_2$
- , or
- α
- amino
- β
- phenyl propionic acid

- (17) Tyrosine,
- $C_9H_9NO_3$
- , or
- α
- amino
- β
- parahydroxy phenyl propionic acid

III HETEROCYCLIC AMINO ACIDS

- (18) Tryptophane,
- $C_{11}H_{11}N_2O_2$
- , or
- α
- amino
- β
- indole propionic acid

Indole nucleus

- (19) Histidine,
- $C_6H_7N_3O_2$
- , or
- α
- amino
- β
- imidazol propionic acid

Imidazole ring

- (20) Proline,
- $C_5H_7NO_2$
- , or pyrrolidine-
- α
- carboxylic acid

Pyrrole nucleus

- (21) Hydroxyproline (orvproline),
- $C_5H_7NO_3$
- , or
- γ
- hydroxy pyrrolidine-
- α
- carboxylic acid

Thyroxine (ch 58), 3,5 diiodotyrosine or iodogorgonic acid, citrulline (α amino- δ -carbamido *n* saleric acid) and ornithine (α,δ -diamino valeric acid), and several others, would have to be added to complete the list of naturally occurring amino acids

nitrogen excreted as ammonia, others are utilized without alteration by the tissues. The greater part of the amino acids reaching the liver are there retained and deaminated. The ammonia which is split off combines with carbon dioxide to form urea as described on page 780. The deaminated remainder, i.e., the keto acid residue of the amino acid molecule may either undergo oxidation, and thus furnish energy to the body, or be transformed into glucose. The glucose may be burned or be stored as glycogen, or again it may be transformed into fat. Not all amino acids, however, are sugar or glycogen formers. Those which play the chief role in this respect are glycine, alanine, aspartic, glutamic and hydroxyglutamic acids, serine, cystine, hydroxyproline and proline. With the exception of hydroxyproline and proline these are all straight chain amino acids with less than six carbon atoms. Arginine, caffeine, and threonine form sugar to a limited extent,

TABLE 45 3

Approximate isoelectric points of some amino acids

Amino Acid	Approximate Isoelectric Points pif
Glycine	6.1
Alanine	6.1

sufficient to form some 58 grams of glucose.* A depancreatized or phloridized dog, for instance, or the subject of severe diabetes, although upon a carbohydrate-free diet, continues to excrete large quantities of glucose. Also, the normal animal during prolonged starvation maintains its blood sugar at practically the normal level, which suggests that body protein is undergoing conversion to glucose. When protein is fed after a

* Since different proteins contain varying amounts of sugar forming amino acids (this is an average figure). It was arrived at by calculation from the proportion of glucose (dextrose) to nitrogen in the urine—the so called G N (or D N) ratio—in phloridized dogs fed exclusively upon protein or during a period of starvation. Lusk found the G N ratio under such circumstances to be 3.65:1. The nitrogen of the urine is derived of course almost entirely from protein. The urinary glucose of an animal under the influence of phloridzin and whose glycogen stores have been exhausted is also assumed to be derived exclusively from protein. Now each gram of urinary nitrogen represents catabolism of 6.25 grams of protein. Therefore with a G N ratio of 3.65:1 every 3.65 grams of glucose excreted indicates the conversion of 6.25 grams of protein. Thus,

$$(3.65/6.25) \times 100 = 58 \text{ per cent}$$

In diabetic (depancreatized) animals during starvation or upon a protein diet the G N ratios obtained by different observers vary widely. Minkowski's figure of 2.8:1 is most usually quoted (this would indicate the conversion of 45 per cent of protein to sugar). Macleod and his associates, however, have obtained ratios in depancreatized dogs after the withdrawal of insulin as high as 6:1 in some experiments, and less than 2:1 in others. The ratio did not show a constant value, either in different animals or in the same animal at different times. They have seriously questioned the reliability of the G N ratio as an index of the extent of the protein to glucose conversion, and consider that protein is not the only source of the urinary glucose.

period of starvation, glycogen accumulates in the liver. There is also evidence that the conversion of protein to glucose occurs even in a normal animal upon a mixed diet. The conversion process probably occurs almost entirely in the liver. Mann and Magath found that the hypoglycemia following hepatectomy was not affected by the intravenous injection of glycine. The conversion process is influenced by the anterior lobe of the hypophysis and the adrenal cortex.

Although deamination is a function of the kidney and other tissues as well, its main site is the liver. In the dog it appears to be carried on exclusively by hepatic tissue. Mann and his colleagues found no evidence in dogs of extrahepatic deamination. The injection of amino acids into the blood stream of a normal dog caused a rapid rise in the amino acid concentration of the blood and increased amino acid excretion in the urine. The level in the blood returned to normal in about two hours. About 25 per cent of the injected amino acid nitrogen appeared in the urine as urea. After hepatectomy, the urea concentration of the solid tissues, blood and urine fell, whereas the concentration of amino acids rose, amino acids injected into the blood stream were completely recovered unchanged, about a third from the urine and the remainder from the muscles. There was no sign of deamination or of urea synthesis.

Deamination is generally believed to be an oxidative process brought about by various enzymes in liver, kidney, and to some extent in other tissues. Oxidation of the α -carbon atom, i.e., the carbon atom to which the NH_2 group is attached, first occurs with the production of an α -imino acid. This involves the transference of two hydrogen atoms to a hydrogen acceptor through the action of α -amino-oxidase, glycine oxidase, or of L-glutamic dehydrogenase.

The imino acid then undergoes spontaneous hydrolysis to form an α -keto acid.

TRANSAMINATION. An important reaction occurring in the metabolism of protein is the inter-

conversion of amino acids by transference of the amino group from an α amino acid to an α keto acid. The change is catalyzed by an enzyme *transaminase*.

The reaction is reversible and occurs according to the equation

Transamination was first suggested as a possibility by Needham and later demonstrated in pigeon breast muscle by Braunstein and Kritzmann. They found that when β -glutamic acid and pyruvic acid were incubated with chopped liver or muscle α -ketoglutaric acid and alanine were produced, the amino group of the glutamic acid being transferred to pyruvic acid.

According to these investigators the majority of the amino acids (lysine is an exception) can take part in transamination reactions, their NH_2 groups being transferred to other amino acids or to various keto acids. Glutamic acid is especially active in this respect. Transamination occurs not only in liver and muscle but has been demonstrated in a number of other tissues and appears to be a function of tissues in general. Krebs observed that glycolysis in brain and retina was inhibited by glutamic acid, an effect which has since been shown to be due to the conversion of pyruvic acid to alanine through the transference of amino groups from the glutamic acid. Since transamination is a rapid process and concerned chiefly with those compounds which play key roles in intermediary metabolism, Cohen suggests that it represents a 'shuttle mechanism in tissue respiration' whereby certain key protein and carbohydrate intermediates are rapidly interconverted. The demonstration of transamination affords further evidence for the highly dynamic character of protein metabolism. Amino groups are being continually exchanged between nitrogenous and non-nitrogenous compounds and

amino acids thereby synthesized. When an amino acid into which isotopic nitrogen (^{15}N) has been incorporated is fed and the tissues of the animal are analyzed, a large number of amino acids are found to contain the isotope. Even ammonium citrate containing ^{15}N fed to rats upon a low protein diet is utilized for amino acid synthesis. Aspartic acid, histidine, arginine, glutamic acid and proline isolated from the animals' bodies were found to contain the isotope.

TRANSMETHYLATION. Although it has long been known that certain compounds when fed are excreted by the kidney in methylated form, e.g., pyridine as N -methyl pyridine, the mechanism involved in the transference of the methyl group from one compound to another has been discovered comparatively recently by du Vigneaud and his associates. Homocysteine can be converted in the body to methionine by the addition of a methyl group. The methyl group is furnished by choline or betaine. An animal fed upon a diet lacking in methionine but containing homocysteine fails to grow; growth is resumed upon the addition of choline or betaine, the essential amino acid, methionine being thus formed. The transference of the methyl groups from methionine or choline to glycochamine with the formation of creatine is described on page 782. Methionine, choline and betaine are therefore spoken of as transmethylating agents. The conversion of nicotinic acid to trigonelline may be another example of transmethylation, although it may be due in part to direct methylation. The methyl group is not improbably derived from methionine.

Transamidation. This is the transference of an amidine group NH_2 as from arginine to glycine

The Synthesis of Amino Acids

That the body tissues, given the necessary amino acids, can link them together and so synthesize protein is of course unquestioned. The extent to which the amino acids themselves can be synthesized has been a more difficult question to decide. That synthesis of amino acids does occur is clearly indicated by the fact that only a limited number (10) of amino acids found in animal tissue are essential constituents of the diet. Undoubtedly the body is able to synthesize glycine—the simplest amino acid. For example, milk proteins contain no more than 0.1 to 0.3 per cent of glycine yet from 100 grams of the

suckling animal can build up 78 grams of tissue protein containing 2.5 grams of glycine (Magnus-Levy). Also, the liver and kidney detoxicate benzoic acid by combining it with glycine to form hippuric acid which is excreted in the urine. When large quantities of benzoic acid are fed the glycine in the excreted hippuric acid is greater in amount than that which could have been supplied preformed from body tissue. Analogous experiments with the detoxication of phenylacetic acid to phenylacetyl glutamine indicate that glutamic acid can also be synthesized. The mode by which synthesis of the amino acids takes place is obscure. The formation of amino acids by the transference of amino groups to non nitrogenous compounds e.g. pyruvic acid formed in the breakdown of carbohydrate or even the utilization of ammonia fed in the form of ammonium salts has been mentioned. The ammonia probably unites with a keto acid to form an aminated hydroxy acid which by reduction yields an amino acid.

Embden found that alanine was formed by the surviving liver perfused with blood to which the ammonium salt of pyruvic acid had been added. Phenylalanine and tyrosine were also formed when the liver was perfused with the ammonium salts of the corresponding keto acids. Even the addition of ammonium chloride to the fluid perfusing a glycogen rich liver resulted in the production of alanine. The latter also followed perfusion with ammonium lactate. Furthermore it was shown by Knoop that when γ phenyl- α keto butyric acid was administered to dogs the corresponding amino acid appeared in the urine whereas the experiments of Cox and Rose and of Sherwin and their associates indicate that histidine an essential amino acid can be formed in the body when imidazole pyruvic acid or imidazole lactic acid is fed. The synthesis of arginine has also been demonstrated by Rose and his colleagues.

To sum up it is established that glycine can be synthesized from precursors already present in the body. The same may also be said for glutamic and aspartic acids, alanine and arginine. The perfusion experiments just mentioned suggest that alanine may be synthesized from the derivatives of carbohydrate metabolism plus the ammonia

which would otherwise be excreted as urea. Other more complex amino acids, e.g., tryptophane, histidine, and proline, etc. (p. 775) contain special groupings which cannot be formed in the body. They are therefore essential constituents of the diet (ch. 46). If, however, the special groups are supplied, as in the form of the keto acid or hydroxy acid, the corresponding amino acid can in some instances be formed.

Protein Synthesis

The synthesis of protein from free amino acids requires energy, the latter is derived from the oxidation of carbohydrate and fat. The energy liberated during oxidative catabolism is not contributed directly to the reactions involved in protein formation but is first used to synthesize adenosine triphosphate (ATP) which acts as an intermediate source of energy (see Carbohydrate Metabolism). Thus in conditions such as diabetes mellitus, where carbohydrate and fat utilization are severely impaired, peptide synthesis is also unpaired. Protein formation is also reduced by substances such as dinitrophenol which interfere with ATP synthesis and allow the energy liberated from oxidative reactions to be dissipated as heat.

The mechanisms responsible for the formation of peptide bonds and the factors which guide the selection of amino acids so that they may be linked together in the specific sequence that characterizes a particular protein are not thoroughly understood. An increasing amount of data supports the view, originally proposed by Borsook, that there are three steps involved in the formation of a protein molecule. The first step consists of activation of the carboxyl group of an amino acid. The results of recent investigations indicate that this is achieved in the following manner:

It is pertinent that through this reaction it is always the carboxyl group that is activated and the activation occurs at the expense of ATP. It is believed that in the second step the activated amino acids are transported to a template or mold which aligns them in the specific sequence characteristic of the protein to be synthesized. In the third step the activated carboxyl groups combine with the amino groups of the adjacent molecules to form peptide bonds. The newly

formed molecule then peels off the template. According to this concept, the whole protein molecule is formed through the simultaneous condensation of the activated amino acids, the formation of polypeptides of intermediate sizes is not involved in the process. If this is true, it accounts for the fact that protein synthesis cannot occur unless all of the essential amino acids are available simultaneously. The template upon which protein is formed appears to be ribonucleic acid (RNA) for it has been shown that inhibition of RNA synthesis is invariably followed by an inhibition of protein synthesis. Similarly, a stimulation of protein synthesis is always associated with an increased synthesis of RNA.

The Classical as Opposed to the Modern View of Protein Metabolism

The classical view of protein metabolism was proposed originally by Folin. He believed that the creatinine and neutral sulfur excreted in urine were derived from the wear and tear of the body tissues and the amounts of these substances in the urine were taken as indices of endogenous protein metabolism. The urea, on the other hand, was believed to be derived solely from the catabolism of dietary or exogenous protein. Since creatinine represents a very small amount of the total urinary nitrogen and remains constant in amount, it was concluded that the tissue proteins were relatively inert and that only minute amounts of the dietary amino acids were needed to replace the protein lost from body tissues. This concept was challenged in 1935 by Borsook and Keighley who, on the basis of much indirect evidence, suggested that endogenous protein metabolism was a very active process and that a large proportion of the dietary amino acids were utilized by various tissues. Direct substantiation of this concept was obtained by Schoenheimer and his associates through the use of isotopically labelled compounds. Schoenheimer fed rats leucine and glycine labelled with N^{15} . If, as Folin believed, the body proteins were inert, nearly all of the label from the amino acids should have been recovered from the urine. However, only a fraction of the isotopic nitrogen was found in the urine whereas the remainder was found incorporated into the body tissues. It appears therefore, that the body proteins are in a constant state of turnover, they are continually being broken down and replaced by new protein synthesized from dietary amino acids. Subsequent work indicates that the replacement of protein is

rapid in plasma, liver, kidney and intestinal tract, and comparatively slow in hemoglobin, muscle and skin.

The rapid turnover of amino acids in various tissues has been considered by some to be due to the degradation and re-synthesis of the intracellular proteins. Cohn and Monod have expressed reservations concerning this belief. They point out that what has been interpreted as evidence of intracellular turnover of protein may represent a turnover of whole cells that is to say, the rate at which cells, not just the protein within them, are destroyed and replaced. It appears then that protein turnover may be due to both intracellular degradation and re-synthesis and to replacement of whole cells.

Protein Storage—Labile Protein

In the latter half of the 19th century Voit observed that when dogs were starved, or fed a diet free of protein the nitrogen excretion fell rapidly for 5 or 6 days and then became relatively constant. The larger amounts of nitrogen excreted during the first few days were believed by Rubner to arise from unorganized storage protein that was utilized to fill a metabolic need for nitrogen during times of protein deprivation. Research during the intervening years has failed to reveal a depot or special form of protein that functions exclusively as a reserve supply. However, the body tissues, particularly those of liver, thymus, prostate, seminal vesicles, alimentary tract, pancreas, spleen and kidneys, do contain labile proteins that can be drawn upon when the need arises. These organs lose their labile protein rapidly. This process seems to account for the rapid fall and subsequent stabilization of urinary nitrogen excretion that occurs during the first few days of starvation. Some of the protein mobilized is utilized for the synthesis of other body proteins. This phenomenon is well illustrated by the experimental findings of Madden and Whipple. When severe hypoproteinemia was produced by repeated plasmapheresis a normal dog re-synthesized 40 to 60 per cent of its plasma proteins while fasting. This however is not the only function of the protein. A large proportion is converted into carbohydrate, which is subsequently used to provide the energy required for vital processes. It appears then that the body tissues, particularly those of the viscera, do contain labile proteins, the supply of which, however, is quickly exhausted. The temporary loss of this protein does no permanent damage to the organ involved, there is no reason to believe that it

differs chemically or functionally from the proteins that normally constitute the donor cell

The End Products of Protein—Metabolism, Urea

The great proportion of the nitrogen released by the catabolism of the amino acids appears in the urine of man, mammals, amphibia and elasmobranch fish as urea. In birds and reptiles, on the other hand, the chief end product of protein breakdown is *uric acid*. In man and other mammals the latter is derived from the metabolism of the purines (ch. 47). Urea is formed directly (i.e., without preliminary decamination), from *arginine* which is hydrolyzed by the action of an enzyme—*arginase*—into *urea* and *ornithine*. *Arginase* is present in the liver of mammals but not in that of birds and reptiles. The reaction may be represented thus:

This important mechanism has been thought

to account for the greater proportion of the urea formed in the body. When ornithine was incubated with slices of liver in the presence of ammonia and carbonic acid, large amounts of urea were formed. It is supposed that the ornithine combines with the ammonia and carbonic acid to form arginine which in turn is hydrolyzed by arginase into urea and ornithine. Thus arginine serves as an intermediary in the production of urea from the ammonia supplied by other amino acids. The ornithine liberated by the decomposition of arginine is used over again. Ornithine thus acts after the manner of a catalyst to facilitate urea production.

According to Krebs and Henseleit the formation of arginine from ornithine occurs in two steps: (1) The formation of the amino acid *citrulline* by the addition of a molecule each of ammonia and carbon dioxide to ornithine:

(2) The addition of a second molecule of ammonia to citrulline, with the production of *arginine*. Therefore, the production of urea from ammonia and carbonic acid may be represented thus:

The ornithine cycle

Although the ornithine cycle is probably not the only mechanism involved in the production of urea, it is generally considered to be the major one. Some of its details have been clarified by the work of several investigators (Cohen and Hay-

ano, Borsook and Dubnoff, and Ratner and associates). Cohen and Hayano reported that for the production of arginine from citrulline glutamic acid rather than ammonia appeared to be the nitrogen donor and that Mg ions, adenosinetriphosphate (ATP) and oxygen were required for the reaction. The transfer of the NH_2 group it has been suggested is effected by transamination and the simultaneous loss of two H atoms (transamination). The citrulline-arginine conversion occurred only in the presence of oxygen. Glutamate also acts as an acceptor of CO_2 and NH_2 in the synthesis of citrulline from ornithine in the first stage of the ornithine cycle. Aspartic acid is, however, according to the researches of Ratner and her colleagues the specific nitrogen donor in the conversion of citrulline to arginine, which occurs anaerobically in the presence of Mg ions and ATP. Fumaric acid is also formed in this reaction, but undergoes oxidation to oxalacetic acid. Through this latter reaction the tricarboxylic and ornithine cycles are interlocked. The following scheme is given by Ratner:

Urea is decomposed into NH_3 and CO_2 by the action of *urease*. This enzyme is found in leguminous plants especially in soy bean, and in relatively high concentration in the gastric mucosa (ch. 38). *Urease* is employed in the deter-

mination of urea (from ammonia evolved) in urine and in other body fluids and in tissues

THE EXCRETION OF UREA AND ITS DISTRIBUTION IN THE BODY On an ordinary mixed diet from 80 to 90 per cent of the urinary nitrogen is urea-nitrogen. The absolute amount of urea nitrogen excreted daily is usually from 9 to 13 grams (20 to 30 grams of urea). Minimal amounts are also excreted in the sweat (ch 52), salivary, intestinal and mammary secretions. The urea-nitrogen varies with the protein content of the diet. Upon a low protein diet the output may be as low as 2 grams and on a diet rich in protein it may be over 25 grams. The value of urea-nitrogen is therefore taken as an index of the magnitude of the catabolism of food protein (exogenous metabolism, see table, p 784).

The blood contains from 8 to 15 mg of urea-nitrogen (18 to 35 mg urea) per 100 cc. Urea is readily diffusible and is found in about the same concentration in the various tissues and other fluids, e.g., lymph, bile, cerebrospinal fluid and pancreatic juice, as in blood. The kidney, however, is an exception since it contains some 150 to 200 mg of urea per 100 grams of tissue. We have already seen that the urinary ammonia is formed from glutamine and amino acids in the kidney and not from urea (ch 34).

THE SITE OF UREA PRODUCTION It has long been known that the liver is an important site of urea formation. Perfusion of the liver with amino acids or their addition to sliced liver tissue leads to the production of urea. Urea is very widely

distributed throughout nature, being a constituent of the body fluids of the lowest forms of animal life. It is also found in plants. For this reason its formation in animals might be thought to be a function common to all tissues. But the experiments of Mann and his associates in hepatectomized dogs, points to the liver as being the main if not the sole site of urea production. After complete removal of the liver the formation of urea ceased, so that its concentration in the blood and urine fell progressively. If the kidneys as well as the liver were excised there was no accumulation of urea in the blood although the amino acid concentration rose. Also after the injection of glycine or alanine into the hepatectomized animal, in contrast to the result obtained in the normal animal, the concentration of the injected amino acid rose in the blood and urine and there was no evidence of urea production. That these results in dogs apply to man is indicated by the observation of Rabinowitch. He has reported that in a case of extensive damage to kidneys and liver (acute yellow atrophy) the excretion of urea was almost suppressed yet the blood was urea-free. The appearance of leucine and tyrosine in the urine which occurs in acute yellow atrophy of the liver may also be ascribed to the failure of decamination of these amino acids. Nevertheless, although the liver undoubtedly plays the predominant role in the production of urea, certain other tissues may under certain circumstances share to some degree in its formation. Graham and associates found, for example, that the active mammary gland produces not inconsiderable amounts.

Creatine and Creatinine

Creatine ($\text{C}_4\text{H}_7\text{N}_3\text{O}_2$) (methyl guanido-acetic acid or methyl glycoylamine)

may be looked upon as a derivative of glycine, of guanidine or of guanido-acetic acid. It is also related to arginine. It is readily converted by acid *in vitro* to creatinine.

Creatinine, $\text{C}_4\text{H}_7\text{N}_3\text{O}$ (methyl glycoylamidine) is the anhydride of creatine. Its molecular constitution is shown by the following formula

Distribution of creatine and creatinine There are about 120 grams of creatine contained in the adult human body. Of this 98 per cent is contained in the muscles and 1.5 per cent in the nervous system. The remaining 0.5 per cent is distributed throughout the other organs of the body, of these, the testes contain it in highest concentration. The skeletal and cardiac muscles and the gravid uterus are a great deal richer in creatine than the smooth muscle of the gastrointestinal tract and elsewhere. About 80 per cent of the creatine in muscle is combined with phosphoric acid as *phosphocreatine* (ch 51). Of the striated muscles the rapidly contracting, pale type contain more than the slowly contracting red variety (p 1165). In the muscle of invertebrates creatine is replaced by arginine.

Creatinine is present in muscle in much smaller amounts. One hundred grams of skeletal muscle, for example, contain 300 to 500 mg of creatine and only 10 mg of creatinine. The creatine of whole blood amounts to from 3.5 to 5.0 mg and the creatinine to about 2.5 mg per 100 cc. By far the greater part, if not all of the creatine is contained in the corpuscles. The creatinine is about equally distributed between cells and plasma.

Excretion of creatine and creatinine Creatine is normally absent from the urine of men, but is present in the urine of male and female children up to the age of puberty and frequently in the urine of women. The significance of these sex differences is not evident. In nonpregnant women the *creatinuria* is intermittent but is not related to menstruation. During pregnancy creatine is present continuously in the urine. This may be related to high creatine content of the uterus. For two or three weeks after childbirth the quantity excreted is even higher than during pregnancy. Reduction in the muscular mass of the uterus (involution) may account in part for the high output during the puerperium, but that uterine involution is not the chief cause is shown by the fact that it occurs although Caesarian section and removal of the uterus have been performed. Creatine also appears in the urine of either sex under the following conditions: *high protein diet, starvation, carbohydrate deprivation, diabetes, wasting diseases and fevers, exophthalmic goiter* and in certain *muscular dystrophies*. The *creatinuria* in all of these conditions except the last is probably due to an increase in the normal catabolism of muscular tissue, the liberation of creatine occurring more rapidly than its conversion to creatinine. Protein food, for example, has a stimulating effect upon metabolism (p 787), whereas in wasting diseases,

fevers, etc., tissue breakdown is accelerated. Carbohydrate deprivation probably acts indirectly in that its sparing effect upon protein catabolism is absent. In the muscular dystrophies, e.g., *myasthenia gravis, progressive muscular atrophy, amyotonia congenita, anterior poliomyelitis*, etc., the urinary creatine is probably derived from the degenerating muscle fibers, the muscles also appear to be defective in their power to store creatine. The *creatinuria* of normal children has received no satisfactory explanation. It is said to be due to an increased production of creatine induced in some way by the growth impulse and also probably to a low capacity for creatine storage of the undeveloped muscles. Another possibility is that children have a relatively low power to convert creatine to creatinine (Hunter).

The origin of creatine and creatinine Creatinine is undoubtedly derived from creatine but there has been much uncertainty concerning the latter's origin. One or other of the substances to which its chemical formula suggests a relationship, e.g. guanidine, glycine or arginine, has been considered as a possible precursor. The opportunity afforded by the *creatinuria* of muscular dystrophies has been taken advantage of by Brand and his colleagues in the investigation of this question. Various amino acids and other guanido compounds were fed to patients suffering from such disorders, ingested glycine, or gelatin which is rich in this amino acid, causes a pronounced rise (40 per cent) in the creatine excretion of these patients but not of normal persons. The proportion of ingested creatine which is retained is also much less than the normal (*creatin tolerance test*). Arginine and glycocyanine (guanidoacetic acid) were also effective. Feeding benzoic acid which drew upon the body's glycine store for detoxication purposes (p 721) caused a decrease in the creatine excretion. The importance of glycine in creatine synthesis is emphasized by the observation of Almquist and Vecchi that glycine, which is an indispensable amino acid for clucks, can be replaced in the diet of this species by creatine. These results pointed to arginine, guanidoacetic acid and especially glycine as precursors of creatine.

The subject of creatine synthesis has been clarified recently through a number of experiments in which isotopes were used as markers to identify the particular substance under investigation after it had been absorbed. The administration of isotopic glycine (i.e., heavy nitrogen, N^{15} , incorporated in the glycine molecule) was shown by Bloch and Schoenheimer to give rise to creatine

with a high concentration of the nitrogen isotope. Of all the other amino acids investigated by this method, arginine alone was found to be a primary precursor of creatine. The isotope N^{15} was incorporated into the amidine part ($NH_2-C=NH$) of the arginine molecule. When the isotopic arginine was fed, the creatine isolated from the tissues of the animal was found to contain the isotope in this part of its molecule. The researches of du Vigneaud, and of Borsook and Dubnoff, show clearly that the methyl group of creatine is furnished by methionine. The former worker prepared methionine in which the three hydrogen atoms of the S-methyl group were present as the isotope H^2 (deuterium). When this was fed and the creatine of the animals' bodies determined, the isotope concentration indicated that nearly 70 per cent of the methyl groups of the creatine molecule had been derived from methionine. Borsook and Dubnoff incubated liver slices with guanidoacetic acid (glycocyanine) which they found was slowly converted to creatine, the conversion being hastened by the addition of methionine. Glycocyanine is apparently an intermediary in the synthesis of creatine in the body, when the isotopic form of this compound is fed isotopic creatine is formed. The conclusions to be drawn from these experiments are that arginine, glycine and methionine enter into the synthesis of creatine but that other amino acids do not serve as precursors. The first reaction, it appears, is between the amidine part of arginine and glycine with the formation of glycocyanine. The guanidoacetic acid then undergoes methylation by the transference of the methyl group from methionine. Thus

The site of creatine production is not known definitely but it is probably in the muscles. These also in all probability are the site of creatine-creatinine transformation (by dehydration). Mann and Magath found that removal of the liver was without effect upon creatinine production. The creatine which gives rise to urinary

creatinine is derived very largely from the phosphocreatine of muscle.

Creatine is not, as was held by some authorities in the past, simply a waste product of protein metabolism like urea. If, for example, a large dose of creatine is fed the greater part or the whole is retained in the body.² Creatinine, on the other hand is purely a waste product. Up to 80 per cent or more of an amount fed can be recovered unchanged in the urine. The investigations of recent years into the chemistry of muscular contraction have revealed the essential importance of creatine (as phosphocreatine) in the contractile process (ch 51).

CREATININE EXCRETION AS AN INDEX OF MUSCLE METABOLISM

The daily output of creatinine in the urine is constant for the individual, amounting to from 1.5 to 2.0 grams for men and from 0.8 to 1.5 grams for women. This corresponds to about 2 per cent of the creatine of the body. Unlike the excretion of urea, which is derived largely from exogenous sources, the creatinine output is practically independent of the protein level of the food. This is evident from table 45.5. The creatinine excretion is therefore considered to be an index of the magnitude of the metabolism of the tissues and especially of muscle. The daily output of creatinine is extraordinarily constant for the individual, it is not influenced by ordinary exercise or by the urine volume. The creatinine coefficient—

$$\frac{\text{milligrams creatinine}^4 \text{ excreted per day}}{\text{body weight in kilograms}}$$

is from 20 to 26 for the majority of normal men and from 14 to 22 for women. Its value depends upon the muscular development of the individual, the sex variation being due presumably to the different relative amounts of fatty and muscular tissues of male and female bodies. Athletic women for this reason have a coefficient as high as or higher than a man of obese build and poor muscular development.

¹ In the experiments of Benedict and Osterberg over half a gram of creatine hydrate was fed daily to dogs for a period of several weeks. In the first week none of the administered creatine was excreted either as such or as creatinine. During subsequent weeks when the creatine reservoirs had apparently become filled a large part was excreted unchanged. A rise in the creatinine output also occurred indicating the transformation of creatine to creatinine. Nevertheless of some 33 grams of creatine administered over the entire period of 70 days about 20 grams were retained. Retention of ingested creatine is also demonstrable in man.

² Or creatine + creatinine, creatinuria exists.

TABLE 45 5

Effect of dietary protein on composition of urine
(After Fohn)

	Nitrogen Rich Diet	Nitrogen Poor Diet
Volume of urine	1170 cc	385 cc
Total nitrogen	16.8 grams	3.60 grams
Urea nitrogen	14.70 grams = 87.5%	2.20 grams = 61.7%
Ammonia nitrogen	0.49 gram = 3%	0.42 gram = 11.3%
Uric acid nitrogen	0.18 gram = 1.1%	0.09 gram = 2.5%
Creatinine nitrogen	0.58 gram = 3.6%	0.60 gram = 17.2%
Undetermined nitrogen	0.85 gram = 5.0%	0.27 gram = 7.3%
Total sulfur	3.64 grams	0.76 gram
Inorganic SO ₂	3.27 grams = 90.0%	0.46 gram = 60.5%
Ethereal SO ₂	0.19 gram = 5.2%	0.10 gram = 13.2%
Neutral S	0.18 gram = 4.8%	0.20 gram = 26.3%

THE METABOLISM OF SULFUR

Sulfur enters the body mainly as a constituent of the amino acids *cystine* and *methionine*. Food also contains inorganic sulfates, small amounts of sulfur in the form of sulfolipids (sulfatides) in certain glycoproteins (mucosin-sulfuric acid and chondroitin-sulfuric acid) and in organic sulfides, isothiocyanates, and sulfonium compounds. Sulfur in inorganic form cannot be used in the construction of body protein. Practically speaking, the body is dependent for its sulfur supplies upon the two sulfur-containing amino acids mentioned above.

THE DISTRIBUTION OF SULFUR IN THE BODY

Sulfur is contained in the ordinary tissue proteins, in hair, horn, feathers, etc., in mucin, as mucosin-sulfuric acid and chondroitin-sulfuric acid, in certain glycoproteins of tendons, vitreous humor, cornea and connective tissues, in glutathione and insulin, in the taurocholic acid of bile, as sulfocyanate in saliva, in ergothionine, a compound found in red corpuscles, in certain pigments (melanins, urochrome), and in nervous tissue as sulfolipoids. Inorganic sulfates are contained in the body fluids generally.

The loss of sulfur from the body occurs in the shedding of hair, nails, etc., in the bile, saliva and

gastrointestinal secretions. The great bulk of the sulfur loss, however, occurs through the kidneys.

The history of sulfur in the body. The sulfur liberated in the catabolism of dietary protein is largely converted to inorganic sulfates. A part of the inorganic sulfate derived from this and other sources becomes conjugated in the liver with substances produced in the intestine by the bacterial decomposition of protein to form *etheral sulfates*. The latter are excreted in the urine. The products of bacterial action, among which are phenol derived from phenylalanine and tyrosine, and indole and skatole from tryptophane, possess toxic properties. Their excretion as etheral sulfates constitutes a detoxicating mechanism. When the detoxicating function of the liver is depressed as a result of hepatic disease, some of these toxic substances are excreted by the kidney in abnormal amounts in the free state.

Urinary sulfur. The total urinary sulfur is made up of the following:

(1) Inorganic sulfur (85 to 90 per cent). Compounds of sulfuric acid with Na, K, Ca and NH₄.

(2) Etheral sulfate sulfur (6 to 8 per cent), e.g., potassium and sodium salts of indoxyl sulfuric acid (p. 721). The former is known as indican.

(3) Neutral sulfur (4 to 5 per cent) e.g., sulfur containing amino acids, urochrome, thiosulfates, thiocyanates, taurocholic and oxyproteic acids.

The quantities of inorganic and etheral sulfates in the urine vary with the protein level of the diet, and run more or less parallel with the nitrogen excretion, the neutral sulfur is influenced to a less degree. For this reason the two former partitions of the urinary sulfur were considered by Fohn to represent food (exogenous) sulfur while the neutral sulfur was taken to be

derived mainly from body protein (endogenous sulfur). On a diet of meat or during prolonged starvation the ratio of sulfur to nitrogen in the urine is about 1 to 14, i.e., for every gram of sulfur there are approximately 14 grams of nitrogen. This is approximately the S:N ratio found in muscular tissue. A graphic summary of sulfur metabolism is shown above.

As a result of the excessive production and absorption of putrefactive products the excretion of ethereal sulfates is increased in acute intestinal obstruction. They are also increased in carcinoma of the liver. Chronic constipation, however, exerts little or no influence upon the excretion of these substances.

The excretion of neutral sulfur is increased in the rare metabolic anomaly known as *cystinuria* and in cases of *melanotic sarcoma*, when an abnormal sulfur-containing pigment appears in the urine.

The nonprotein sulfur of blood. The sulfur of blood, other than that present as a constituent of protein, amounts to from 3 to 5 mg per 100 cc. The concentrations of the three forms are given in table 45 6.

AMMONIA (SEE PAGE 565)

NITROGEN BALANCES

The difference between the nitrogen taken in the food and that excreted in the feces and urine is spoken of as the nitrogen balance (that lost in the hair, sweat, saliva, etc., is negligible). On an ordinary diet, the amounts of nitrogen excreted daily in the feces and urine, respectively, average 1.5 and 13 grams. The nitrogen of the feces is in part unabsorbed nitrogen of the food and in part nitrogen excreted through the intestinal wall. When the intake and output are equal, the body

TABLE 45 7

Example of adjustment of nitrogen balance to increased intake

Day	Nitrogen in Food	Nitrogen in Feces	Nitrogen Absorbed	Nitrogen in Urine	Nitrogen Balance
	grams	grams	grams	grams	grams
1	14.40	0.70	13.70	13.60	+0.10
2	14.40	0.70	13.70	13.80	-0.10
3	14.40	0.70	13.70	13.60	+0.10
4	20.96	0.82	20.14	16.80	+3.34
5	20.96	0.82	20.14	18.20	+1.94
6	20.96	0.82	20.14	19.50	+0.64
7	20.96	0.82	20.14	20.00	+0.14

* Modified from H. C. Sherman 'Chemistry of Food and Nutrition,' 4th edition

is said to be in *nitrogen equilibrium*. When the intake exceeds the output the body is in *positive nitrogen balance*—nitrogen is being retained. If the reverse is the case, i.e., the output exceeds the intake, the balance is said to be *negative*—the body is losing nitrogen. When the nitrogen of the food is increased a greater quantity for a time thereafter is retained, but the body soon becomes adjusted to the higher intake and gradually a balance is re-established (table 45 7).

The healthy adult requires protein to replace the inevitable loss of tissue protein. When given a sufficient amount of protein to repair this so-called 'wear and tear' his output and intake of nitrogen will balance, i.e., he will be in *nitrogen equilibrium*. If his diet contains protein in excess of this amount the nitrogen not employed for repair is excreted and *nitrogen equilibrium* maintained. In starvation or on a low protein intake, or on a diet which lacks certain essential amino acids, the individual continues to excrete nitrogen derived from the dissolution of his own protoplasm, and so goes into negative balance. In children, in adults recovering from wasting diseases or undergoing muscular training, and in pregnant women, the body, if the protein intake is liberal, does not excrete as much nitrogen as it received. Nitrogen is retained for the manufacture of new tissue. The daily excretion of nitrogen of a man of average weight upon a nitrogen free diet amounts to from 0.75 to 3 grams. It might be thought that nitrogen equilibrium could be re-established by simply feeding this quantity of protein nitrogen. It is found however that a considerably larger quantity is necessary. Part of the reason for this is that the amino acids are required by the body in different proportions from

TABLE 45 6

Concentrations of different forms of sulfur in whole blood and serum

(After Denis)

	Whole Blood	Serum
	per 100 cc mg	per 100 cc mg
Inorganic sulfur	0.1-1.1	0.5-1.1
Ethereal sulfate sulfur	0.1-1.0	0.1-1.0
Neutral sulfur	2.2-4.5	1.7-3.5

The inorganic sulfur of blood is elevated in renal insufficiency, intestinal obstruction and leukemia.

those present in the food protein. In order that the body shall obtain a sufficient quantity of suitable amino acids for the replacement of its own protoplasm and for the manufacture of various secretions and other essential materials, a relatively large assortment must be available from which it can choose. Those not required are discarded. For this reason, equilibrium can be established upon a smaller quantity of animal protein, such as beef muscle which contains amino acids more nearly in the same proportions as those in human body protein, rather than upon vegetable proteins. The wastage of nitrogen is less in the former instance. If the only protein in the food is one entirely lacking in certain essential amino acids (lysine, threonine, etc.) the loss of nitrogen resulting from the breakdown of such amino acids in the body's protoplasm cannot be replaced. A negative balance results no matter how much of the inferior protein has been fed (see ch 46).

The quantity of protein required to establish nitrogen equilibrium depends very greatly upon the content of the diet in the other two food principles—fats and carbohydrates. It is impossible, for example, to establish nitrogen equilibrium in man upon an exclusively protein diet, the excretion of nitrogen always exceeds the intake even though the individual ingests protein to his full capacity. The reason for this is that man cannot consume and digest sufficient amounts of protein to satisfy his energy requirements. Under such circumstances he draws upon his stores of carbohydrates and fats, but after these have been exhausted the protein elements of his tissues are disrupted. The non nitrogenous portions of the amino acid molecules are burned to make up the calorie deficiency, and, as a consequence, quantities of nitrogen derived from food and body protein are excreted. It has been calculated that the human subject would have to consume, daily, some 8 pounds of meat—practically an impossible feat for a civilized man—in order to furnish the necessary energy and maintain the body in nitrogen equilibrium. On the contrary, a carnivorous animal such as the dog which possesses a large capacity for the digestion of protein food^{*} thrives

upon a diet composed entirely of lean meat. The Eskimos are also capable—according to Krogh—of consuming relatively enormous quantities of meat. On a mixed diet, as we shall see immediately, nitrogen equilibrium can be established on a very low protein intake.

PROTEIN SPARERS

Carbohydrates and fats are called *protein spacers* since their presence in the diet relieves tissue protein of the necessity of furnishing energy. The protection of body protein by carbohydrate has been shown clearly by numerous experiments. The following experiment performed by Lusk upon himself may be cited in illustration of this important principle. After a period during which a mixed diet had been fed and a small positive nitrogen balance established, 350 grams of carbohydrate were withdrawn from the diet. The nitrogen excretion increased from 19.84 to 27.00 grams daily, the balance becoming negative. Also, the nitrogen excretion in the urine in starvation is nearly three times greater than that upon a diet, nitrogen free, but of adequate energy value (i.e., one composed exclusively of fat and carbohydrate). The nonprotein food has reduced the breakdown of tissue protein.

The nitrogen excretion on such a protein-sparing diet is therefore an index of the inevitable disintegration of body protoplasm which occurs under ordinary physiological conditions. For this reason it was called, by Rubner, the "wear and tear" quota of protein metabolism (see p 779). One of the lowest values reported for nitrogen excretion is that of Boothby and Sandiford, namely, 1.74 grams daily (0.024 gram per kg. of body weight).

Carbohydrate exerts a specific sparing action quite apart from the fact that it furnishes energy and so relieves protein of the necessity of performing this duty, for the sparing effect exhibited by a given quantity of carbohydrate cannot be brought about by an amount of fat possessing double the caloric value. Carbohydrate when fed alone has a marked sparing action, whereas fat alone has little or no protein-sparing effect and a positive nitrogen balance cannot be established in man on a diet composed entirely of fat and protein. Nor will fat by itself, when given after a period of fasting, reduce the nitrogen excretion below that during the fast. Indeed, it actually increases the output of nitrogen. A diet whose calories, up to 50 per cent or more, are derived from fat and the remainder from carbohydrate has, however, as

* The daily energy requirement of man is say, 3000 Calories. Eight pounds of meat (3600 grams approximately) which is 20 per cent protein, has a caloric value of $(20/100) \times 3600 \times 4.1 = 2900$. The energy expenditure of an average sized dog on the other hand is around 600 Calories. It can consume in less than a minute 2 pounds (900 grams) of meat, yielding more than 700 Calories.

great a protein-sparing action as one whose calories are derived from carbohydrate alone. Lactic and pyruvic acids, products of carbohydrate metabolism, are also protein-sparers to some extent. The sparing effect of carbohydrates can be demonstrated in the well-nourished animal as well as during starvation. When dogs in nitrogen equilibrium are given extra glucose, nitrogen is retained but the balance is re-established when the administration of glucose is stopped (Larson and Cibaikoff).

The difference between the sparing actions of fat and carbohydrate is not easily explained. According to one view (Landergrén) the specific sparing effect of carbohydrate depends upon the fact that glucose is vitally essential to the body and must be constantly supplied whatever the cost. If it is not available from outside sources or from the glycogen stores, tissue protein is broken down to yield materials from which it may be synthesized.

Another more probable explanation of the peculiar sparing action of carbohydrate is, that it is used in the synthesis of the amino acids which are incorporated into body proteins. According to this view the nitrogen resulting from the breakdown of tissue protein during fasting (or from tissue and food protein when the diet consists exclusively of protein and fat) is largely or entirely excreted. If, on the other hand, certain intermediary products of carbohydrate metabolism are available, e.g., pyruvic acid, etc., it is possible for amino acids to be resynthesized. That is, nitrogen which would otherwise be wasted is retained.

THE SPECIFIC DYNAMIC ACTION OF FOOD

When a subject in the basal state ingests food, an increase is observed in the rate of heat production. This increase above the BMR due to ingestion of food is known as the specific dynamic action (SDA) or the calorimetric effect of food. The amount of extra heat produced and the length of time during which the heat production is above basal depends upon the kind and amount of food ingested. The heat production commences to rise within an hour after the food has been eaten, attains a maximum in about the third hour and is maintained above the basal level for several hours. The greatest specific dynamic action is exerted by protein food. When protein is fed alone to a fasting animal, in an amount possessing a heat value equivalent to the animal's estimated basal metabolism, the heat production is raised 30 per cent or more above the basal level. Carbo-

hydrate causes a rise of about 6 per cent and fat of 4 per cent. That is to say, when a quantity of protein, carbohydrate or fat possessing an energy value of 100 Calories is fed separately to an animal whose basal metabolism is 100 Calories daily, its actual heat production will be 130, 106 or 104 Calories, respectively. The extra heat is generated by the combustion of body substance, so if loss of weight is to be prevented such an animal must be supplied with slightly more than 130 Calories if his diet is protein or if carbohydrates and fats are also consumed. Extra allowances must be made for the amounts of these substances which have been included.

To take a theoretical case in illustration: if a man with a basal metabolism of 1500 Calories were kept on a 1500-Calorie diet, his body weight would decline until the total heat production (basal + SDA) would just equal the energy value of the food. From there on, the body weight and total metabolism would remain steady at the new levels. But if the energy value of the food were again reduced to the point where it just balanced the basal metabolism (no allowance being made for SDA) a further weight loss and diminution in basal metabolism would occur, and should the adjustment of food to basal heat production be carried out repeatedly, the body tissues would be gradually consumed, as long as the subject survived, in order to furnish the extra heat caused by SDA. In planning a diet, therefore, an extra caloric allowance must be made for the SDA of the food itself (ch. 55).

The extra heat resulting from protein food cannot be employed for the production of mechanical or other forms of energy. It is waste heat and is simply added to heat produced by the muscular exertion. A diet very rich in protein is therefore unsuited to heavy muscular work. The SDA of protein is an important factor, however, in the regulation of body temperature (p. 52). With fat and carbohydrate the case is different, for the extra heat is harnessed in the performance of work. When exercise is undertaken upon either of these substances the heat due to their specific dynamic action is almost abolished, the extra energy being incorporated in the energy exchanges of the exercise (table 45 B).

When new tissue is being formed, i.e., when the nitrogen balance is positive, protein does not exert its usual specific dynamic action. Nor does it occur in a fever, such as typhoid, when there is great destruction of tissue protein. The ingested food then merely replaces or spares the tissue protein.

TABLE 45 8

The results of an experiment of Rapport's which illustrates the utilization of the "waste heat" of the specific dynamic action of fat and glucose in exercise

Heat production at rest and in exercise and recovery

	Resting (per hour)	Deviation from (A)	Excess in Ex- ercise and Re- covery (per kg of Work)*	Deviation from (A)
	calo- ries	per cent	calories	per cent

200 grams	17.8	+40.1	3.48	+45.0

* Based on $\frac{3}{4}$ hour period after beginning of exercise

THE CAUSE OF THE SPECIFIC DYNAMIC ACTION

Several explanations for the phenomenon have been offered. It is certainly not due to digestive processes, i.e., to the contractions of smooth muscle of the alimentary canal or to the work entailed in the secretion of the digestive juices. This is proved by the following facts. Bones given to a dog, or agar agar, saline cathartics, water or meat extracts (which stimulate powerfully the gastric secretion) given to man, have no effect upon the heat production. Also, as already mentioned, protein has no SDA when new tissue is being laid down. On the other hand, the injection of certain amino acids into the blood stream is followed by a specific dynamic effect.

The cause of the SDA is still imperfectly understood. It is generally accepted that the extra heat produced by protein food is associated with the metabolism of the amino acids. They exert in some way a stimulating effect upon the tissue cells, raising their heat production to a high level, i.e., the oxidation of the cells' own fuel material is increased, the rate of other metabolic processes within the cells is raised. The extra heat is not due to the amino acids themselves being utilized as fuel nor to a stimulating action upon the tissue cells of these materials in the unchanged state. It is in the intermediary reactions of the amino acids

that the specific dynamic action of protein should be sought—e.g., in the deamination process. Borsook and Winegarde conclude from their studies that the SDA of protein results from the metabolism (deamination and urea production) and the excretion of nitrogen, an increased excretion of nitrogen accompanies the greater heat production. According to Borsook an increase of from 7 to 10 Calories of extra heat are produced for each gram of extra nitrogen excreted. The remainder of the extra heat produced is a more variable and usually a larger fraction of the total, it is attributed to the metabolism of the carbon part of the protein molecule. There is a considerable body of evidence for the view that the deamination of the amino acids with the formation of urea contributes very considerably to the specific dynamic action of protein. Lundsgaard found, for example, that although the administration of sodium acetate or sodium lactate was followed by only a slight increase in heat production, ammonium acetate or ammonium lactate caused a pronounced rise, even ammonium chloride caused a well marked increase in heat production.

The reactions responsible for the SDA of protein are apparently situated in the liver and not in the tissue cells generally, since Wilhelmj, Bollman and Mann were unable to obtain any effect in hepatectomized dogs following the injection of amino acids. Dock also found that after the administration of casein to rats the oxygen consumption of the hind quarters (muscular tissue) was 8 per cent greater than in the corresponding tissues of a control group, whereas the oxygen consumption of the abdominal viscera was 141 per cent greater.

The specific dynamic action of carbohydrates is thought to represent the energy liberated in excess of that required for the conversion of glucose to glycogen. After a fast which depletes the glycogen stores, ingested glucose is oxidized in a negligible amount, yet it causes a pronounced specific dynamic action (Dann and Chambers).

The specific dynamic action of fat is ascribed to the increased concentration of fat in the tissue fluids and, as a consequence, to its more rapid oxidation ("plethora theory" of Lusk).

The glands of internal secretion appear to have no direct influence upon the SDA of protein, the usual effect has been observed in a cretin with a basal metabolic rate 20 per cent below normal and it is not altered in hyperthyroidism. Thyroidectomy in animals is said, however, to reduce the SDA of carbohydrate and fat. Cushag and Fulton found the SDA of protein within the normal range in a number of cases of pituitary disease (hypopituitarism and acromegaly). Gaebler found it of normal value in hypophysectomized animals. In undernutrition the SDA of all foods is increased. It is, according to some observers, diminished in simple obesity (ch. 50).

The SDA of carbohydrate and protein or of carbohydrate and fat is less than the sum of the values of each when fed separately. There is only a slight discrepancy, however, between the values for protein and fat, fed together or separately.

PROTEIN METABOLISM—Continued

The Nutritional Value of Various Proteins

Two factors must be considered in determining the nutritional value of a given protein (a) its digestibility, i.e., the amount absorbed, and (b) its suitability for the construction of tissue protein.

1 **THE BIOESTIMABILITY OF PROTEINS** Although by far the greater part of the nitrogen arising from the catabolism of amino acids within the body is excreted in the urine, a small fraction is eliminated through the secretions of the digestive glands and intestinal mucosa. This, the so-called *metabolic nitrogen*, is estimated from the nitrogen of the feces upon a nitrogen-free diet. In a man it amounts to from 0.5 to 1.5 gram daily, varying in amount with the bulk (roughage) of the diet. In order, therefore, to determine the proportion of a given protein which has undergone digestion and absorption, the total nitrogen content of the ingested protein is determined (each 6.25 grams of protein equals 1 gram of nitrogen), and from this value the nitrogen of the feces less that for the metabolic nitrogen is subtracted. Thus—

$$\text{food N} - (\text{feces N} - \text{metabolic N}) = \text{absorbed N}$$

The digestibility of the particular protein is then expressed as a percentage of the food nitrogen which has been absorbed. This percentage value is referred to as the *coefficient of digestibility*. For example, if the food contains, let us say, 10 grams of nitrogen and it is found that 9.5 grams have been absorbed the digestibility is 95 per cent. Digestibility in the sense just defined is quite different from the popular meaning of the term which refers rather to the subjective sensations accompanying digestion.

Proteins of animal origin have the highest digestibility which runs from 95 to 100 per cent. That is, the wastage in digestion is 5 per cent or less. The digestibility of the proteins of nuts and fruits is low, that of the proteins of legumes and of potatoes is around 80 per cent (see table 46.1). The digestibility of wheat proteins is from 90 to

100 per cent thus approaching that for animal proteins.

2 **THE SUITABILITY OF A GIVEN PROTEIN FOR THE SYNTHESIS OF BODY PROTEIN** This depends upon the amino acid constitution of the protein. It is obvious that the greater the proportion of amino acids in the dietary protein which can serve for the construction of tissue protein, the greater will be its potential nutritive value. In other words, the more closely the amino acid assortment in the food protein resembles that in body protein the less of the former need be furnished. A smaller proportion of the amino acids will then be discarded, their nitrogen eventually being excreted in the urine, i.e., less of the food protein will be wasted.

Methods employed for estimating the nutritive values of proteins Osborne and Meadel, employing rats, added a known amount of the protein to be tested to a diet free from all other proteins, but adequate in other respects (i.e., one possessing the necessary energy value, minerals, and the vitamins then known). They expressed the nutritive value of the protein as the weight, in grams, gained by the animals per gram of protein fed, in the case of young rats (value for growth), or in the case of adult rats, the smallest quantity of the fed protein in grams, per gram of rat per week, necessary to maintain a constant body weight (value for maintenance). McCollum and associates also employed rats, feeding a basal diet of first class quality in all respects except that it lacked protein. The lack was made good by adding the protein to be tested, and the percentage of protein required to be added to the food mixture in order to promote normal nutrition gave an index of its nutritive value. The general state of nutrition of the animals, as indicated by rate of growth, fertility, care of young and longevity, was noted over a period corresponding to two thirds or more of their life span. On this basis proteins were classed as "excellent," "good," or "poor." An excellent or first class protein is one which "will support nearly optimum nutrition over periods approximating two-thirds or more of the normal life

^b The metabolic nitrogen in the feces is assumed to equal 0.23 gram per 100 grams of dry matter of food. See Bulletin National Research Council, 1926 xi, part 1, no. 55, p. 23

^c Cooked

^d The cut tested was not recorded. It proved to be very fibrous. Analysis for shoulder cut assumed.

upon the rat when fed in amounts corresponding to 9 per cent in the food mixture. Nine per cent is therefore the critical level for a protein of the highest nutritive value. Inferior proteins must be fed at higher levels. The relative values of several food proteins are shown below in descending order.

Fish muscle, beef muscle
 Beef liver and kidney
 Egg (whole)
 Milk
 Soyabean
 Oats (rolled)
 Wheat (whole)

The determination of the minimal quantities of different proteins required for the maintenance of nitrogenous equilibrium in adult animals or of a positive balance (storage of nitrogen) in growing animals is also used as a means of arriving at the nutritional values of proteins.

The nutritive value of a particular protein, based upon the nitrogen metabolism following the feeding of known amounts, is employed by Mitchell. In this method, the value of the protein for repair (maintenance) or building of new tissue (growth) is given as a percentage of its adsorbed nitrogen which is not lost in the urine, i.e., the percentage retained in the body. This is called its *biological value*. The animal is placed upon a basal diet complete in so far as nonprotein factors are concerned. In order that none of the protein shall be burned for energy purposes, its level in the diet is kept low, i.e., there should be no excess over that required for growth or maintenance. The following example from Mitchell will serve for illustration.

A rat receiving a diet containing about 4 per cent of protein, ingested daily 56.9 mg. of nitrogen and excreted 27.6 mg. of nitrogen in the feces. Of the latter 21.7 mg. constituted metabolic nitrogen (p. 791). The unabsorbed nitrogen was therefore only $(27.6 - 21.7) = 5.9$ mg., and the absorbed nitrogen $(56.9 - 5.9) = 51.0$ mg. The daily urinary nitrogen was 48.6 mg. Of this, 37.7 was derived from the body tissues (estimated from urinary nitrogen on a nitrogen free diet (p. 785)). The total urinary nitrogen less this value for the endogenous nitrogen must represent the quantity of absorbed nitrogen which was excreted that is, $(48.6 - 37.7) = 10.9$ mg. is the quantity of absorbed nitrogen which had been wasted in metabolism. The absorbed nitrogen, as just stated, amounted to 51.0. So $(51.0 - 10.9) = 40.1$ mg. were retained in the body. The biological value of the dietary protein was therefore $((40.1/51.0) \times 100) = 79$ per cent.

In order to know the value of a food as a source of protein the "biological value" must be considered as well as the quantity present (nitrogen $\times 6.25$). A food may contain a first class protein in small amounts or a poor protein in larger amounts. In some foods the protein is both poor in quality and low in amount whereas in others both the quantity and quality of the protein are high. The *protein value* of a food must take both these factors into account.

The values of individual amino acids were tested by Osborne and Mendel by feeding purified proteins known to be deficient in their amino acid constituents. The weights of the animals on the deficient protein were observed for periods before and after the missing amino acid had been added to the diet. Rose's method consists in feeding a mixture of purified amino acids such as are found in casein. The effect upon growth was then determined after one or other amino acid had been omitted from the mixture.

The value of a protein in nutrition depends entirely upon its amino acid constitution. Block and Mitchell have shown a very close correlation between the biological value of a protein and its

amino acid content. Thus, by the hydrolysis of a protein and determining the percentages of the various amino groups of which it is composed, a very accurate appraisal of its nutritive value can be made. Although animal proteins are usually superior to those of plant origin, no generalization can be made in this respect. It is a matter of the amino acids of which the protein, animal or vegetable, is made up. In table 46 2 the amino acid percentages in the proteins of liver and of soy bean are compared.

THE ESSENTIAL IMPORTANCE OF CERTAIN AMINO ACIDS FOR GROWTH AND MAINTENANCE

In 1907 Willcock and Hopkins found that when young mice were fed upon a diet which contained zein (a protein of maize) as its sole protein, growth was arrested and the animals died in about 17 days. Zein is almost completely free from tryptophane. Yet, the addition of this amino acid to the diet was not capable of promoting growth, and the survival period of the animals was extended to only 33 days. The addition of tyrosine was without effect since zein already contains this amino acid in adequate amounts. It was shown by Osborne and Mendel that when lysine, which is also absent from this protein, was added to the zein diet together with tryptophane, the animals grew normally and remained in good health (fig. 46 1). Lysine added alone was of no more benefit than tryptophane alone. *Gelatin*, like zein, is an incomplete protein. It lacks tyrosine and tryptophane and is very deficient in cystine. A diet which contains gelatin as its sole protein will not permit growth nor even maintain nitrogen equilibrium in an adult animal. When, however, the lacking amino acids are added to the gelatin diet its defects are corrected.

Casein. Casein is deficient in glycine and has a low cystine content. However, when, casein is fed in sufficient quantity—about 18 per cent of the diet—or if cystine is added, normal growth results (fig. 46 2).

Edestin (a protein in hemp seed) is relatively poor in lysine as is also *gladin* (of wheat) whereas *phaseolin* (of navy bean) is deficient in cystine and tryptophane. If these, or other incomplete proteins, are supplemented by adding to the diet the amino acids in which they are deficient, growth is supported. Also when the amino acid deficiency is not too great, growth can be promoted by increasing the percentage of the incomplete protein in the diet (see table 46 3).

An essential or indispensable amino acid has been defined by Rose as one that cannot be syn-

TABLE 46 2

(From data of Block and Mitchell)
Approximate amino acid content of liver and of soy bean compared
(Calculated to 16.0 grams of nitrogen)

Amino Acid	Liver	Soy Bean
	grams	grams
Arginine	6.6	7.1
Histidine	3.1	2.3
Lysine	6.7	5.8
Tyrosine	4.6	4.1
Tryptophane	1.4	1.2
Phenylalanine	6.1	5.7
Cystine	1.4	1.9
Methionine	3.2	2.0
Threonine	4.8	4.0
Leucine	8.4	6.6
Isoleucine	5.6	4.7
Valine	6.2	4.2

FIG. 46 1 Shows the indispensability of lysine for growth (After Mendel)

thesized by the animal organism out of the materials ordinarily available, at a speed commensurate with the demands for normal growth and which must therefore be supplied in the diet.

Of the 25 amino acids which have been identified as constituting protein material, 10 are indispensable for normal growth. They are as follows:

Arginine	Methionine
Histidine	Phenylalanine
Isoleucine	Threonine
Leucine	Tryptophane
Lysine	Valine

Experiments in which it was shown that casein when constituting the sole protein of the diet would not support growth unless fed in relatively large amounts or in smaller amounts and supplemented by cystine, led to the belief that this amino acid was indispensable. The mistake was evidently the result of confusion with the other sulfur-containing amino acid, *methionine*. The failure of growth on the low casein diet was due to this protein's inadequate methionine content, but this could be made good by the addition of

FIG. 462. Chart on left shows satisfactory growth of rat when 18 per cent of casein was present in the diet as the sole protein. With a smaller amount of casein—9 per cent—much less rapid growth ensued. That the insufficiency of the smaller amount of casein is essentially due to its relative deficiency in cystine is shown by the marked accelerating influence upon growth brought about by the addition of this amino acid to the food containing 9 per cent of casein and the prompt retardation of growth which resulted from the withdrawal of cystine from the diet. Chart on right shows the favorable effect upon growth of supplementing a protein (zein), incapable of maintaining animals when it is the sole protein furnished in the diet, with a more "perfect" protein (lactalbumin). The proportion of the lactalbumin used—4.5 per cent—was of itself insufficient for full growth. It evidently furnished the amino acid groups which were lacking in zein. (After Mendel.)

cystine. In other words, cystine can substitute in part for methionine, cystine itself is not essential, for it can be completely replaced in the diet by methionine¹ which can be converted to cystine in the body. Proof of the derivation of cystine from methionine was obtained by Tarver and Schmidt who fed animals methionine containing the radioactive isotope of sulfur (S^{35}) and later isolated isotopic cystine from their tissues. Cystine is a constituent of plasma protein and unless it or methionine is furnished in adequate amounts in the diet hypoproteinemia results. Cystine is also an essential component of keratin, the protein of hair, feathers, nails, horn, etc. Arginine (p. 774) can be synthesized in the body but not in adequate amounts for normal growth, it is therefore an essential constituent of the diet of young animals. Tyrosine can be formed from phenylalanine.

¹ To make this point clear we may use an illustration the case of a typesetter who has lost a number of dies for say, the letter A. He can continue to set type so long as his supply of A letters lasts but when this is exhausted his work must cease though there is still a large number of other letters. His typesetting is limited by his supply of A letters.

In rats deprived of *valine* grave nutritional defects develop which have been the subject of studies of Epstein and Rose. The animals become very sensitive to touch and show severe muscular incoordination, (e.g., staggering gait and circus movements) together with loss of appetite, emaciation and eventually death.

The amino acid requirements for building new tissue (growth) are more exacting than those for repair (maintenance), i.e., for the maintenance of nitrogen equilibrium in the adult and the prevention of a loss of weight. Some amino acids which are essential for the growing animal can be dispensed with in the adult. Arginine, for example, is not required in the diet of the adult dog, and in the adult rat nitrogen equilibrium can be maintained upon a diet lacking in this amino acid, but, as just mentioned, it is not synthesized rapidly enough to promote maximal growth. Even of the amino acids essential for maintenance the level in the diet need not be as high for maintenance as for growth. Adult man can be maintained in nitrogen equilibrium upon eight amino acids, histidine being dispensable.

TABLE 46 3^a
The amino acid content of a number of proteins, grams per cent

Amino Acid	Gelatin	Casein	Lactalbumin	Egg Albumin	Glutadin	Zein	Edestin

^a Modified from Mitchell and Hamilton, "The Biochemistry of the Amino Acids" Am. Chem. Soc. Monograph Series No. 48, p. 191

The utilization of a protein deficient in one or other amino acid is limited by that deficiency. For example, if edestin, which is poor in lysine, is the sole protein of the diet, the other amino acids of which it is composed are utilized only in certain proportions limited by the lysine content. A large part of the remainder is discarded. Similarly the utilization of casein is limited by its cystine plus methionine content. Now if lysine is added to the diet of which edestin is the sole protein, or cystine or methionine is added to the casein diet, the other amino acids in these proteins can be utilized and built into body tissue. Lysine is essential for maintenance as well as for growth, but for the former, relatively small quantities are required. Glutadin (of wheat), which contains less than 1 per cent lysine, is inadequate for growth even though fed in large quantities but is suitable as the sole source of protein in an adult. Zein, on the other hand, which is entirely lacking in lysine and contains little tryptophane is inadequate for either growth or maintenance. Serum albumin is deficient in tryptophane and isoleucine, it will not promote growth in young rats and will scarcely maintain body weight. The proteins of several common foods are given in table 46 4.

Most of the work relating to the indispensability of the various amino acids has been carried

out upon rats. The amino acid requirements of adult man have been investigated by Holt and his colleagues and by Rose and his coworkers. Their results in general accord with those of animal experiments. Methionine, as the sole source of sulfur-containing amino acids, was found to be capable of maintaining nitrogen equilibrium. The nitrogen balance could not be maintained upon a diet completely lacking in lysine, whereas histidine and arginine proved to be dispensable. Others have found, however, that while nitrogen equilibrium can be maintained in men on a diet lacking in histidine, loss of weight occurred. Tryptophane was found to be indispensable, the subjects developing negative nitrogen balances within a few days after having been placed upon a diet lacking in this amino acid, nor could nitrogen equilibrium be maintained when valine, threonine, leucine, isoleucine or phenylalanine was lacking from the diet. Lysine and methionine were also found to be indispensable, but as mentioned above, adults can be maintained in nitrogen equilibrium in the absence of histidine.

Rose and his collaborators using synthetic diets have attempted to determine quantitatively the amino acid requirements of man. The diets used supplied from 6.7 to 7.1 grams of nitrogen per day and contained in addition to essential amino

TABLE 46 4*

Character of proteins in some common foods

Food Materials	Chief Kinds of Protein Present	Complete or Incomplete
Almonds	Excelsin Casein	Complete Complete (low in cystine)
Cheese	Lactalbumin Glutelin Zein	Complete Complete Incomplete (lacks lysine and tryptophane, low in cystine)
Corn	Ovalbumin Ovovitelin	Complete Complete
Eggs	Gelatin	Incomplete (lacks tryptophane and tyrosine, only a trace of cystine high in lysine)
Lean meat	Albumin Myosin Casein	Complete Complete Complete (low in cystine)
Milk	Lactalbumin	Complete
Navy beans	Phaseolin	Incomplete (low in cystine)
Peas	Legumin	Incomplete (low in cystine)
Soy beans	Glycinin Legumelin Ghadin	Complete Incomplete Incomplete (lacks lysine)
Wheat	Glutenin	Complete

* From M. S. Rose, *Foundations of Nutrition*

TABLE 46 5

Amino acid requirements of adult man

Amino Acid	Range of Requirements Observed	Proposed Tentative Minimum	Safe Intake
	grams per day	grams per day	grams per day
L-Isoleucine	0.65-0.70	0.70	1.40
L-Leucine	0.50-1.10	1.10	2.20
L-Lysine	0.40-0.80	0.80	1.60
D,L-Methionine*	0.80-1.10	1.10	2.20
L-Phenylalanine†	0.80-1.10	1.10	2.20
L-Threonine	0.30-0.50	0.50	1.00
L-Tryptophan	0.15-0.25	0.25	0.50
L-Valine	0.40-0.80	0.80	1.60

* L-Cystine may replace up to 80 to 89 per cent of the minimal methionine needs. † Methionine is fully as active as L-methionine.

† L-Tyrosine may replace up to 70 to 75 per cent of the minimal phenylalanine requirement.

acids, glycine and urea. The latter two compounds served as a source of nitrogen for the synthesis of the dispensable amino acids. The amount of a given amino acid in the diet was decreased until the nitrogen balance of the subject became negative. The diet was then supplemented with the amino acid until nitrogen equilibrium was re-established. The amino acid requirements of man determined by Rose in this manner are shown in table 46 5.

It seems that, generally speaking, the several amino acids which have been found indispensable for rats are also essential dietary constituents for other mammals, including man. There are, however, certain minor species differences, the growing mouse, for example, can dispense with arginine in the diet, since, apparently, it can synthesize this amino acid in greater amounts than can the rat. *Glycine* which is required especially for the manufacture of collagenous tissue and of protoporphyrin (ch. 6) can be synthesized by the body and, therefore, is not an essential constituent of the diet in mammals. It is indispensable, however, for the growth of chicks, although it can be replaced in this species by creatine. The chick, also unlike the rat, has no ability to synthesize arginine. The essential or nonessential nature of a particular amino acid, as well as the species differences, may possibly depend upon bacterial synthesis in the intestine, the bacterial synthesis of amino acids and even of protein is known to occur in the intestinal tract of ruminants. It has been found by Martin, for example, that rats fed a diet containing all the essential amino acids and the known vitamins fail to grow if succinylsulfazole, a bacteriostatic drug, is added to the food.

The most suitable proteins for growth are those of animal origin and especially those which nature has provided for the nourishment of the growing animal, namely,

lactalbumin (of milk) *ovovitelin* (of hen's egg)
ovalbumin (of hen's egg)

These support growth when given at a level of about 9 or 10 per cent in the diet. Next in order of their biological value come,

proteins of meat *glutelin* (maize)
glutenin (wheat) *glycinin* (soy bean)
casein (milk)

These support growth if given in sufficiently high concentration in the diet. Casein, for instance, is required to be given at a level of 18 per cent for growth and 10 to 12 per cent for maintenance. A comparison of the value for growth of several proteins, when given in the same percentage in the diet, is shown in figure 46 3.

FIG 48.3 Comparison of growth on diets containing approximately the same percentage (4.5 per cent) of different proteins, namely, lactalbumin, edestin, casein, globulin (squash seed) and glycinin (soy bean) (After Lusk)

The following vegetable proteins are incapable of supporting growth but are suitable for maintenance

- gladin (wheat or rye)
- legumin (pea)
- legumelin (soy bean)
- phaseolin (kidney bean)
- hordein (barley)

The following are incomplete proteins and are unsuitable for either growth or maintenance

- zein
- gelatin

The biological values of the protein mixtures in the various foods are shown in table 46.1, p. 792, from which it is seen that the values are in descending order as follows: eggs, milk, meats, whole wheat and potato, rolled oats, corn, white flour and beans. The nutritional value of ordinary meat varies largely with the cut—a tough fibrous meat, i.e., one with a high proportion of collagen and elastin has a low coefficient of digestibility and a

low biological value. The biological value of some samples of very fibrous beef, for instance, may be little higher than that of white flour.

THE SUPPLEMENTARY RELATIONS AMONG PROTEINS

It does not necessarily follow that because a certain protein is inadequate for growth or even for maintenance that it is worthless in nutrition. It is evident from what has been said in the preceding paragraphs that an incomplete protein can be utilized if its shortcomings in one or more of the essential amino acids are made good by the addition to the diet of some other protein, rich in the elements which the first one lacked. Zein, for instance, fed in any quantity, is inadequate for either growth or maintenance. Lactalbumin at a level of less than 8 or 9 per cent is incapable of promoting normal growth. Yet normal growth and nutrition are supported by a diet containing 13.5 per cent zein and 4.5 per cent lactalbumin.

(fig 46 2) The proportions of tryptophane and cystine and probably also of lysine are higher in lactalbumin than in body protein. Therefore, the excess of these amino acids in lactalbumin, instead of being wasted, combines with the amino acids of zein (which otherwise would be discarded) to form tissue protein.

In a similar manner the amino acids of gelatin are utilized if supplemented by a protein rich in tryptophane and cystine. Even two incomplete proteins, if one contains an abundance of the amino acids which the other lacks supplement one another. So, the biological value of two proteins given together may be much greater than the sum of their values when fed alone. Proteins which lack the same amino acid (e.g., casein and phaeosol in which are deficient in cystine) cannot of course supplement one another. The supplementary relations of proteins is evident in the chief natural foods: these all contain two or more proteins (see table 46 4). For example, in milk the deficiency of casein in cystine and methionine is made good by the relatively high percentage of these amino acids in the other milk proteins. Also, though gliadin of wheat will not support growth, wheat itself will. The lysine poor gliadin is supplemented by the other wheat protein, glutenin, which is rich in lysine. Maize contains, besides zein, the supplementary protein glutenin. These facts obviously, are of fundamental importance in dietetics, especially in the economy of agricultural feeding. Cheaper foods can be fed and good nutrition promoted if due consideration be given to the supplementary relations of their contained proteins. Gelatin rich in lysine improves the nutritional value of wheat and oats, both relatively poor in this amino acid. There is also a pronounced supplementary relation between the proteins of milk and those of oats and wheat.

THE METABOLISM OF THE PURINE AND PYRIMIDINE BASES

One class of conjugated proteins—the *nucleo-proteins* (p 771)—are compounds of simple basic proteins *protamines* and *histones*, with *nucleic acid*. The protein is in saltlike combination with the acid but appears to be present in excess. When a nucleoprotein is hydrolyzed the protein is split off leaving nucleic acid. Cell nuclei contain nucleoprotein in relatively high concentration, and it was from pus cells obtained from used bandages of surgical wards, and from the heads of salmon sperm, that this conjugated protein was originally isolated by Miescher.

The nucleic acids are composed of (a) phosphoric acid, (b) a pentose and (c) a nitrogenous group—a purine or a pyrimidine. A mononucleotide—the fundamental unit of the complex nucleic acid molecule—may therefore be represented thus

The pentose part of the mononucleotide may be either 2-d-deoxyribose or d ribose and the resulting compounds are referred to respectively as deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Early investigations revealed that the thymus gland is a rich source of DNA and it was thought that this nucleic acid was found only in animal tissues whereas the RNA isolated from yeast was present only in plants. However, this belief was erroneous for it has been amply demonstrated that DNA and RNA are normal constituents of both plant and animal cells.

It was originally believed that each nucleic acid molecule contained four bases which were present in equimolecular amounts. In view of this Levene proposed that four mononucleotides each containing a different nitrogenous base, were linked together to form a tetranucleotide. The tetranucleotides were considered to be the subunits of long chain polymers that constitute the nucleic acid molecules. The tetranucleotide theory had to be abandoned when more accurate techniques showed that the different bases contained

in a nucleic acid molecule were not necessarily present in equimolecular amounts. The four pyrimidine bases commonly found in the nucleic acids are cytosine which is present in both DNA and RNA, 5-methyl cytosine and thymine which appear to be found only in DNA and uracil which is found only in RNA.

Cytosine

5 Methyl cytosine

Uracil

Thymine

The purine bases *adenine* and *guanine*, are present in both the DNA and RNA.

Guanine

Adenine

Estimations of the molecular weight of nucleic acids by various methods have produced results that vary over a wide range. Values of 10 000 to 23 000 have been postulated for the molecular weight of RNA whereas figures for DNA lie between 500 000 and 3 000 000. Upon hydrolysis nucleic acid is split into its constituent nucleotides. The purine nucleotides are termed *adenylic acid* and *guanylic acid* respectively. The further action of hydrolytic agents splits off phosphoric

acid from the nucleotides. The residue (sugar + purine or pyrimidine) is then called a *nucleoside*. The adenine-containing nucleoside is known as *adenosine*, the one containing guanine is called *guanosine*.

THE NUCLEIC ACID DISTRIBUTION IN THE CELLS

The chief nucleic acid of animal cells is desoxyribonucleic acid (DNA). Smaller amounts of ribonucleic acid (RNA) are also present, largely in the nucleolus. DNA is found mainly in the chromosomes together with small amounts of RNA. The protein with which the nucleic acid is combined is usually a histone, but is a protamine in sperm cells. The cytoplasm of the cells also contains both nucleic acids but RNA predominates; it appears from the ribonuclease test¹ that the RNA is contained mainly in inclusion bodies (e.g., mitochondria) within the cytoplasm.

There is little doubt that nucleic acids are closely associated with the physiology of cells, and especially of the chromatin material of the nucleus during reproduction. During the different phases of mitosis changes in concentration and distribution of the nucleic acids of the cells occur. In the metaphase the DNA of the chromatin increases whereas the RNA of the cytoplasm diminishes. In mitosis (sperm cells) the concentration of DNA is doubled during the first division but not in the second; an increase again occurs in the later spermatid. The nucleic acids are believed to play an essential role in the multiplication of the genes. A number of pathogenic viruses have been shown to be complex nucleoproteins. Staphylococcus bacteriophage also is most probably a nucleoprotein.

THE END PRODUCTS OF PURINE AND PYRIMIDINE METABOLISM

Nucleoprotein is split by the digestive enzymes into protein and nucleic acid. Specific tissue enzymes known as *desoxyribonuclease* and *ribonuclease* break the respective nucleic acid molecules into smaller groups of nucleotides—*oligonucleotides* and *tetranucleotides*. These enzymes are present in pancreas and other animal tissues, in yeast,

and in certain bacteria (see streptodornase, ch. 12). The further changes which the molecule undergoes in the tissues are not clear, but nucleotidases and nucleosidases which break off phosphoric acid and sugar groups respectively have been described.

URIC ACID (first isolated by Steele in 1776 from urinary calculi). This urinary constituent is the end product of purine metabolism in man (see scheme below), higher apes, birds and reptiles.² *Adenine* is deaminated by a specific tissue enzyme, *adenase* to form *hypoxanthine*. Hypoxanthine is then oxidized by the enzyme, *hypoxanthine oxidase* to *xanthine* which in turn is oxidized, by means of *xanthine oxidase*, to uric acid. The other purine, *guanine*, is converted by the deaminative action of *guanase* to *xanthine* and by further oxidation to *uric acid*.³ In mammals other than the primates, and in insects excepting the *Diptera*, from 80 to 98 per cent of the uric acid is oxidized further by an enzyme *uricase*, to *allantoin* and carbon dioxide.⁴ These animals would appear to possess an advantage over man, since allantoin is some 250 times more soluble than is uric acid. The conversion of uric acid to allantoin occurs in the liver (dog). Mann and his associates, for example, have shown that after hepatectomy uric acid accumulates in the blood, and when uric acid is injected, from 70 to 100 per cent can be recovered from the urine unchanged. This is in marked contrast to the behavior of the normal dog which excretes 98 to 100 per cent as allantoin. Extracts of dogs' liver are rich in *uricase*.

In some classes of ureotelic animals (most fishes and amphibia) further degradation of uric acid occurs, allantoin being converted to *allantoic acid* (catalyzed by *allantoicase*) and then to *urea*. In

¹ In birds and reptiles uric acid is the end product of protein metabolism as well as of purine metabolism. Arginase is absent from the liver of these forms. According to Benedict from 60 to 70 per cent of the urinary nitrogen of these species is in the form of uric acid. Thus the end product of nitrogen metabolism differs according to the animal class. Those animals—birds and reptiles in which the main end product is uric acid are called *uricotelic* (Gk. *telos*, end) whereas mammals which excrete nitrogen mainly as *urea* are termed *ureotelic*.

² The production of uric acid may follow an other course, namely, conversion of the nucleoside *adenosine* or *guanosine* by deamination to *hypoxanthosine* or *xanthosine*, which is then split into its pentose and purine groups—*hypoxanthine* or *xanthine* respectively (see plan on p. 801).

³ The spotted coach dog (Dalmatian) oddly enough is an exception like man and unlike other canine breeds it excretes uric acid.

⁴ Guanine is the end product of purine metabolism in the spider.

¹ This test depends upon the fact that basophilic granules in the cytoplasm are stained red by pyronine, a basic dye, but fail to do so after incubation with an aqueous solution of ribonuclease. A specific test (Feulgen's) for DNA in cell nuclei consists in treating the tissue with HCl and then immersing it in fuchsin-sulfurous acid reagent (Schiff's reagent), in the presence of DNA a purple color appears. By means of these two tests DNA and RNA can be distinguished.

Diagram A
Nucleic acid

crustacea, the latter is finally broken down to ammonia and carbon dioxide

The stages through which uric acid or allantoin is derived from nucleic acid are shown in the scheme on page 805

The chemical changes involved in the conversion of guanine and adenine to uric acid or allantoin are indicated in the formulae

Little is known concerning the fate of the pyrimidines in man. In animals they are for the most

part completely oxidized, the nitrogen being excreted mainly as urea. The urine contains pyrimidines in insignificant quantities.

THE SYNTHESIS OF PURINES IN THE BODY

There is no doubt that purine synthesis occurs in the young mammal, for, when upon a diet composed exclusively of milk, which is almost purine free, it excretes uric acid or allantoin, and at the same time manufactures nucleic acid for the construction of cell nuclei. That synthesis also occurs in the adult was shown by Benedict who kept a Dalmatian dog under a purine free diet for nearly a year, during which time the animal excreted 100 grams of uric acid. This had not apparently been derived from body tissue since the animal maintained a constant weight. In more recent studies with isotopically labelled nitrogen (N^{15}), purine synthesis has been proved conclusively, after the administration of amino acids or ammonium salts containing N^{15} the isotope has been found in the nucleic acids of the animal's tissues. Glycine has been demonstrated in the same way to participate in the formation of the purine ring.

Much of the recent success in delineating the metabolic sequences through which simple compounds are incorporated into the more complex purines and pyrimidines has been due to the isolation by Kornberg and his associates of 5-phosphoribosylpyrophosphate (PRPP). This substance which is formed enzymically in body tissues through the reaction of adenosine triphosphate (ATP) with ribose phosphate, plays a central role in the biosynthesis of the nucleotides. Simplified schemes depicting the metabolic steps in the synthesis of some mononucleotides are presented below.

THE PRODUCTION, DESTRUCTION AND EXCRETION OF URIC ACID

In man, uric acid is formed in part from purines taken in the food (*exogenous uric acid*) and in part from body purines (*endogenous uric acid*). The latter are derived from the breakdown of nuclear

material as well as from free mononucleotides e.g., adenylic, inosinic and guanylic acids, found in muscle and glandular structures. Muscle and more especially glandular tissues, e.g., thymus, liver, kidney, pancreas, testes, etc., and leguminous vegetables are foods rich in purines.

Uric acid is formed from ammonia in the liver of the bird but little is known of the intermediate stages of the synthesis. As already mentioned (footnote, p. 800) uric acid is the end product of both protein and purine metabolism in birds and most reptiles, when ammonium salts containing N^{15} are fed to birds, uric acid labelled with the isotope is excreted. According to Krebs and his associates hypoxanthine is first produced. Just as in the dog no urea is formed after hepatectomy, so in birds no uric acid is produced after removal of the liver, ammonia accumulates in the blood. The site of uric acid production in man is unknown, but the liver, according to Jones, is the only tissue which contains xanthine oxidase, which suggests that uric acid production is, in part at least, a function of the human liver. The results of the investigations of Folin and associates indicate that from 30 to 70 per cent of the uric acid produced by the human subject is destroyed, the remainder appearing in the urine. The liver is probably the site of uric acid destruction in man. We have already seen that uric acid accumulates in the blood of the hepatectomized dog, which indicates that uric acid production occurs in extrahepatic tissues and that the uric acid/allantoin conversion is a function of the liver. Little information is available concerning the process whereby uric acid is destroyed in the human body, its end products are unknown. Allantoin is not one of them; however, since human urine contains insignificant amounts of this substance, and what little is present is simply that taken preformed in the food. Uric acid is excreted in the urine as the urates of sodium, potassium

Diagram B

Diagram C

and ammonium, and in the free state. After urine has been voided a crystalline deposit of urates and free uric acid appears. The average daily output of uric acid, on an ordinary diet, is from 0.5 to 1 gram. Of this the endogenous uric acid amounts to from 0.3 to 0.4 gram. Muscular tissue most probably furnishes the precursors of endogenous uric acid, exercise causing a rise in the uric acid of the blood, and increased excretion in the urine.

Protein (purine-free, e.g., milk, eggs) and carbohydrate foods accelerate the excretion of uric

acid, and lower its level in the blood.* Food fat has the reverse effect—reduced excretion and a raised level in the blood.

Small quantities (15 to 45 mg. daily) of purines are excreted in the urine. These include adenine (but not guanine), hypoxanthine and xanthine as well as the methyl purines contained in beverages.

*The possibility has been suggested in the past that a proportion of the uric acid formed in the human body is derived, as the great part of it is in birds, from the catabolism of protein. There is no reason to believe, however, that a conversion of this nature occurs to any significant extent.

Diagram D

The latter are caffeine (1-3,7 tri methyl xanthine) of coffee, theophylline (1,3 di methyl xanthine) of tea and theobromine (3,7 di methyl xanthine) of cocoa. The methyl purines undergo partial demethylation in the body and are excreted as mono and dimethyl purines. It appears that theobromine is excreted entirely in this form and is not converted to uric acid. Caffeine and theophylline on

the other hand are converted in considerable amounts to uric acid and excreted as such. This is an important point to bear in mind when considering dietary restrictions for gouty subjects.

Gout

Gout is a disease which predominantly affects the human male. Its incidence is very low in

women and it is not known to occur in other animal species. The acute attack generally starts suddenly (overnight) and is characterized by the development of inflamed swollen joints that are excruciatingly painful. The joint of the big toe is often affected first although any one may become involved. Gouty arthritis is frequently precipitated in people predisposed to this disease by traumas such as local or general infections and may follow overindulgence in rich foods or alcohol. The acute stage lasts from about one to six weeks and eventually subsides spontaneously.

The uric acid content of normal blood averages about 3 mg per 100 cc. In gouty individuals the blood uric acid concentration is elevated and may reach levels 10 to 20 times the normal value. The hyperuricemia of gout is usually accompanied by the presence of deposits of uric acid in the cartilaginous tissue about the joints of the great toe and fingers and in the helix of the ear and tarsal plates of the eyelids. These deposits, which in some areas may reach the size of golfballs, are called *tophi* and are completely painless.

The cause of uric acid deposition in the tissues is obscure. It is not a result of the blood becoming saturated with this metabolite for although the uric acid concentration may be greatly elevated the limit of its solubility in blood is never reached. In other conditions associated with hyperuricemia (such as nephritis and leukemia) *tophi* do not usually occur. It has been suggested that local changes which increase the affinity of cartilaginous tissues for uric acid are responsible for the growth of the *tophus*.

Reports in the early literature indicated that the hyperuricemia of gout was the result of a renal defect in the excretion of uric acid. However, in numerous recent investigations, where more refined methods have been used to assess kidney function, no evidence has been obtained of any abnormality in urate excretion in victims of gout. The result of investigation carried out by Stetten and colleagues and by Wyngaarden leave little doubt that the *overproduction* of uric acid is largely responsible for the high concentration of this metabolite in the blood. These workers have consistently found that people afflicted with gout incorporate two to five times as much glycine-1-¹⁴C into uric acid as do normal individuals.

The factors responsible for the production of acute inflammation in gout are unknown. The following observations serve as convincing evidence that the high blood level of uric acid is not directly responsible for the attack of gouty ar-

thritis. (a) Although a diminished excretion of blood uric acid may precede an attack there is no rise in the blood uric acid at this time. Substances such as cortisone and benemid will increase the excretion of uric acid but fail to relieve an acute attack. (c) The administration of uric acid orally, intravenously or subcutaneous around the joints, to gouty individuals during periods when the disease is quiescent, fails to precipitate an attack. (d) Hyperuricemia may be present in a number of other diseases (leukemia, polycythemia, nephritis) with no signs of gout.

Although the production of uric acid is greatly accelerated in gout the substance itself does not produce acute inflammation. This strongly suggests that a precursor of uric acid is the offending agent.

Other conditions associated with a high level of blood uric acid are (a) *Leukemia and polycythemia*. The elevation of the blood uric acid in these conditions is not associated with symptoms of gout, the high level of blood uric acid is evidently due to increased production and not to failure in excretion. In leukemia, for example, the amount passed daily in the urine may be as much as 12 grams. The increased uric acid production in this condition is probably due to the disintegration of body tissue generally rather than, as has been supposed, to the destruction of white cells. (b) *Pneumonia*. (c) *Nephritis*. In renal failure the uric acid is one of the first of the nitrogenous substances of the blood to show a rise. (d) *Lead poisoning*. (e) *Toxemias of pregnancy*. (f) In certain other conditions associated with a high nonprotein nitrogen of the blood.

CARBOHYDRATE METABOLISM

Without doubt the carbohydrate substance most important in metabolism is glucose. All organisms seem to be able to utilize glucose. Glucose (sometimes called dextrose because its solution rotates the plane of polarized light in a dextro-rotatory direction and often written *d* glucose) dissolves in water to give an equilibrium mixture of α and β glucose approximately two-thirds of the glucose being of the α form. The formulae of these two isomers are written

It will be noted that a cyclic structure has been accorded the glucose molecule.¹ In this case the ring is composed of five carbon atoms and one

¹ To account for the characteristic reducing properties of glucose it is presumed that in solution there exists a very small amount of the open chain aldehydic form in equilibrium with the cyclic forms.

oxygen atom (sometimes referred to as an amylenic oxydic ring). α and β isomers of glucose may also possess a ring composed of four carbon atoms and one oxygen atom. This is the so-called γ -glucose. Such a ring is a butylene oxydic ring. These forms of glucose are very reactive; that is, unstable. They have not been isolated. It may be pointed out as an example of their reactivity that they reduce Fehling's solution in the cold. Because of this marked reactivity it has been postulated that such compounds must be the first intermediaries in glucose metabolism. But there is no conclusive evidence for such a change, and all theories of glucose metabolism involving the formation of a reactive form of glucose have very little factual basis. Glycogen or animal starch is a polysaccharide composed of glucose units and so is written $(\text{C}_6\text{H}_{10}\text{O}_5)_x$ [according to Haworth, *x* = 12]. In liver glycogen formed from galactose *x* may equal 18 (Bell). Glycogen is widely distributed in the animal body, but the bulk occurs in the muscles and the liver. Glycogen may be isolated from tissue by hot water extraction or more readily and completely by hot alkali. It is worthy of note that whereas polysaccharides are very stable in alkaline solution, monosaccharides (glucose, fructose, galactose, etc.) are unstable. The reverse behavior is exhibited in acid solution. The glycogens, as Cori has shown, are a series of branched polysaccharides differing mainly in the degree of branching and the length of the so-called inner and outer chains. Step-wise degradation by the action of phosphorylase and amylo-1,6-glucosidase and synthesis by phosphorylase and the branching enzyme of liver and muscle has revealed the structure.

Glucose occurs in the body in combination with other substances, such as salts of glucose phosphoric acids, and in the lactating animal in combination with galactose as lactose. The latter sugar (glucose β galactoside) may be obtained in two distinct crystalline forms referred to as α and β lactose respectively.

The slight difference in chemical configuration between glucose and galactose should be noted. Carbohydrates occur as substituent groupings in certain proteins. Such proteins may be extracted from tissues paying due regard to their solubility properties. From such extracted proteins there have been isolated glucose (from glycoproteins), glucosamine, mannose (from certain blood proteins) and various pentoses, that is 5 carbon sugars possessing the general formula ($\text{C}_5\text{H}_{10}\text{O}_5$) in nucleic acid which is combined with certain proteins to give the so-called nucleoproteins (ch 47). It may be pointed out that pentoses also occur in combined form as nucleotides, and that very rarely cases of human pentosuria are encountered.

Carbohydrates also occur linked with fatty substances. Thus the cerebroside contains within their molecule galactose units. The galactose is present in the normal or amylenic oxide ring form. Cerebrosides may be extracted with the usual fat solvents. The galactose may be split off from such extracted substances by acid hydrolysis. Glucose may also be present in cerebroside (p 843).

Methods of Estimation

Glucose. The simple sugars have four properties which permit their identification and estimation: (1) their ability to reduce the salts of heavy metals in alkaline solution; (2) their optical activity; (3) fermentation by yeast and by various microorganisms; (4) oxidation by specific enzymes (glucose oxidase). The methods depending on the reduction of the salts of heavy metals have been of great value in physiological work, but since other

compounds present in the body also possess this property it is necessary to prove that the reduction is due to glucose. This is accomplished by utilizing the third or fourth property mentioned above, i.e. by fermenting the glucose with yeast or with certain microorganisms or oxidizing with a specific enzyme such as that derived from *Penicillium notatum*. The optical activity of the carbohydrates is an invaluable property when they are present in solutions uncontaminated by various other optically active substances which are present in physiological fluids.

Glycogen. Glycogen is very resistant to alkaline hydrolysis but as Claude Bernard discovered readily yields reducing sugar on acid hydrolysis Pfluger boiled glycogen for several weeks in strong alkali without destroying it. Advantage is taken of this property to free glycogen of contaminating substances. After alkaline hydrolysis of the tissue the glycogen is precipitated from solution by alcohol. This material is then broken down by acid hydrolysis to glucose which is stable in acid solution. The sugar is then estimated as described above and the amount of glycogen calculated from the result. The histochemists using the most effective vital staining procedures will probably soon be able to tell us the approximate amount of particulate glycogen in the living cell and perhaps also of the soluble form which is of course one step nearer the metabolic pathway.

Lactic acid. In muscle glycogen is broken down to lactic acid during muscular exercise and in the recovery from exercise part of it is resynthesized to glycogen. The lactic acid is estimated by oxidation to acetaldehyde and the latter is determined by distilling it into sodium bisulphite with which it forms a double compound. Residual unbound bisulphite is titrated with iodine.

APPROXIMATE DISTRIBUTION OF CARBOHYDRATES

	Liver per cent	Muscle per cent	Blood per cent
Glucose	0.06-0.15	0.02-0.04	0.08-0.11
Glycogen	0.2-10	0.2-1.8	trace
Lactic acid	0.01	0.01	0.01

Human liver is about 3 per cent, muscle 50 per cent and blood 7 per cent of body weight (Brody and Kibler). Glucose and lactic acid are found in the other soft tissues and some of these contain small amounts of glycogen. The glycogen content of kidney and of heart muscle has been extensively studied under various physiological and pathological conditions.

Absorption of Sugar

The monosaccharides formed during digestion are rapidly absorbed from the small intestine. In the rat, galactose disappears from the intestine

most rapidly, glucose a little more slowly and fructose much more so. There is, therefore, a selective action of the intestinal cells in the absorption of sugars (Cori). Evidence is accumulating that the absorption of sugar may proceed against a concentration gradient, i.e., when the concentration is lower in the lumen of the small intestine than in the blood. There is an increase in the amount of esterified phosphate in the intestinal mucosa during the absorption of both glucose and fructose but this phosphorylation may be related to metabolism rather than to absorption. It has, however, been suggested by Lundsgaard that the relatively high level of esterified phosphate in the intestinal mucosa during the absorption of fructose may be due to slow dephosphorylation and thus account for the well known delay in the rate of absorption of this sugar.

The slow absorption of glucose from the small intestine after hypophysectomy or adrenalectomy may be a part of the picture of inanition rather than a result of the loss of a specific adrenal phosphorylating factor, as has been suggested. The fact that the administration of sodium salts restores the rate of glucose absorption in adrenalectomized animals (Deuel) is in favor of the non-specific effect.

Glucose is not absorbed in appreciable amounts from the stomach until high concentrations are reached, and only slowly from the large bowel.

The Fate of Ingested or Injected Glucose

There is good evidence that no other monosaccharide is as effective in the liverless animal as glucose. This finding suggests, and there is indeed good evidence, that the other monosaccharides are normally changed to glucose in the liver. Fructose is a better glycogen former than glucose but galactose is much inferior in this respect. When glucose is absorbed or is injected some of it can be accounted for by the increase in liver glycogen, some is converted to muscle glycogen. The concentration of glucose in the soft tissues is temporarily raised. The use of isotopes has revealed a rapid and extensive conversion of glucose to fat (Stetten) and a more delayed increase in oxidation (Wick and Drury). Various intermediates in glucose metabolism may be converted to amino acids by transamination reactions and the amino acids subsequently converted into protein (p. 777). These processes but not the precise time relationships have been well established.

The Formation of Glucose in the Body

Glucose is apparently formed in large amounts only in the liver. When this organ is removed (Mann and Magath) hypoglycemia soon appears and sugar must be provided if the animal is to survive more than a few hours. Sugar is made from protein in the liver and evidence obtained on phloridized animals indicates that some of the amino acids—glycine, alanine, cystine, aspartic and glutamic acids—may yield glucose in the theoretical amounts (Lusk). It is well established that plants form sugar from fat. There are a certain number of reports of respiratory quotients below 0.7 which disturb those who believe in the unitarian significance of the quotient, but this ratio should not be used as a weapon against itself. It has been established that an appreciable amount of sugar is formed in the kidney (Bergman and Drury, Remecke), but this appears to be a small fraction of that supplied by the liver.

The Common Metabolic Path

The recent discovery of the nature of the active "2-carbon" fragment which has long been postulated as being an important intermediate in the metabolism of fatty acids, indicates pathways by which the conversion of carbohydrate to fat (or the reverse change) occurs. The labile acetyl groups found in acetyl-coenzyme A which arise in the oxidation of pyruvate or from the oxidation of fatty acids, appear to be identical. It is not surprising therefore in view of this common pathway in the metabolism of carbohydrate and fat to note that the old controversy as to whether or not conversion of fatty acid into glycogen can occur has been settled in the affirmative by the use of isotopes. The small amount of isotopes incorporated into glycogen agree, however, with the view that fat is not quantitatively an important precursor of glycogen or glucose. Since certain amino acids form sugar, it is becoming increasingly clear that the various metabolic materials share a common pathway and that acetyl-coenzyme A provides a link which joins them (see Fat Metabolism).

Formation and Breakdown of Glycogen and the Oxidation of Sugar

Great advances in our knowledge of the most fundamental aspects of carbohydrate metabolism have been made in recent years. Most of the steps

in the formation and breakdown of glycogen and the oxidation of sugar have been revealed by the work of Harden, Young, Lmbden, Meyerhof, Warburg, Cori, Lohmann, Peters and numerous other investigators. Many of the individual steps are not observed in the intact cell since the intermediate products which have been identified *in vitro* do not accumulate. There are, for example, at least twelve enzymatic reactions involved in the anaerobic conversions of glycogen to lactic acid. Practically all of these have been shown to be reversible but since the final product of one reaction is immediately removed by the following step the process proceeds in one direction. The phosphorylation of glycogen and of glucose has been proved to be the introduction to a long series of changes by which these products are transformed through various phosphate esters to pyruvic or lactic acid. Glycogen after phosphorylation breaks down to glucose-1-phosphate. This (Cori ester) is converted to glucose-6-phosphate which is also the first step in the oxidation of glucose.

The work of Cori and Cori in which the enzyme phosphorylase, which catalyzes the reversible reaction glycogen (or starch) + inorganic phosphate $\rightleftharpoons$ glucose 1-phosphate, was isolated and purified, is of great interest. This cozyme is widely distributed in animal tissues and is responsible for the first stage in the breakdown of glycogen. It also affects the synthesis of a polysaccharide indistinguishable from glycogen. Some glycogen must be present to "prime" this latter reaction and adenylic acid is an essential constituent of the mixture for activity in either direction. It is now well established that this transfer of phosphate groups is of paramount importance in the mechanism by which cells derive energy from the breakdown of food materials. Muscle glycogen breaks down to CO_2 and H_2O under physiological conditions. The steps from glycogen to pyruvic acid can occur anaerobically but from pyruvic acid on, an adequate oxygen supply is necessary. When there is a relative lack of oxygen lactic acid is formed. Pyruvic and lactic acids are interconvertible in the body. This lactic acid may diffuse out into the blood stream. It may be used directly by other peripheral tissues or may be converted to glycogen in the liver.

This part of the cycle is apparently not brought into play under ordinary circumstances but may be involved in muscular exercise or under conditions of anoxia.

The Cori Cycle

Glycogen-containing tissues, with the exception of the liver, exhibit the same pattern of breakdown of this polysaccharide as has been described in muscle. In the liver, glycogen does not normally break down to CO_2 and H_2O or to lactic acid but to dextrose. This is probably due to the fact that the liver contains a very active phosphatase which converts the glucose-1-phosphate and the glucose-6-phosphate to glucose and thus removes these esters from the medium.

Under certain conditions *in vitro*, glyceric aldehyde phosphate and dihydroxyacetone phosphate can be isolated from the breakdown products of muscle glycogen. In the diabetic dog these substances, and also pyruvic acid, form "extra sugar," but so does methyl glyoxal which is not a part of the accepted schemes.

The Regulation of Blood Sugar

The blood sugar level represents the resultant of oxidation, storage and excretion on the one hand and formation and absorption on the other. This may be represented graphically (fig. 48-1).

The relative constancy of the blood sugar which is an equilibrium mixture of α and β -glucose in the normal fasting animal is made more remarkable by the fact that the production, storage, and utilization of sugar are affected by a great number of chemical and nervous factors.

When sugar is not being absorbed from the intestinal tract it must be made in the liver or kidney from non-carbohydrate sources or liberated by the breakdown of glycogen. The liver glycogen is the emergency supply which is available while the process of gluconeogenesis is gathering speed. In the average man approximately 100 grams of glycogen are present in the liver and this would only supply the demands for sugar for some five hours if the gluconeogenesis were to cease. The rate of glycogen breakdown is affected by adrenaline which is liberated in emergencies (see also glucagon) and the rate of gluconeogenesis by the internal secretions of the anterior pituitary gland, the adrenal cortex, the thyroid and the pancreas, as will be discussed later. An important part of this homeostatic mechanism for the regulation of blood sugar appears to be the level of

FIG 48 I

blood sugar itself (Sokolin and Levine) Under experimental conditions in which variation in the rate of secretion of insulin is impossible, i.e., in the depancreatized dog given insulin at a constant rate, indirect evidence indicates that the adminis-

tration of dextrose decreases the rate of output of sugar by the liver. In the intact animal the pancreatic mechanism is also involved. The insulin content of the blood may determine at what level of blood sugar gluconeogenesis in the liver will be

(Other intermediate steps in this process shown in ch. 51)

inhibited. In the absence of insulin only extremely high levels of blood sugar exert a protein-sparing action

Hyperglycemia

An increase in the blood sugar beyond the normal range constitutes a hyperglycemia. This may be a protective phenomenon. With the exception of insulin a rise in blood sugar provides the greatest single stimulus for the formation of glycogen and the utilization of glucose.

Prolonged hyperglycemia may be present when either or both of the following processes are operating: (1) diminished utilization of glucose, (2) overproduction and discharge of sugar from the liver. Disturbances in endocrine function are the main causes and the mechanism of these changes will be discussed later.

Transient hyperglycemia may be due to either physiological or pathological processes. Alimentary hyperglycemia is a physiological process and its height depends on the amount and nature of the carbohydrate in the meal. Adrenaline hyperglycemia is a part of the physiological response to an emergency. Nerve impulses acting on the liver, changes in hydrogen ion concentration of liver cells due to asphyxia or other causes, may produce a transient rise in blood sugar. Toxic products of infection acting on the liver to increase gluconeogenesis or on tissues in general to diminish utilization of sugar may produce a hyperglycemia of short or long duration. The role of glucagon will be discussed later.

Glucosuria

The occurrence of glucose in the urine is the result of hyperglycemia except when the renal threshold to glucose is lowered (phloridzin diabetes in animals, renal diabetes in man). The following list of the methods of causing experimental glucosuria is slightly modified from Ingle.

1. Pancreatic (insulin) insufficiency

Pancreatectomy—Von Mering and Minkowski

Alloxan—Dunn, Sheehan and McLetchie
Subtotal pancreatectomy and high caloric intake—Allen

Withdrawal of insulin following its prolonged injection in the force-fed normal rat—Ingle and associates

2. Hormonal

Crude anterior pituitary extract or purified growth hormone—Houssay and

Biasotti, Evans, Young, Campbell, Anderson

Adrenal C-11-oxygenated steroids—Long, Katzin and Fry, Ingle

Estrogens—Dolin, Joseph and Gaunt, Ingle

Thyroid—Houssay

Glucagon—Cavallero, Ingle, Salter, Davidson and Best

3. Dietary

Starvation and subsequent feeding—Lehmann

Overfeeding—Hofmeister

Sudden shift from high fat to high carbohydrate diet

4. Glycogenolysis

Piqure—Bernard

Emotion—Cannon, Shohl and Wright

Epinephrine, drugs, toxins, trauma

Glucagon—transient hyperglycemia partly by glycogenolysis and partly by gluconeogenesis

5. Renal

Phloridzin—Von Mering

Pancreatic Diabetes

Removal of the Pancreas

When the pancreas is completely removed from a dog or cat, a characteristic syndrome rapidly develops (Mering and Minkowski, 1889). When a diet including the known essentials is provided, the animals may live indefinitely if adequate amounts of insulin are administered. The animals recover rapidly from the operation and appear normal, but the diabetic state quickly supervenes when insulin is discontinued. The sugar content of the blood begins to rise within a very short time, depending on the size of the last dose of insulin, and increases from the normal level of 0.08 to 0.11 per cent to 0.20 to 0.40 or higher within 24 hours. The urine gives a positive Benedict's qualitative test for sugar when the blood sugar rises above approximately 0.16 per cent. This point, the so-called renal threshold, is the level of blood sugar above which large amounts of sugar are excreted in the urine. In some animals the "threshold" rises when the diabetic state is allowed to persist. (There is some glucose in normal urine and small amounts of other sugars.) The excretion of nitrogen is increased and this may be taken to indicate protein breakdown or decreased protein formation. The ratio of glucose to nitrogen excreted in phloridzin poisoning is

36.1 but this ratio is not observed in depancreatized dogs and indeed that obtained is so variable that little significance can be attached to it. The ratio is low in animals on a high protein diet and there is evidence that the addition of fat may increase it somewhat. It is established that glycerol may be converted to sugar. In the fasting diabetic the blood sugar and sugar excretion are maintained at high levels. The sugar is apparently formed from body protein in the liver since the blood sugar of the diabetic falls rapidly after hepatectomy. The amino acid contents of the blood and urine are increased. The loss of protein contributes to the decrease in body weight.

The disturbed metabolism of fat in the depancreatized animal is indicated by the accumulation of the ketone bodies in the blood and by the excretion of excessive amounts in the urine. The ketosis in a fat dog is greater than in a lean but this species is characterized by its efficiency in metabolizing fats, without ketosis. The loss of body fat is rapid but the ketosis may be so severe, even in this species, that the animal dies in coma before the fat reserves are depleted.

β Hydroxy-butyric and acetoacetic acids and others derived from tissue breakdown appropriate base and thus when the available reserve of base is depleted may produce an acidosis. In acidosis the respiratory center is stimulated and "air hunger" and coma are produced. The mechanism of coma production in diabetes is not completely known. Some observers believe that acetoacetic acid is particularly toxic. This acid is oxidized in the bladder and lungs to form acetone which is excreted in the urine and expired air.

The neutral fat content of the blood increases, due probably to the increased rate of mobilization of depot fat, and there is also a rise in cholesterol esters and the phospholipid.

While there is proof that the depancreatized dog can still burn sugar—all the criteria of sugar combustion in the normal have been satisfied—it is not permissible to conclude that there is no interference with this process. The rapid sugar utilization in the hepatectomized diabetic animal and the production of a diabetic condition by the administration of cortisone, which apparently acts in part, by stimulating the liver to produce more glucose, tend, however, to emphasize overproduction rather than underutilization. On the other hand the anterior pituitary and the adrenal cortex contain substances which inhibit the utilization of glucose. The evidence now indicates that both overproduction of sugar from protein and

diminished utilization play a part in the creation of the diabetic state. Calculations of these rates of production and utilization of glucose based on the rate of disappearance of ingested C^{14} -glucose in diabetic animals have indicated that underutilization is a more prominent feature than overproduction (Weinhouse, de Bodo, Wrenshall).

The respiratory quotient of the depancreatized animal not receiving insulin assumes the low level 0.69 to 0.73 and is not usually raised when sugar is given. Under certain conditions, in animals which have received a high protein diet and insulin for a time the quotient may be higher (Soskin). The characteristic low quotient may indicate combustion of fat but if any process such as conversion of fat to sugar which gives a very low quotient should be taking place the ratio might indicate the resultant between sugar combustion, fat combustion and the conversion. In brief, since more than one interpretation of a quotient is possible great caution must be observed in drawing conclusions with regard to its significance. When the liver is removed from a depancreatized dog the quotient rises, indicating either that relatively more sugar is being burned or that conversions giving a low quotient are taking place to a smaller extent.

The glycogen content of the muscles of a depancreatized animal may be reduced below the normal level but appreciable amounts remain. There is no diminution of heart muscle glycogen and indeed convincing evidence of an increase has been obtained. Liver glycogen falls to very low levels. A slight increase in both muscle and liver glycogen can be produced by giving large amounts of sugar without exogenous insulin. This might be due to small amounts of residual insulin which would now appear to persist under certain conditions for rather long periods.

Whereas the glucose utilization of the normal heart is low that of the diabetic animal is even less when the blood sugar concentrations are the same. Lactate, however, is used almost as well by the diabetic as by the normal heart (Lovatt Evans). These findings eliminate the necessity of supposing that the diabetic heart depends for its energy entirely on protein and fat. The rate of usage of glucose but not of lactate by the diabetic heart is increased when insulin is supplied.

The excretion of phosphorus is increased in the depancreatized animal. The administration of sugar or adrenaline does not cause the prompt fall in the inorganic phosphate of the blood which is observed in normal animals. These substances,

therefore produce their effects by raising blood sugar which in turn calls forth insulin. Adrenaline and insulin thus affect blood inorganic phosphate similarly, but insulin is effective in the absence of the adrenal glands, i.e., the action is in both cases due to the pancreatic hormone.

The diabetic animal is very susceptible to infections but it is not established that this is due to the raised sugar content of the tissues. Some diabetic patients have a decreased ability to form antibodies. This defect appears to be more closely related to hypoproteinemia than to hyperglycemia. Pathological conditions are observed with considerable frequency in the eyes of diabetic animals. Many of these abnormalities including cataracts may be eliminated in the diabetic dog by adequate treatment with diet and insulin. The liver rapidly undergoes extensive fatty degeneration and there may be an accumulation of large amounts of neutral fat.

Although there is considerable variation in the length of life of the depancreatized dog or cat, most individuals fed on a mixed diet do not live for more than two or three weeks without insulin. Under certain conditions dogs may survive for seven weeks. It is now established, however, that when the anterior pituitary is also removed the animal (dog) may live for nine months, at least.

and exhibit only a mild form of diabetes. Severe diabetes produced under these conditions by administration of the diabetogenic substances of the anterior pituitary is alleviated by insulin.

The Antidiabetic Hormone—Insulin

The name *insulin* was suggested by de Meyer in 1909 for the hypothetical internal secretion of the pancreas the search for which had been stimulated by von Mering's and Minkowski's findings (1889). While other workers, among whom Hédou, Zuelzer, and Scott may be mentioned obtained very suggestive results, which in some cases were probably due to the presence of insulin, Banting and Best working in Macleod's laboratory (1922) were the first to obtain a preparation containing the antidiabetic hormone in a form which consistently alleviated all signs of diabetes in completely depancreatized dogs (fig 48 2).

SOURCE OF INSULIN

Small amounts of insulin are presumably present in tissues other than the pancreas but methods are not yet available for their quantitative estimation. Blood provides an exception to this generalization and this subject is discussed on page 818. In the mammalian organism the pan-

FIG 48 2 Effect of insulin on the blood sugar curve of a depancreatized dog (redrawn from Banting and Best) (1) Injection of extract of degenerated pancreas (2) extract after incubation with pancreatic juice (3) extract incubated without pancreatic juice. Blood sugars by Myers Bailey modification of Lewis Benedict method.

creas appears to be the only organ to manufacture insulin or to store it in more than minute amounts

The islet cells of the pancreas are of four types— α , β , γ and δ . The α and β types contain granules. The γ are non granular. The δ cells have been seen only in human pancreas (Bloom) and are not well defined. In dog pancreas the number of cells per islet varies greatly, as do the relative numbers of the various types of cells. One study gives the average number per islet as 30 and the average ratio of α to β -cells as 20/75. The islet volume may be about one one-hundredth of the pancreas. The β -cells occupy the periphery of the islets and are smaller than the others. It is these cells which are considered to be producers of the antidiabetic hormone, indeed, the granules of these cells may consist, in part, of this substance. Epithelial cells of the small ducts are considered to be the "mother cells" of the islet and acinar cells. New islet cells may, therefore, be produced from them. The reader is referred to recent papers by Lazarow in "Diabetes" and other journals.

The main points of evidence which indicate that the hormone is produced in the islet cells are as follows: (1) Histologically, the islets are glandular structures, the obvious outlet for the secretion of which is through the blood stream. (2) There are relatively large amounts of the hormone in the principal islets of teleostean fishes, in which few enzyme-producing cells are found. (3) The active substance is found in degenerated pancreas in which the loss of acinous tissue has proceeded more rapidly than that of the islet cells. Ligation of the pancreatic ducts eventually produces a decrease in the insulin content of the pancreas, but moderate amounts of insulin may still be extracted when very few enzyme-producing cells remain. (4) When most of the pancreas, approximately nine-tenths, is removed from a dog, characteristic lesions (glycogen infiltration) are found in the β -cells of the remnant. These changes can be accelerated by a high carbohydrate diet, and prevented or eliminated by administration of insulin or by fasting. (5) The clinical condition known as hyperinsulinism occurs when the pancreas liberates abnormally large amounts of anti diabetic hormone. In many of the cases there are definite tumors of the islet cells. After operative removal of these masses of islet cells the blood sugar is maintained at higher levels. (6) Metastases in other tissues arising from carcinoma of the islet cells have been shown to contain insulin. (7) The injection of anterior pituitary extracts

leads to destructive changes in the islet cells, chiefly in the β -cells, while there is little or no effect on the α -cells. (8) Alloxan and other chemical substances destroy the cells of the islands of Langerhans, leaving the other cells essentially intact. The pancreases from a number of dogs treated with diabetogenic materials have been assayed for their insulin content, and the values obtained were roughly proportional to the concentration of granules in the β cells as determined by histological studies of these tissues. Good agreement between the amount of extractable insulin and the size and number of granules in the β -cells of human pancreas has also been obtained (Hartroft and Wrenshall).

CHEMISTRY OF INSULIN

Insulin was first isolated in crystalline form by J. J. Abel in 1926. In 1934 D. A. Scott showed that it could be readily crystallized as the zinc salt and that Abel's crystals contained zinc, nickel, calcium and cobalt also aid in effecting crystallization of insulin preparations. There is about 0.5 per cent of metal in the crystals. The "salts" of the insulin protein may appear in various forms—the zinc compound usually as twin platelike rhombohedra. Chemical analysis by Brand and by the Cambridge workers under the leadership of A. C. Chibnall indicates that the insulin molecule is built up entirely or almost entirely of amino acids. Insulin is richer in the amino acids leucine, glutamic acid, and cystine than most other proteins, methionine, tryptophan and hydroxyproline, which are common in many proteins, are absent from the insulin molecule (fig. 48.3).

The maximum molecular weight of insulin is 48,000, pH 7.0 to 7.5, protein concentration 0.4 to 0.9 per cent. However, when more dilute solutions of the hormone are used below pH 4 or above 7.5 the insulin molecule dissociates into subunits having a molecular weight of about 12,000 (Gutfreund). The single insulin molecule has a weight of 5733 (Harfenist and Craig, Sanger).

When insulin is oxidized with performic acid the molecule is split into its separate polypeptide chains. Two fractions can be isolated: A, an acidic fraction containing no basic amino acids and B, a basic fraction. These two physiologically inactive components are joined by disulfide linkages. Sanger made a great contribution by introducing the use of partial hydrolysis of dinitrophenyl derivatives of the fractions to determine the sequence of the amino acid components. He had

insulin may be slightly and sometimes reversibly decreased by certain minor chemical changes in the molecule, whereas appreciable chemical alteration gives a considerable diminution or complete absence of activity. Other changes have been suggested, such as the action of sulphydryl groupings, as in glutathione, which may reduce the cystine disulfide linkage, a change which is known to be accompanied by inactivation.

STANDARDIZATION OF INSULIN

Zinc insulin crystals from all sources so far examined (man, cattle, hog, sheep, bison, fish) have the same potency. The fourth international standard, a preparation of zinc insulin crystals, contains 24 units per mg. There are two well established methods of assaying the potency of an insulin preparation. The lowering of blood sugar in fasting rabbits and the production of convulsions in fasting mice are both satisfactory effects of insulin for the comparison of unknown and standard products. This new international yardstick of insulin is free of glucagon.

LIBERATION OF INSULIN

The arrangement of the capillary loops about the islet cells and the reported scarcity of lymph channels provide morphological evidence in favor of the capillary blood stream as the pathway by which insulin reaches the systemic circulation. It is important to remember that insulin passes first to the liver, but there is no proof that this tissue takes advantage of this favorable arrangement.

Although there are many pieces of experimental evidence which support the conclusion that the level of blood sugar is an important factor in the regulation of insulin liberation, the possibility that a decrease in the rate of discharge of sugar from the liver may also be produced when the blood sugar is raised, is frequently overlooked. This latter effect is apparently produced by a direct action on liver cells. The injection of small amounts of glucose into the artery supplying a pancreas grafted into the neck of a depancreatized dog or into the pancreatic artery in a decerebrate cat causes a prompt lowering of blood sugar. In this latter case the effect was not obtained when the splenic or portal vein was used. The production of hyperglycemia, glycogen infiltration of the beta cells of the islets and permanent diabetes by the intraperitoneal administration of glucose (Lukens and Dohan) strongly suggests an overstimulation of pancreatic islets by the raised blood sugar level. Anderson and Long have demonstrated an

output of insulin from perfused rat pancreas when dextrose was added to the perfusion fluid and Lukens and his group have obtained similar results in the dog. The results of experiments with denervated pancreatic grafts indicate that the nervous control is not essential. The nerve impulses which affect the islet cells are apparently conducted in part, at least, by the vagus. Vagus fibers have been traced to the islet cells and nonmedullated branches are said to pierce them. The results of stimulating the vagus appeared to be clear cut and the pathway was traced by one group of investigators to the hypothalamic region, but other workers have as yet been unable to confirm these findings. There may, of course, be a constant liberation of a small amount of insulin.

Information on the factors controlling the secretion of insulin has accumulated very slowly. The finding of Houssay, Foglia and their collaborators that two or three pancreases from normal dogs, when introduced in series into the carotid-jugular circulation of a depancreatized dog, produce no more effect than one pancreas, is strongly indicative of a chemical control of insulin liberation. These workers have studied the rate of liberation of insulin from the pancreas of hypophysectomized dogs, and of dogs made transiently or permanently diabetic by anterior pituitary extracts. The findings in general conform to those obtained by studying the insulin content of pancreas in relation to the state of carbohydrate metabolism of the animal (p. 825). Neither of these methods yields information as valuable as that which will be obtained when the insulin content of blood, and the rate of pancreatic blood flow can be accurately determined in intact unanesthetized animals. When this technique is perfected, the effects of agents which may affect the level of plasma insulin can be carefully studied.

INSULIN IN BLOOD

As a result of the work of Gellhorn, Anderson, Bornstein, Groen, Tuerkischer and Wertheimer, and their collaborators, methods for estimating the amount of insulin in blood are now available. These depend on the blood sugar response of hypophysectomized, adrenalectomized, alloxan-diabetic rats or mice or on the increase in sugar uptake of segments of isolated rat diaphragm. While few laboratories have the necessary procedures readily available some interesting results have been obtained. The value for normal human blood was approximately 4×10^{-10} mg. per cc.,

i.e., $1/250$ μg per cc. Some insulin can be detected in the blood of most maturity-onset diabetics but none in the blood of growth-onset, i.e., childhood, diabetics (Lawrence and Bornstein). These findings are in accord with Wrenshall's reports on extractable insulin from the pancreas in these two groups of diabetics.

In recent years as a result of the work of Randle and of Vallance-Owen, who use the rat diaphragm technique, and of Renold and his colleagues, who use the epididymal fat pad of the rat, this field has become much more active. Plasma insulin is low in cases of hypopituitarism, high in acromegalias and in hyperinsulinism. The administration of dextrose, of somatotropin and possibly of the hypoglycemic sulfonamides increases plasma insulin.

GENERAL EFFECTS OF INSULIN ON THE DIABETIC ORGANISM

It is well established that insulin restores to the depancreatized animal its ability to utilize sugars and fats in a normal manner. The excessive breakdown of protein is prevented. The ketosis rapidly disappears. Glycogen is deposited in large amounts in the liver. Muscle glycogen may be increased. The respiratory quotient rises when sugar is made available, or in fact when insulin alone is administered. Animals recover their ability to deal with infective agents. In brief, a well treated depancreatized animal is difficult to distinguish from a normal one. There has been the difficulty, of course, that in the animal without a pancreas relatively large amounts of insulin are made available (by subcutaneous or intravenous injection) while in the intact animal small or large amounts are presumably liberated from the pancreas as the need arises. Adult depancreatized dogs on an adequate diet including the enzymes of the external secretion of pancreas have been maintained in good condition for more than six years (Macleod, Hédon, Bliss, Fisher, Wrenshall).

THE MECHANISM OF ACTION OF INSULIN

In both the diabetic and the normal animal the level of blood sugar is lowered by the administration of insulin. The sugar is not used in the blood itself but its rate of passage out into the tissues is accelerated.

GLYCOGEN STORAGE. Small amounts of glycogen may be deposited in the muscles and liver of the depancreatized dog when no insulin is given but the administration of insulin produces a dramatic

increase in the rate of deposition in both these tissues. Stetten's work, using deuterium as a tracer, indicates that the diabetic organism makes its liver glycogen from three carbon compounds (lactic acid) while the normal or insulin treated animal uses largely the six carbon compound (dextrose). In the normal animal one of the most clear cut effects of insulin is the increase in the rate of glycogen deposition in the muscle. It is obvious that insulin also promotes glycogen storage in the liver of the normal animal and this situation should not be confused with the results of adding more insulin to an already normal supply. In the normal adult animal there may be an actual loss of glycogen from the liver when extra insulin is administered. This may be due to the accelerated glycogen deposition in muscle—a process which has a high priority in the disposition of sugar, to the presence of glucagon in the insulin used, or to the increased rate at which fat is formed and sugar oxidized. These latter processes would decrease the amount of sugar available for storage as glycogen in the liver. The liver slice is not a good preparation for the study of glycogen formation.

The action of insulin can be well demonstrated in eviscerated and in isolated perfused preparations such as the hind limbs of the cat or dog. Dextrose must be supplied. Very great use has been made of the finding by Gemmill in 1940 that the rat diaphragm *in vitro* takes up more sugar and forms more glycogen when insulin is added. As little as 0.1 unit of insulin per kilo will double the diaphragmatic glycogen in the fasting adrenalectomized rat. Nelson (1944) demonstrated the inhibiting effect of a prior injection of anterior pituitary extract. The isolated rat diaphragm does not respond to insulin with an increased use of oxygen but the skeletal muscle from the same species does.

There is an increase in the glycogen of heart after removal of insulin from the body (Cruickshank). The renal tubules exhibit a deposition in the diabetic state which may be related to the increase in sugar which they are attempting to reabsorb. The beta cells in the islands of the pancreas show glycogen infiltration (Duff and Torenson) in the diabetic organism. This used to be termed hydropic degeneration.

ON FAT METABOLISM. In the depancreatized animal insulin decreases the lipemia and cholesterolemia and prevents the deposition of the large amounts of excess fat which accumulate in the liver in the untreated animal. The level of the ketone bodies in the blood is restored to normal.

The fact that insulin increases the formation of fat has been obvious ever since the first emaciated dog or diabetic patient demonstrated a fine pad of adipose tissue, made as a result of treatment with the hormone. This effect was not perceptible in short term experiments without the aid of tracers and the disappearance of sugar was usually attributed to oxidation or perhaps in part to decreased gluconeogenesis. Using the technique of isotopic tracers, Stetten has calculated that in the well nourished rat only about 3 per cent of the glucose ingested each day is converted to glycogen, while 30 per cent is used to make fatty acids. In the absence of insulin the diabetic animal exhibits a much lower level of lipogenesis, as well as of glycogenesis.

In 1913 Bloch and Kramer were the first to demonstrate an *in vitro* effect of insulin on fat formation. Liver slices incubated in the presence of pyruvate and labelled acetate showed incorporation of the label into fatty acids and this process was enhanced by prior administration of insulin. This work has been strongly supported and extended by Gurn with Brady and Lukens and by Chaikoff and his group. Thus we learn that insulin has widespread effects on fat formation and mobilization. It promotes lipogenesis from glucose and acetate in the liver and in many extrahepatic tissues. It prevents the loss of depot fat and the accumulation of fatty deposits in the liver. It suppresses ketosis by inhibiting the formation of ketone bodies. It is probable that these different effects of insulin are closely interrelated and that they are all linked with its action on the oxidation of glucose, i.e., lipogenesis is dependent on glycolysis. The effect of insulin on the unesterified fatty acids of the blood plasma is discussed under fat metabolism (ch. 49).

ON PROTEIN METABOLISM The early work on insulin in Toronto demonstrated that insulin reduced the elevated nitrogen excretion characteristic of the diabetic state. In 1926 Janney and Shapiro noted a fall in blood urea and nonprotein nitrogen of normal human subjects given insulin and other investigators found a fall in blood amino acids in animals and man. In a classical study Mirsky showed that insulin decreased the rate of protein catabolism in the nephrectomized dog. Chaikoff and Forker in extension of F. N. Allan's original findings established a linear relation between insulin dose and nitrogen retention in depancreatized dogs. The evidence obtained by Forker, by Lotspeich, and by Sinex, MacMullen and Hastings indicates that insulin encourages the

incorporation of labelled amino acids into protein. Krahl has reported the incorporation of C^{14} labelled glycine into glutathione and into protein in liver slices. This process is greatly reduced in diabetes but is restored to normal by insulin. The evidence suggests that insulin stimulates peptide synthesis rather than inhibiting breakdown. Sinex and associates, Krahl, and Manchester and Young have provided evidence that the incorporation of amino acids into the protein of isolated rat diaphragm is augmented by insulin in the absence of added carbohydrate. These findings suggest that this action of insulin is largely independent of a stimulation of carbohydrate metabolism. It may be produced by either or both of two mechanisms, (1) increasing intracellular protein synthesis or (2) accelerating the transfer of amino acids across the cell membrane.

The literature records that Mirsky, Young, Gaebler, Lotspeich, Frame and Russell, and Lukens in distinct investigations have agreed that the presence of insulin is essential for the protein anabolic effect of the pituitary growth hormone, somatotropin. There is now direct evidence that an increased secretion of insulin occurs in response to somatotropin in several species of normal animals. Somatotropin has little anabolic effects in the complete absence of insulin and recent work has shown that insulin can stimulate growth, i.e., nitrogen retention, bone growth, fat formation, etc., in the complete absence of somatotropin (Salter and Best). Normal growth undoubtedly requires the coordinated action of somatotropin, insulin and the other hormones.

ON OXIDATION OF SUGAR The interpretation of most of the early work on this subject was confused by the lack of a suitably labelled dextrose. In 1949 Viles and Hastings found that insulin increased the oxidation of glucose as judged by the rate of appearance of the carbon label in the CO_2 formed by the isolated rat diaphragm. Similar results have been secured by Sacks and Sinex who found that insulin increased the turnover of isotopic phosphorus in various phosphorus compounds, the deposition of C^{14} -labelled glucose as glycogen and the oxidation of glucose. Feller, Chaikoff and associates, using C^{14} -glucose have established that the rate of utilization was reduced to half the normal value in dogs by removal of insulin and restored completely by giving the hormone. Using C^{14} -labelled glucose in eviscerated rabbits Wick, Drury, Bancroft, and MacKay were able to distinguish between the glucose oxidized and the total amount which dis-

appeared. When insulin was given there was a delayed, but large, increase in the labelled carbon of the expired air and therefore in the amount of glucose oxidized. The rest of the labelled carbon was found in glycogen, fatty acids, proteins and in nonglucose water-soluble compounds.

ON CELL PERMEABILITY. The suggestion that a key point in the action of insulin may be on the permeability of muscle cells to glucose has been revived and strongly supported by Levine and Goldstein. This view has been supported by Drury and Wick who interpret their evidence to indicate that insulin is not an oxidative catalyst and by Mirsky, who finds that entry into cells does not depend on the molecular configuration of the sugar as previous authors had suggested. Park, Bornstein, Post and Johnson have found an increase in the intracellular content of glucose after insulin administration and this finding favors an action on the cell membrane rather than one on intracellular enzymes. These authors and Randle and Smith have noted an increased glucose uptake of isolated rat diaphragm by procedures which inhibit oxidative phosphorylation. Insulin does not inhibit oxidative phosphorylation (Stadie). Randle and Smith suggest that insulin may promote glucose uptake by diaphragm by preventing access to the process regulating glucose entry of some substance generated during oxidative phosphorylation. Shaw and Stadie have suggested that glucose may be utilized partly at the cell surface and partly within the cell.

THE COMBINATION OF INSULIN WITH TISSUES. Stadie and his colleagues have obtained evidence to support their working hypothesis that insulin and other hormones must form a rather firm chemical compound with the intact cells on which they act. Isolated rat diaphragm dipped for a few seconds in a solution of insulin fixes insulin which reveals itself by increased utilization of sugar by the tissue. Diabetic tissue has a decreased ability to bind insulin. Growth hormone and cortisone inhibit this combination of insulin with muscle cells. Insulin injected into the living animal and much much higher concentrations in the fluid bathing the diaphragm *in vitro* lead to the binding of about the same effective amounts of insulin. Mammary and adipose tissue also bind insulin.

INSULIN AS A GROWTH HORMONE. The various anabolic effects of insulin show that it possesses some of the characteristics of a growth hormone. True growth, including lengthening of the epiphyseal discs, can be elicited in completely hy-

pophysectomized animals by giving gradually increasing amounts of slow acting insulin (Salter and Best). While it had been known that young hypophysectomized animals may grow for a time after removal of the pituitary (Selye and Collip), and while it had been suggested that growth hormone liberates insulin (Young), proof that hypophysectomized rats, which had in some cases not grown for months, could be made to resume growth by insulin had not been previously secured. When hypophysectomized rats are forced (Scow) or made hyperphagic by hypothalamic puncture (Kennedy) endogenous insulin is presumably liberated and this may be an essential factor for the growth and nitrogen retention observed. Under these circumstances the effect of exogenous insulin may not be demonstrable, i.e., an optimal concentration of insulin may already be present.

ON PHOSPHATE AND POTASSIUM. Insulin produces a dramatic fall in the inorganic phosphate of blood plasma (Harrop). Ingestion of glucose or injection of adrenaline has the same effect but not in the absence of the pancreas. Levine, Loube and Weisberg (1949) have shown that the intravenous administration of fructose to untreated depancreatized dogs consistently produces a fall in blood inorganic phosphate. The change in phosphate is apparently a consequence of the rapid entry of hexoses into cells. Insulin is necessary for the entry of glucose but not of fructose. After insulin there may be a rise in the hexose monophosphate of muscle. This is an indirect effect apparently due to adrenaline liberation and a stimulation by it of phosphorylase action on glycogen and the formation of the first breakdown product, glucose-1-phosphate. Insulin does not significantly change the amount of adenosine triphosphate (ATP), phosphocreatine, or inorganic phosphate in muscle. There may be a rise in the ATP fraction of liver. The rate of turnover or regeneration of these phosphate compounds is increased by insulin and this is probably an index of the increased rate of phosphorylation of sugar which is, as we have seen, an indispensable preliminary step in its metabolism. The free energy for this change is made available by the conversion of ATP to adenosine diphosphate (ADP) plus a high energy phosphate grouping. This phosphorylation of glucose then permits glucose to make available the free energy which it possesses. New molecules of ATP are provided as a result of subsequent steps in the anaerobic breakdown of glucose.

Bornstein and Park in Cori's laboratory have found that serum from alloxan-diabetic rats inhibits the uptake of glucose *in vitro* by the diaphragm of normal fasted rats. Removal of either the adrenals or pituitary from the diabetic rat eliminates this inhibitory effect of its serum, and the injection of both growth hormone and cortisone restores the effect. These findings, therefore, suggest that the insulin-reversible inhibitor of glucose uptake is formed as the product of joint pituitary and adrenal activity. Studies will undoubtedly soon be made on the sera of diabetic patients.

Various changes in the concentration of the metallic constituents of the blood have been reported after insulin injection. These, and particularly that in the concentration of potassium, suggest a fundamental relationship between electrolyte and carbohydrate metabolism. The decrease in blood sugar produced by insulin is accompanied by a simultaneous fall in potassium.

It is now well established that the administration of insulin lowers the insulin content of the pancreas in fasting or fed animals. Furthermore it protects the islet cells against the degenerative changes which occur after the removal of a large part of the pancreas. Similarly the degenerative changes in the islets and the loss of insulin content produced by the administration of the diabetogenic substance of the anterior pituitary gland are prevented if insulin is supplied. If, after the diabetic state has been produced in partially depancreatized cats by administration of diabetogenic preparations, insulin is given in adequate amounts, the diabetes may disappear. Thus insulin under these experimental conditions can both prevent and cure diabetes (Haust, Campbell and Best, Lukens and Dohan).

INTERFERENCE WITH THE ACTION OF INSULIN

Other hormones There are five internal secretions the action of which may be considered to be antagonistic to that of insulin. There is no evidence of any chemical interaction of these hormones with the antidiabetic substance.

Enzymes Insulin is destroyed by pepsin HCl and by the activated proteolytic pancreatic enzyme, chymotrypsin. Crystalline trypsin does not destroy insulin. A Mirsky and his colleagues have shown that the liver and to a lesser extent other tissues contain a factor which is capable of inactivating insulin and a second one which inhibits this action. These factors are referred to as insulinase and insulinase-inhibitor. Their physio-

logical significance is not established but their presence suggests the possibility that an increased rate of destruction of insulin as well as a decreased formation must be considered.

Reaction of tissues Since insulin acts on the cells of the liver and muscles, factors which influence these tissues, acidosis for example, may modify insulin action. Furthermore, since the liver is so largely responsible for the regulation of blood sugar, influences affecting this organ may cause a change in sugar content quite apart from the action of insulin. A change in the acid-base equilibrium of the body toward the acid side renders injected insulin less effective, a change toward the alkaline makes insulin more effective.

Products of infection The toxic products elaborated by many microorganisms may interfere with the action of insulin. There is experimental evidence (1) that the insulin content of pancreas is decreased in certain severe infections but this does not necessarily indicate a decreased rate of liberation of the hormone, (2) that the suprarenal and thyroid glands are stimulated to release more of their internal secretions,² (3) that the synthesis of glycogen from lactic acid in the liver is inhibited and (4) it now appears that normally liver glycogen is changed to glucose by glucose-6-phosphatase. Amylase, which splits glycogen to dextrins, maltose and finally to glucose, does not have access to the liver cells. When certain toxins are administered, however, amylase activity can be demonstrated and this abnormal route of glycogen breakdown provides another mechanism by which the products of infection make the organism resistant to the action of insulin. Insulin has no effect on the activity of amylase. Certain toxins may act on one or more of these mechanisms but investigation of this field is still in the preliminary stages.

Anesthetics All anesthetics interfere somewhat with the action of insulin. More or less asphyxia is produced by all general anesthetics. In asphyxia (1) adrenaline is liberated and (2) acid products tend to accumulate. Chloralose and amytal cause the least disturbance of carbohydrate metabolism.

INSULIN REQUIREMENT AND ADMINISTRATION

Interesting studies have been made of the insulin requirements of depancreatized dogs under different conditions. Thus the blood sugar has

² The first effects of the products of infection may be to excite liver tissue to increased gluconeogenesis and discharge of glucose. Later the liver cells may be damaged so that less glucose is produced.

been kept at a normal level by simultaneous and continuous intravenous injection of insulin and dextrose solutions. The insulin required was between 0.06 and 0.4 units per kg. per hour, while the corresponding requirement of dextrose was 0.2 and 0.6 gm. per kg. per hour. The higher values for insulin and dextrose were those required by unanesthetized dogs, the others by anesthetized dogs. In another study the amount of insulin necessary to keep the blood sugar at a normal value in depancreatized dogs under basal conditions was between 0.005 and 0.035 units per kg. per hour, with an average value of 0.017 units per kg. per hour. The duration of action of insulin is not proportional to the size of the dose injected but is a simple function of the logarithm of the dose, i.e., insulin is inactivated in the body at a rate proportional to the amount in the body at the time. Thus if 1 unit lasts four hours, 10 units would last eight hours. It is established that the completely depancreatized human subject may require less insulin than many "spontaneous" diabetics. Similarly, the alloxan-diabetic dog may require more insulin than the depancreatized. There are three obvious possibilities to be advanced in explanation: (1) The absorption of food is reduced by removal of the pancreas. Comparisons should be made on the same levels of nutrition. (2) The α -cells of the pancreas elaborate an antagonist of insulin, glucagon. (3) The alloxan or the meta-pituitary diabetic may and frequently does have some pancreatic insulin available. This may be liberated more physiologically than exogenous insulin and thus help to maintain the organism in a condition which creates a demand for more insulin.

Insulin may be administered effectively by the subcutaneous or intravenous route. Some absorption may be obtained by inunction or by application to the sublingual or other mucous surfaces. Rectal administration is ineffective. Studies continue to be made on the problem of the oral administration of insulin. Efforts have been made to combine it with various materials, dyes, phenolic substances, tannic acid, etc. which might protect the protein molecule from destruction by the intestinal enzymes. The difficulties involved are obvious, and it is therefore not surprising that, while some success has attended these efforts in the laboratory, no satisfactory application to the treatment of diabetic patients has yet been made.

MODIFIED INSULIN

One of the most obvious difficulties in the use of regular insulin in clinical diabetes is its transient

and sometimes too violent action. This difficulty has been much more frequently encountered since the highly purified preparations of insulin have been made available. The cruder products were absorbed more slowly. While a great many attempts have been made to slow and prolong the action of insulin, the first important success has been obtained by Hagedorn, Jensen, Krarup and Wod-trup. These investigators have shown that a compound of insulin with any one of several protamines exerts a slower and more prolonged anti-diabetic effect than regular insulin. This has been shown by microscopic observation (Beecher and Krogh) to be due to the much slower absorption of the insulin combined with protamine than is the case with the regular preparations of this substance.

Completely depancreatized dogs may be maintained sugar free, while receiving a very liberal diet, on one dose of protamine insulin daily without the development of any hypoglycemic reactions (Kerr and Best).

Scott and Fisher demonstrated that protamine insulin is greatly improved by the addition of a small amount of zinc. The resulting product, protamine zinc insulin, exerts a more prolonged hypoglycemic action and forms a much more stable suspension than protamine insulin.

Various other forms of modified insulin have been prepared and tested clinically. Histone insulin and globin insulin are examples. Protamine zinc insulin has been prepared in crystalline form (Hagedorn) and free insulin is stable when added to this compound. Zinc insulin preparations, without protamine, exerting a prolonged action, have recently been made available by Hallas-Møller and associates.

Hypoglycemia

Under certain exceptional circumstances hypoglycemia may be produced by excessive utilization of glucose (prolonged very violent muscular exercise) but interference with the formation of sugar in the liver is largely responsible for most types. The three main factors which diminish sugar production may be classified as follows: (1) abnormality of liver cells, (2) the inhibiting action of insulin on gluconeogenesis in the liver, and (3) the decreased hepatic gluconeogenesis resulting from diminished output of the anterior pituitary, thyroid, or cortical and medullary adrenal secretions. Under the first heading a great variety of experimental and clinical conditions may be¹—for example—phosphorus or hydrazine.

	Surgical in- terference with blood flow	

There may also be excessive utilization of sugar by muscles—dogs in tread mill marathon runners etc

* The term hyperinsulinism was introduced by Seale Harris in 1921 to describe cases exhibiting signs of hypoglycemia. The first report of a tumor of the islet cells which in this case had secondary growths in the liver was made by Wilder, Allan, Power and Robertson in 1927. Many cases of tumor have now been studied. A histological section from the first tumor successfully removed is shown in fig. 48 5

ing, yellow fever, acute yellow atrophy, and the bacterial infections. When the normal liver is completely removed, profound hypoglycemia occurs promptly. Approximately 80 per cent of the normal liver must be removed before hypoglycemia is produced. Under the second heading we may consider hyperinsulinism. This term should be reserved for conditions in which it is established that there is liberation of excessive amounts of insulin from the pancreas. This has been the case in numerous instances in which the removal of a tumor of islet cells has corrected the hypoglycemia. Correction of the condition by removal of a large part of the pancreas does not prove that the cause was liberation of abnormal amounts of insulin since decreasing the amount of insulin may merely compensate for the first abnormality. The relative importance of the three glands of internal secretion listed under the third heading may vary in different species. Removal of the thyroid increases the sensitivity of an animal to insulin and the same is true of the adrenal medulla but hypoglycemia is not produced. When the anterior pituitary is extirpated however there may be profound hypoglycemia and this finding suggests that diminished secretion of the diabetogenic substance may be an important factor in certain clinical cases in which the liver and pancreas appear perfectly normal. In some species removal of the whole adrenal gland causes hypoglycemia and this is at least partially corrected by the administration of cortical extract. Clinically certain cases of Simmonds disease (diminished anterior pituitary secretion) and of Addison's disease (involvement of adrenal cortex) may exhibit hypoglycemia. (See table 48 I and fig. 48 5)

SIGNS AND SYMPTOMS

The signs of hypoglycemia were first adequately described by Mann and his collaborators. The low blood sugars were produced in dogs by removal of the liver. The description of this condition enabled the Toronto investigators to recognize that the effects of large doses of insulin were the same as those due to hypoglycemia produced by other means. The signs and symptoms vary in the different species. The first signs in the rabbit are hyperexcitability and desire for food. The excitability becomes greater, and mild and then severe convulsions are exhibited. The head is retracted and the hind limbs extended in the intervals between convulsive seizures. Coma is frequent. The

animals may exhibit rigor mortis immediately after death. The signs in dogs are quite similar. Mice in some instances may become comatose without exhibiting convulsions. Cold blooded animals do not show any signs until many hours or even days after insulin injections.² The signs and symptoms in man have been extensively studied in the laboratory and clinic. The initial symptoms may be hunger or a feeling of nervousness—a sense of impending danger. A little later there may be profuse perspiration, alternate pallor and flushing of the face, vertigo and diplopia. The blood sugar at this stage is 0.06 to 0.04 per cent but the level varies greatly in different individuals. Most hypoglycemic reactions proceed no further than this. In very severe cases there may be delirium, convulsions and death. The true blood sugar may decrease until only nonsugar reducing power remains.

Sakel's insulin-shock treatment for schizophrenia has focussed attention on the metabolism of brain and the effects of prolonged hypoglycemia. Brain tissue utilizes carbohydrate almost exclusively. Hypoglycemia interferes with the supply and produces much the same condition as O_2 deficiency. The electrical activity of the cerebral cortex is depressed in hypoglycemia and restored to normal by the administration of glucose. The reduction in the oxidative metabolism of brain is undoubtedly responsible for this and other changes.

Cerebral damage which may be permanent has been observed in both animals and man as a result of prolonged hypoglycemia.

ALLEVIATION OF HYPOGLYCEMIA

The intravenous administration of glucose is the most effective method of alleviating hypoglycemia. The prompt recovery of almost moribund animals provides one of physiology's most fascinating demonstrations. Mannose is almost as useful as glucose and fructose also occupies a preferential position. Galactose and maltose have a slight but transient effect. Sucrose, lactose and pentoses are not effective. Glycogen and glycerol have been shown to exert some beneficial action. The effect of these substances in hypoglycemia is probably largely dependent on the rapidity with which they are transformed into glucose in the

² Similar prolonged delay may be observed in mammals after injection of huge doses of insulin.

⁴ Carbohydrates which form glucose are of course effective. The above statement refers to the results of intravenous injections.

FIG. 485 Photomicrograph of adenoma of pancreatic islets associated with clinical hypoglycemia. This tumor illustrated is the first to be surgically removed. Hematoxylin and eosin stain. X 1000. From Howland G. Campbell, W. R. Maltby, J. J. and Robinson, W. L. J. N. A. 83: 674-79, 1929.

liver. Fructose may be converted slowly to glucose in muscle but there is a possibility that it may be burned directly (Griffiths and Waters). It is generally assumed that the only sugar directly oxidized in the muscle where a large part of the total oxygen use takes place is d-glucose. The usefulness of the other carbohydrates would therefore depend on the ease of their conversion into this sugar. Adrenaline and pituitrin may be used to alleviate hypoglycemia but glucose is much more efficacious and safe. Liberation of adrenaline is however one of the physiological mechanisms by which hypoglycemia is corrected. Intense anger such as that which might well be experienced by a diabetic whose hypoglycemia was mistaken for alcoholic intoxication (Duncan) may correct hypoglycemia through liberation of adrenaline.

The Insulin Content of the Pancreas under Different Conditions

The insulin content of the pancreas has been determined in various animal species. The insulin is extracted from minced pancreases with an acid aqueous alcohol solution. Certain contaminating material is removed and the active material is precipitated. This is then redissolved and estimated by the mouse method of assay. In the dog the insulin content of the free splenic end of the pancreas is greatest, that of the attached duodenal portion has an intermediate value while that of the free duodenal end is lowest, the values being about 4, 3 and 2 units per gram respectively. In

rat's pancreas to about half the normal value, which is about 2½ units per rat. These animals have their insulin stores speedily restored to normal (in six days) when they are returned to a balanced diet, carbohydrate alone effects a partial restoration. Daily injection of insulin into rats causes an even more marked decrease in the insulin content of the pancreas than does starvation (Haist and Best). Massive doses of insulin over prolonged periods may produce atrophic changes in the pancreatic islets of partially depancreatized dogs which survive the treatment (Mirsky).

The injection of anterior pituitary extracts in certain strains of rats increases the islet volume and the insulin content of pancreas (Young, Richardson and Marks). In other strains there is no increase in insulin content.

The factors which affect the volume (growth) of the β -cells of the pancreas are given in table 48 2.

Subcutaneous estrogen transplants or the administration of stilbestrol produce an increase in the insulin content of rat's pancreas. This effect is not observed in the absence of the pituitary (Griffiths, Marks and Young, Funk). Stilbestrol may exert a diabetogenic effect in force fed normal and partially depancreatized rats and under these conditions Ingle has been able to demonstrate diabetogenic effects of all the estrogens. Under more physiological conditions Houseay, Foglia, Martinez and their colleagues have demonstrated that the estrogenic substances decrease the incidence of diabetes in partially depancreatized rats—presumably by stimulation of the β cells in the pancreatic remnant.

The effect of age on the insulin content of the pancreas has been studied in the cow. In fetal calves under 5 months the concentration was 34 units per gram. In calves 6 to 8 weeks old, 10 units per gram, in heifers 2 years old, 5 units per gram, in cows over 9 years, 2 units per gram. Pregnant cows 7 years old and older showed no change from the normal insulin content of about 2 units per gram (Scott and Fisher). In Wistar rats the total insulin content of the pancreas increases with age.

Pancreases obtained from nondiabetic persons at autopsy have an average insulin content of about 2 units per gram. This is probably somewhat lower than the true value. Pancreatic tissue from diabetic persons shows wide variations. The pancreas from diabetic children contains very little insulin. Pancreas from diabetic adults contains on the average some 40 per cent of the normal amount of insulin (Wrenshall). The insulin content of a tumor of islet tissue surgically re-

partially depancreatized dogs, provided sufficient pancreas is left to prevent the onset of diabetes, the insulin content does not differ from that of the corresponding part in a normal dog, nor are any degenerative changes in the β -cells noted. If diabetes supervenes, hydropic degeneration of these cells is observed, and the insulin content of the remnant of pancreas falls to extremely low values. The daily injection into dogs of diabetogenic extracts from the anterior lobe of the pituitary gland produces a prompt and profound decrease in the insulin content of the pancreas (in seven days to 0.2 units per gram). If the injections are stopped at this stage, the insulin content is restored to normal within four days. If the administration is continued the insulin is reduced to negligible amounts. No recovery will occur when this point is reached. Simultaneous administration of insulin prevents or greatly modifies the fall in the insulin stores. This fact strongly suggests that the β -cells are permanently damaged by the extract through overwork and that the simultaneous administration of insulin relieves the cells of some of this excessive demand for the hormone.

Starvation (seven days) or a diet rich in fat produces a decrease in the insulin content of the

moved from a patient suffering from hyperinsulinism may be as high as 214 units per gram

It is, of course, apparent that these "insulin contents" indicate the balance between the rate of production of the hormone in the islets and the rate of liberation. There is good reason to believe that under certain conditions the rate of liberation is proportional to the content. Under other circumstances this is probably not true, but the rate of liberation of insulin can at present only be inferred from data which are susceptible of various interpretations. The conclusion has been drawn from some of these results, combined with histological studies, that the islet cells are "rested" after administration of insulin, by starvation and by a high fat diet and that less insulin is excreted by the pancreas than under normal conditions. Partial pancreatectomy, sufficiently extensive to result in diabetes, or administration of diabetogenic extracts causes (1) marked stimulation of the islets and (2) subsequent degenerative changes and loss of insulin.*

The Use of Insulin in Nondiabetic Conditions

Favorable results have been claimed for the use of insulin in a very great variety of nondiabetic conditions. It has been used in pernicious anemia, in acute infectious diseases, in eclampsia, in pernicious vomiting of pregnancy, and in hepatitis—to mention only a few. While it is conceivable that insulin might be of slight benefit in some of these conditions, it would appear that equally satisfactory results can be secured by the administration of glucose alone. It is a clinical fact that the administration of glucose produces favorable results in a variety of hepatic abnormalities. A high glycogen content appears to protect the liver cells from damage and inhibition of gluconeogenesis produced by both insulin and glucose may also play a role.

Insulin can now be considered, however, an established adjuvant in the treatment of certain cases in which lack of appetite prevents the ingestion of adequate amounts of food. The physiological basis for this use of insulin in these nondiabetic individuals rests very largely upon the increase in hunger and appetite which may be caused by the administration of sufficient material to produce a definite but not too marked hypoglycemia. In 1924 Bulatao and Carlson reported that production of hypoglycemia in experimental

animals by the subcutaneous injection of insulin was uniformly accompanied by hypertonus and hypermotility of the stomach. The gastric tonicity and motility increase as the hypoglycemia deepens until complete tetanus is reached, which persists until the dog exhibits hypoglycemic convulsions or until sugar is given. The effect of sugar is immediate, but if a large dose of insulin has been given the hyperactivity of the stomach returns as soon as the blood sugar falls again. The first record of the increase in gastric peristalsis in the human individual after insulin administration was that of Dickson and Wilton, 1924. One hour and ten minutes after the administration of insulin the tone, depth and rate of peristalsis and rate of emptying of the stomach were definitely increased. This condition persisted for two hours when the blood sugar was found to be 70 mg per 100 cc. Glucose was then given and while the acute symptoms were definitely relieved the hunger persisted. Subsequently Quigley, Johnson and Solomon studied the effect of insulin on the gastric movements of four human subjects. They found that doses of from 12 to 20 units of insulin definitely increased the gastric activity. The first definite augmentation was observed about an hour after the injection and persisted for at least five hours. There was prolonged duration of the hunger period, and this was considered to be the most characteristic effect of insulin. The increased peristalsis produced by insulin is not inhibited by such procedures as smoking, unpleasant emotions, body discomfort, or the presence of moderate amounts of noncarbohydrate food in the stomach. The increased movement was inhibited by atropine. The immediate relief of the excess peristalsis when appropriate amounts of glucose were given was confirmed. More recently Grossman and Stein have shown that the sensations of hunger induced by insulin with the exception of the epigastric pangs of distress associated with individual gastric contractions, continue to occur after complete vagotomy in man.

It is known that insulin does not exert its effect on gastric motility and secretion after section of the vagus nerves. This means that either insulin acts centrally by stimulating the vagus, or that the continued elaboration of acetylcholine, which we now know is an essential part of the mechanism by which the vagus exerts its action, provides a foundation upon which the peripheral effects of insulin may be superimposed.

Insulin augments also to some extent peristaltic movement in the duodenum and in the colon,

* For references to work on insulin content of pancreas see Haist, 1944 and Wrenshall, 1952

but the effect is not as marked as in the case of the stomach. It will be remembered that one of the early symptoms observed in experimental animals and also in human subjects after the administration of insulin is an increase in hunger. In animals an attempt to consume material of little nutritive value which under ordinary conditions they would not attempt to eat is often observed. It would appear, therefore, that the clinician is able to take advantage of this situation by providing nutritious food for his hungry patient. The increase in weight observed in both animals and patients when appropriate doses of insulin are given for prolonged periods is due to increased deposition of fat, and to a lesser extent to increased deposition of carbohydrate and protein. The increase in weight is not attributable to unphysiological retention of water.

Influence of Other Endocrine Glands on Carbohydrate Metabolism

THE ADRENALS

The glucosuria produced by adrenaline was first noted by Blum. The intravenous route of administration gives the greatest rise of blood sugar but subcutaneous, intramuscular or intraperitoneal injections are effective. The immediate rise in the sugar of the blood is due to breakdown of liver glycogen to glucose. There may be a considerable decrease in the amount of liver glycogen. Adrenaline also mobilizes muscle glycogen (Corti) but here the immediate product is lactic acid and not glucose. A part of the lactic acid is carried by the blood to the liver where it is converted to glycogen, which in turn furnishes the blood with glucose. Muscle glycogen is therefore available indirectly to replenish blood glucose. When lactic acid from the muscles has been changed in appreciable amounts to glycogen in the liver the amount of substance in this organ may be increased over the normal level. Adrenaline therefore in moderate dosage, first causes a decrease and then an increase in liver glycogen. Very large doses over prolonged periods may lower both muscle and liver glycogen. The nervous control of adrenaline secretion will be discussed in chapter 58, and the manner in which thoracic autonomic impulses may affect blood sugar through its liberation will be appreciated. Adrenaline does not accelerate sugar formation from other substances in the liver. Diabetes has not been produced by the continued administration of adrenaline.

Insulin and adrenaline are not chemical antagonists but possess opposing physiological actions. Adrenaline accelerates the breakdown of both

liver and muscle glycogen but the lactic acid made from muscle glycogen may result in an actual increase in the liver. Insulin promotes the formation of glycogen in both organs, but the increase in muscle glycogen may be at the expense of sugar, which would have formed liver glycogen. These are excellent examples of the manner in which the action of a hormone may be obscured by other effects. When the blood sugar is lowered to about 0.06 per cent by insulin an increased rate of liberation of adrenaline may be detected (Cannon-Houssay). Adrenaline has also been reported to increase the rate of liberation of insulin from the pancreas.

Adrenaline is one of the steps in the mechanisms by which liberation of adrenocorticotrophic hormone (ACTH) is released in animals (Vogt, Long and Fry) but it has not been possible to demonstrate this effect in man. Thus a substance released in emergency causes a prompt hyperglycemia and may at the same time set in motion other changes (liberation of ACTH) which stimulate gluconeogenesis and thus provide for the continuation of the blood sugar rise. On the other hand, a meal high in carbohydrate given to fasted rats causes a reduction in the cholesterol content of adrenal cortex (liberation of cortical hormone) which is coincident with a rise in liver glycogen (Abelin). This and related studies are perhaps the beginning of a more complete understanding of the physiological coordination of medullary and cortical activities. There is some evidence that a mechanism even more rapid than one which could be mediated by adrenaline may play a role in ACTH liberation.

THE ADRENAL CORTEX AND CARBOHYDRATE METABOLISM After double adrenalectomy in some species (cat and rat) the carbohydrate reserves of the liver and muscles are depleted and there may be definite hypoglycemia (Britton and Silvette). These workers showed that the hypoglycemic condition may be corrected when the cortical hormone and glucose are provided but not when the latter alone is given. They reported that the administration of extracts of the cortex elevated the carbohydrate stores of adrenalectomized animals well beyond the normal limits. Insulin and glucose do not increase glycogen deposition in the adrenalectomized animal unless cortical extract is supplied (Britton) but it is possible that this effect might occur if the animals were supplied with a diet adequately low in potassium and high in sodium. Long and his collaborators have greatly extended the earlier experiments of Britton and

Silvette and find rather remarkable increases in liver glycogen in fasted or fed normal animals when extracts of the adrenal cortex are administered. Muscle glycogen was not affected by the cortical material in these experiments but may be increased when adequate amounts of sugar are supplied.

After Houssay's demonstration that removal of the pituitary gland attenuates the severe diabetes resulting from total pancreatectomy in the toad and dog, Long and Lukens showed that a very similar change could be produced by adrenalectomy in the depancreatized cat or dog. It has been shown by Lukens and Dolhan that the diabetes of adrenalectomized depancreatized animals and also that of hypophysectomized depancreatized animals can be increased in severity by the injection of cortical extracts.

Long, Katzin and Fry have shown that the rat, partially depancreatized by the method of Shapiro and Pincus, is an excellent preparation for the demonstration of the role of the adrenal cortex in carbohydrate metabolism. Adrenalectomy attenuates the diabetes which may be observed in these animals. The grafting of cortical tissue may restore the glucosuria to the extent which has been observed before adrenalectomy.

The relative diabetogenic potency of various adrenal steroids has been studied by Long and his collaborators, by Kendall and by Ingle and Thorn. In 1941 Ingle demonstrated adrenal steroid diabetes in normal rats which were forced to ingest a diet rich in carbohydrate but of normal caloric value. This adrenal diabetes was highly resistant to insulin. Corticosterone, 17-hydroxycorticosterone and 17-hydroxy-11-dehydrocorticosterone have all been shown to produce hyperglycemia and glucosuria in the normal rat. Ingle, La and Evans have induced these signs of diabetes in normal force-fed rats by the administration of pure adrenocorticotrophic hormone. The hypertrophy of the adrenal cortex was very marked in these animals. The production of a decreased carbohydrate tolerance in human subjects by ACTH (Browne) and of a state of metabolism similar in many respects to clinical diabetes by administering more highly purified adrenocorticotrophic hormone (Conn, Louis and Johnston) are landmarks in the clinical extension of laboratory findings. The diabetes in human subjects which persisted for as long as the injections were continued (10 days) was resistant to insulin. (See also Alloxan Diabetes, p. 836.)

It has been shown by Long and his collaborators

and by Ingle and other workers that the mechanism through which these adrenal extracts produce glucosuria is in part by stimulating gluconeogenesis from protein, but as the increase in nitrogen excretion is insufficient to account for the extent of the glucosuria, interference with glucose oxidation has also been postulated.

Some but not all of the abnormalities of carbohydrate metabolism in adrenalectomized animals are apparently due to the disturbance in sodium and potassium metabolism. Thus the delayed absorption of sugar and fat and the failure to store glycogen from glucose can be favorably affected by appropriate salt treatment. On the other hand the sharp fall in carbohydrate levels in fasting adrenalectomized animals and the amelioration of diabetes in partially depancreatized rats by adrenalectomy are not corrected by feeding salt but are by the administration of suitable cortical material.

While it has been shown that the pituitary preparations may exert a diabetogenic action in the absence of the adrenal a part of the pituitary effect is undoubtedly exerted through the adrenal cortex. The recent work of de Bodo has demonstrated that the sensitivity of the hypophysectomized dog to insulin is considerably greater than that of the adrenalectomized dog.

Many of these findings which have been obtained on experimental animals have been confirmed by Thorn and his colleagues in studies on patients with Addison's disease.

THE PITUITARY AND CARBOHYDRATE METABOLISM

It has been appreciated for many years that abnormalities in carbohydrate metabolism may be associated with acromegaly of long standing or with the presence of various pituitary tumors. In 1903 Borchardt found that an extract of the posterior pituitary raised the blood sugar. In 1911 Cushing observed that "pituitary deficiency" may be accompanied by an increased carbohydrate tolerance. When insulin became available Burn demonstrated an antagonism between "pituitrin" and insulin, and several workers (Olmsted, Geding, Houssay) showed that animals were more sensitive to insulin after removal of the pituitary body.

It appeared for a time that both the oxytocic and pressor principles of the posterior lobe produced hyperglycemia and thus interfered with the action of insulin. The work of Ellsworth and others indicates that the oxytocin is the

more important factor from this viewpoint but it is doubtful, from the dosage necessary, to produce the effect, whether this is of physiological significance. Griffiths has reported that posterior lobe extract, i.e., the vasoconstrictor principle, interferes with the absorption of insulin. The action of subcutaneously administered insulin is inhibited but when the intravenous route is used this effect is not observed.

Interest has been focussed on the anterior lobe of the pituitary by the brilliant researches of Houssay and his collaborators and of other investigators. The main points established in Houssay's laboratory are as follows: (a) Removal of the anterior lobe of the pituitary increases the sensitivity to insulin of the normal animal and diminishes the intensity of diabetes in the depancreatized animal. (b) Injections of preparations from the anterior pituitary into normal or hypophysectomized animals diminish their sensitivity to insulin and increase the severity of the diabetic state in hypophysectomized depancreatized (Houssay) animals. (c) The administration of a suitable extract of the anterior pituitary can induce a diabetic condition. This point was independently established by the reports of Evans and his colleagues and of Baumann and Marine.

The effects of pancreatectomy and hypophysectomy are contrasted in the following summary, and the condition of the animal from which the pancreas and the pituitary have both been removed is briefly described.

<i>Pancreatectomy (Dog)</i>	<i>Hypophysectomy (Dog)</i>
Hyperglycemia	Low blood sugar
Polyuria	hypoglycemic convulsions
Glycosuria	during fasting
Ketonuria	
Azoturia	
Insulin necessary for survival	Greatly increased sensitivity to insulin
Metabolic rate normal or slightly raised	Low metabolic rate
Decreased ability to utilize carbohydrate	Carbohydrate furnishes increased proportion of fuel
Decreased ability to form glycogen fat and protein	Rapid disappearance of liver and muscle glycogen due to utilization of carbohydrate and decreased gluconeogenesis*

Pancreatectomy and Hypophysectomy

Animals survive without insulin. Polyuria, glucosuria, ketonuria, azoturia slight or absent.

* For direct evidence of this effect see Crandall and Cherry.

Administered carbohydrate partially or completely retained i.e., carbohydrate utilization much better than in depancreatized dog. Metabolic rate low. Glycogen deposition.

PERMANENT DIABETES. The anterior pituitary gland contains a number of substances which affect carbohydrate metabolism in a variety of ways. These will now be considered briefly. Evans, Meyer, Simpson and Reichert in 1932 demonstrated the production of a prolonged diabetes in normal intact animals by anterior pituitary extract, F. G. Young, 1938 was however, the first to produce a permanent diabetes comparable in intensity to that resulting from complete pancreatectomy, by injection of extracts of the anterior lobe of the pituitary. He has found, in a very large number of dogs, that he is able consistently to produce a permanent state of diabetes by the daily injection, either intraperitoneally or subcutaneously, of a preparation of anterior lobe material. The permanent state of diabetes may be produced after as few as eleven daily injections but more are usually required. The diabetogenic activity, that is the active material which will produce permanent diabetes in dogs, is associated with the globulin and pseudoglobulin fraction of the pituitary extract. Young's work was confirmed by Campbell and Best and by Dohan and Lukens and many others. Degenerative lesions of the islet cells of the pancreas were first noted in these permanently diabetic animals by Richardson and Young. Signs of proliferative changes in the islet cells in the early stages of the injections were found by these workers and by Ham and Haist who also observed proliferative changes in the acinar and duct cells of the pancreas (fig. 48.6). The diabetogenic extract produced proliferative changes in various other glandular tissues in the body. Campbell, Haist and Best noted that the diabetic state produced by the pituitary extract was not intensified by complete removal of the pancreas and secondly, that the insulin content of pancreas was reduced to a negligible quantity. This latter point has been discussed elsewhere.

It would appear that the main effect of the substance or substances which produced the permanent diabetes is exerted upon the Islands of Langerhans. These cells are apparently first stimulated and then destroyed by the repeated injections of the active material.

The permanent diabetes produced by the above procedures differs from that caused by pancreatectomy, in that the animals may live for long periods without the administration of insulin. In some

(a) Normal dog islet cells

(b) Islet from dog made diabetic with extract of anterior pituitary gland

FIG 48 6

cases however insulin is required. Starvation or a diet very rich in fat causes a marked diminution in the intensity of diabetes in the permanently diabetic animal.

The production of permanent diabetes by the diabetogenic substance of the anterior pituitary can be prevented by the simultaneous administration of large doses of insulin (Haist, Campbell and Best). The islet cells are protected from profound degenerative changes, the insulin content of the pancreas remains at a moderately high level, and

the state of permanent diabetes is not induced. Lukens and Dohan have shown that permanent diabetes produced in partially depancreatized cats by administration of the diabetogenic substance of the anterior pituitary gland can be cured by the use of insulin by a reduction in the caloric value of the diet or by an increase in its fat content. Recovery from early diabetes has followed a reduction in the diet only when the diabetes was very mild but treatment with insulin produced recovery at this stage regardless.

severity of the disease. If treatment were delayed until after the Islets of Langerhans had become atrophic no recovery was possible.

It is to be noted that in the prevention and cure of this experimental diabetes the level of the blood sugar is probably one of the most important factors which determines the direction in which the islet lesions will progress. This interpretation is supported by all the results which Young, Haist, Campbell and Best and Lukens and Dolan have obtained and is in line with the earlier studies of F. M. Allen, Copp and Bireley, and others. The rise of blood sugar in itself would not, however, constitute an adequate stimulus for the production of the extensive changes in the islet cells. The diabetogenic factor must operate through other mechanisms as well. The level of blood insulin may be one of these.

Highly purified growth hormone has been shown to be diabetogenic, i.e. to produce permanent diabetes in cats (Cotes, Reid and Young 1949) and in dogs (Campbell, Davidson, Snair and Lei, 1950). It would appear that this is the main diabetogenic component of anterior pituitary extracts but the cortical hormone liberated by ACTH and the thyroid product by the thyroid stimulating hormone must also play their part as described elsewhere. Growth hormone stimulates growth in young dogs and does not produce diabetes until the animals have matured (Young). If a part of the rat's pancreas is removed, but not enough to cause diabetes, this condition may be produced by large doses of growth hormone, thyroxin or cortisone (Houssay). The rat is very resistant to these diabetogenic influences, perhaps in part because of its ability to make more insulin when needed. In the intact rat, however, on a high carbohydrate diet, growth hormone and ACTH (given together) regularly produce hyperglycemia and glucosuria (Engel).

THE GLYCOTROPIC OR ANTI-INSULIN ACTION OF ANTERIOR LOBE EXTRACTS. It was first demonstrated by Houssay and Potick and adequately confirmed by many later investigators that treatment with anterior lobe extract can induce in either normal or hypophysectomized animals an insensitivity to the action of insulin.

Bennett observed hyperglycemia and increased liver glycogen values upon prolonged administration of the adrenotropic hormone. Jensen and Grattan and Ingle have shown that the adrenotropic substance as well as extracts of the adrenal cortex and crystalline corticosterone produce a definite glycotropic effect. The adrenocortico-

tropic factor failed to produce this anti-insulin effect or to promote deposition of liver glycogen in adrenalectomized mice. These findings, therefore, strongly suggest that the glycotropic effect of an anterior pituitary extract is due to the adrenocorticotrophic factor. A part of the anti-insulin action may be due to the storage of large amounts of glycogen in the liver. This glycogen is presumably available to counteract the hypoglycemic effect of insulin.

It is well established that hypophysectomized animals are unable to preserve their glycogen stores as normal animals do during fasting. It has been found by Russell and Bennett that this function can be restored, under certain conditions, by anterior pituitary extracts. In subsequent experiments it has been shown that this action is not through the adrenal since muscle glycogen can be maintained at a normal level in the absence of both adrenal glands in the fasting animal. In fed animals, however, adrenalcortical activity is required to maintain muscle glycogen. It has recently been shown by Russell and Wilhelm (1950) that purified growth hormone is able to prevent loss of glycogen from skeletal muscle and from diaphragm and to restore heart glycogen to the normal fasting level in hypophysectomized rats. It is unnecessary therefore to postulate a separate glycotropin-sparing factor.

THE PANCREOTROPIC ACTION OF ANTERIOR PITUITARY EXTRACTS. In 1933 Anselmino Herold and Hoffmann reported that frequent injections of anterior lobe extracts in rats produce in a few days an increase in the size and number of the Islets of Langerhans. Richardson and Young were not able to confirm the findings under the conditions defined by the German investigators. They were, however, able to show that the daily treatment of rats with crude anterior pituitary lobe extract for a period of two weeks doubled the amount of islet tissue in the pancreas. More recently Marks and Young showed that the insulin content of rat pancreas was greatly increased under these conditions (See Insulin Content of Pancreas).

It will thus be apparent that the anterior pituitary gland affects metabolic processes by a variety of mechanisms. The permanent diabetes produced by growth hormone is due to destruction of the β -cells of the pancreas but growth hormone inhibits the peripheral utilization of carbohydrate. It raises the blood sugar and intensifies the diabetes of completely depauperized animals. It inhibits the 'binding' of insulin by muscle and

other tissues ACTH, by liberating adrenal cortical steroids greatly increases gluconeogenesis and probably also inhibits peripheral utilization of glucose. Cortisone under certain conditions also stimulates the islets and thus may modify the diabetic state. The action of growth hormone or cortisone in decreasing peripheral utilization of sugar raises the blood sugar and this is undoubtedly part of the mechanism by which the β cells are stimulated and destroyed.

The anterior pituitary gland also affects carbohydrate metabolism through the thyrotropic and probably also the gonadotropic hormones. Removal of the adrenal cortex, thyroid or gonads produces histological changes in the anterior pituitary indicative of overactivity, i.e., of attempts to stimulate the missing target organs.

Inhibition of the anterior pituitary effect on carbohydrate metabolism by the use of X-rays or by injection of estrogenic substances can be demonstrated in animals and in man, but little of practical clinical value can be expected from these procedures.

THE THYROID AND CARBOHYDRATE METABOLISM

The aggravation of diabetes in man by hyperthyroidism and its amelioration by removal of the thyroid establishes a link between this gland and carbohydrate metabolism. It is surprising that very little influence on the diabetes of depancreatized animals can be demonstrated by thyroidectomy. This may be due in part to incomplete removal of thyroid tissue. When very extensive atrophy of the thyroid is produced by hypophysectomy in dogs, the blood sugar and a normal level of urinary nitrogen can be maintained for long periods during fasting if thyroxin is supplied. Without it hypoglycemia may soon terminate the experiment. Thus it appears that the thyroid may play a role in the effect of the anterior pituitary on carbohydrate metabolism. The slight effect of thyroxin administration on the intensity of pancreatic diabetes in some animals still requires explanation. But Houssay, Foglia and their colleagues have shown that in thyroidectomized rats 95 per cent of the pancreas can be removed without causing glucosuria. The administration of thyroid preparations to such animals may result in the development of permanent diabetes (metathyroid diabetes). In some partially depancreatized dogs permanent diabetes could also be induced by large doses of thyroid material.

The administration of thyroid substance or of

thyroxin to normal animals has no immediate effect on blood sugar but a loss of liver glycogen may be demonstrated within six hours. There is also apparently a rise in the protein content of liver due perhaps to mobilization from peripheral tissues. Increased gluconeogenesis from protein can be readily demonstrated when thyroid substance is fed. An increase in the α -amino-acid oxidase activity of liver has been reported.

In clinical hyperthyroidism a mild hyperglycemia and glucosuria may be present. A comparable condition may be produced in animals by administration of thyroid material. At this stage liver glycogen is easily mobilizable (the actual amount present may be less than normal) and adrenaline elicits more hypoglycemia and insulin less hypoglycemia than normally.

When thyroid feeding is continued there is a profound decrease in liver, muscle and heart glycogen. In this second stage the animals are resistant to adrenaline and extremely susceptible to insulin. They may exhibit spontaneous hypoglycemia or develop it as a secondary result of a small injection of dextrose. This latter effect may be due to the liberation of insulin the action of which is not buffered by liver glycogen.

Thus the effect of the thyroid on carbohydrate metabolism is the resultant of several actions: (1) increased oxidation of carbohydrate in tissues generally, (2) the increased rate of hepatic gluconeogenesis, and (3) destruction of islet tissue in partially depancreatized animals.

GLUCAGON

Kimball and Murlin were the first to suggest that the initial transient rise in blood sugar in normal animals which received the solution of crude insulin intravenously was due to a separate substance. They introduced the name "glucagon" which was adopted by Burger (1929) who, with his colleagues, has been responsible for most of the early studies of the properties of this material. Burger demonstrated that glucagon could be separated from insulin and that the hyperglycemia was accompanied by a fall in liver glycogen. Adrenalectomy did not eliminate this effect. Shupley and Humel (1945) showed that crude insulin preparations accelerated glycogen breakdown in liver slices. Sutherland and Cori (1948) obtained evidence that this glycogenolysis was due to glucagon and that this substance activated the phosphorylase system. Staub, Sinn and Behrens (1953) have now obtained glucagon in crystalline form as a polypeptide differing signifi-

cantly from insulin in amino acid content. Bromer, Sinn, Staub and Behrens have shown that glucagon is a single polypeptide chain containing 29 amino acid residues. There are many converging paths of evidence which suggest that this substance is made in the α -cells of the pancreas and perhaps also in similar cells of the fundic mucosa of the stomach. Sutherland and de Duve obtained glucagon activity from these two sources only. Makman, Makman and Sutherland have now reported the presence of a glucagonlike material in the blood of man and dog.

It has been found more recently that glucagon in addition to stimulating hepatic glycogenolysis produces many other metabolic changes in animals and human subjects. It greatly increases the catabolism of amino acids as indicated by the fall in their concentration in blood and the rise in urea production. The deaminated residues of the amino acids are presumably synthesized into glucose. Thus the hepatic glycogenolysis and gluconeogenesis may both contribute to the hyperglycemic action of glucagon. The overproduction of glucose under experimental conditions can be of sufficient magnitude to produce a diabeticlike state in many animal species including man. The characteristic hyperglycemia, glucosuria, and excessive nitrogen excretion persists only as long as the glucagon is administered. A permanent diabetes has not yet been produced. The significance of glucagon, if any, in the pathogenesis of human diabetes remains obscure (Izzo, 1957; Elick, 1958). In man glucagon stimulates ketone body production and reduces creatinuria (Ezrin, Salter and Best, 1958).

The metabolic rate of rats treated with glucagon may show a 50 per cent rise within an hour. Glucagon also affects certain aspects of gastrointestinal function. It has been reported to decrease gastric motility and acidity and the flow of pancreatic juice (Stunkard et al. 1955; Robinson et al. 1957; Necheles et al. 1957).

All of the effects of glucagon noted above have been observed only under conditions of experimental or chemical investigation. The doses used may be far in excess of what may prove to be physiological amounts.

THE NERVOUS REGULATION OF CARBOHYDRATE METABOLISM

As is the case with many other aspects of carbohydrate metabolism, Claude Bernard paved the way for the investigation of the influence of the nervous system. Bernard (1855) punctured

the floor of the fourth ventricle in unanesthetized animals and observed that the piqure produced a prolonged glucosuria. (The blood sugar of a rabbit may rise to 0.40 per cent within an hour and the effect may persist for several days or longer.)

It has been appreciated for some time that lesions in the hypothalamic region may cause glucosuria and the relation of these lesions to pituitary secretion has been in doubt. While lesions in this region might interfere with the absorption of the pituitary hormones or more likely, stimulate or destroy the nerve fibers going to the gland, it has been established that stimulation of the thoracic autonomic center in the hypothalamus may produce hyperglycemia. This gave rise to the idea that lesions lower in the brain stem might act by irritating the fiber tracts from the thoracic autonomic center but the situation is apparently not so simple. Donhoff and Macleod attribute special significance to the pons and there may be various centers, the impulses from which affect the level of blood sugar by more or less indirect paths.

In a paper, with an excellent review of previous work, Anderson, Ruch and Haymaker (1952) showed that in dogs and rats a prolonged (20 to 30 days) decrease in glucose tolerance was produced by transection of the brain whether at the pontine, midbrain or hypothalamic level. In animals in which decortication was performed and in those in which the brain stem was hemisectioned there was no change in glucose tolerance. These findings provide evidence for a homeostatic control of blood sugar level by centers in the brain stem.

It will be appreciated that lesions of the brain involving (1) the pathways which carry glycogenolytic impulses to the liver or (2) the tracts which supply the adrenals, pancreas or pituitary, may cause serious disturbances of carbohydrate metabolism by interfering with these normal mechanisms. The work of Anderson and associates does not suggest that failure of glycogen formation or that increased secretion of adrenal corticoids provides an important part of the answer to this problem. It is apparent that the field demands much further exploration with the light of modern endocrinology and neurophysiology focussed on it.

GLUCOSE TOLERANCE CURVES

When glucose is administered by mouth to a normal animal the blood sugar begins to rise within two or three minutes. This indicates that

the sugar solution passes rapidly through the stomach to the duodenum. If large amounts of sugar are provided there may be considerable loss in the urine, i.e., *alimentary hyperglycemia* and *glucosuria*. After the usual meal, however, the hyperglycemia is not sufficient to produce glucosuria. When moderate amounts of sugar are given the rise in blood sugar is transient and the return to the normal level rapid. This phenomenon is extensively used to test carbohydrate tolerance. The factors which determine the shape of the curve when from 50 to 100 grams of sugar are given by mouth are (1) The rapidity of absorption, (2) the extent of the storage and utilization of glucose by the tissues, and (3) the rate of discharge of sugar from the liver. The first factor may, of course, be eliminated by injecting the sugar intravenously.¹ The reaction of the tissues and of the liver to injected sugar may be direct or indirect. When more sugar is presented to the tissues more is utilized even though the insulin available remains constant. When the blood sugar rises the liver may discharge less sugar (Soskin, Allweiss and Cohn). The hyperglycemia may affect the liver and other tissues indirectly by increasing the insulin output and perhaps by other endocrine adjustments. The insulin liberated increases storage of glucose and fat and may decrease gluconeogenesis. An abnormal curve may indicate inability of the liver or pancreas or of both to perform their normal functions. It might be due in part or completely to defective oxidation and storage in the muscles. It must be emphasized that an abnormal glucose tolerance curve does not necessarily indicate a deficiency of available insulin.

UNDERNUTRITION AND CARBOHYDRATE METABOLISM

In 1873 Lehmann and in 1877 Claude Bernard noted a glucosuria in fasting animals after the administration of carbohydrate, and in 1890, Hofmeister, who made the first quantitative studies, named the condition "hunger diabetes." Utilization of carbohydrates is at a maximum in animals which have been fed on diets rich in these substances. After periods of fasting or of fat feeding, there is a definite impairment of glucose utilization which may easily be detected by the results

of a glucose tolerance test. The feeding of an exclusively fat diet produces effects on glucose utilization indistinguishable from those of complete starvation. Proteins exert an effect intermediate between that of sugar and fat, i.e., some impairment of glucose utilization is produced by an exclusively protein diet. Diets adequate in other respects but providing a low caloric intake cause little disturbance in carbohydrate utilization. The administration to animals or human subjects exhibiting hunger diabetes of a diet containing glucose causes a prompt improvement in carbohydrate tolerance.

The mechanisms of production and alleviation of the defect in carbohydrate utilization produced by fasting are not as yet completely elucidated. It would appear from the recent findings of Chambers, Cori and others that oxidation of glucose in the tissues is interfered with to a much greater extent than is glycogen formation. It has been established that the administration of insulin effects a partial restoration of carbohydrate utilization (Cori and Cori, Dann and Chambers). This finding suggests that insulin liberation may be depressed in hunger diabetes. Hunsworth feels that a change in sensitivity to insulin is involved rather than a diminution of pancreatic output. On the other hand, the observation by Haist, Rudout and Best shows that the insulin content of the pancreas of rats may be reduced to nearly half the normal value by starvation or by fat feeding. This finding in conjunction with others supports the view that insulin liberation may be decreased. The evidence which has been well reviewed by Chambers, does not indicate that the complete explanation of hunger diabetes will be found in the abnormal response of any one organ or tissue. This conception is supported by Ingle's report that insulin alone does not rapidly restore the carbohydrate tolerance of fasted animals to normal and by the finding that at least one important enzyme system (phosphorylase) is increased in activity during starvation (Lundback and Goranson). The hypogenic ability of the liver is reduced to the diabetic level by fasting.

GLYCOGEN DISEASE. A clinical condition characterized by the enlargement of one or more organs resulting from the accumulation of glycogen has attracted the attention of research workers. The disease usually bears the name of von Gierke who published an autopsy report on a case in 1929. Van Creveld, in the previous year, had concluded that the hepatomegaly which he observed in a young boy was probably due to excessive glycogen deposition. The glycogen deposits may

¹ Normal dogs may be given 0.85 gram of glucose per kg. per hour for long periods (Woodyatt) without producing glucosuria. This is approximately the same value as the maximum rate at which glucose is absorbed from the intestinal tract.

the liver, kidney, heart or in other tissues. The disease is characterized by hypoglycemia and ketosis in the fasting condition, by an abnormal effect of adrenaline which causes only a slight rise in blood sugar and lactic acid but a large increase in ketosis and by an increased sensitivity to insulin. The glucose tolerance test gives a prolonged hyperglycemia without glucosuria. The glycogen content of the blood is increased and van Creveld noted a resistance of this material to glycogenolysis. The glycogen in liver and kidney does not disappear at a normal rate after removal from the body and an interference with the glycogenolytic process is therefore indicated.

It would appear probable, as van Creveld has suggested, that glycogen disease is a continuation in childhood of a fetal condition in so far as certain aspects of carbohydrate metabolism are concerned. There are large deposits of liver glycogen in the fetus and this material is resistant to the action of adrenaline. It is well established that in some species this fetal pancreas, at or near term, contains very high concentrations of insulin. Hyperinsulinism may produce excessive deposits of glycogen in well fed animals and ketosis under fasting condition. It has been suggested that the secretion of the anterior pituitary gland makes liver glycogen more resistant to breakdown. But all these observations must be considered in the light of the findings by Cori and associates that the structure of glycogen from the liver of these cases is sometimes definitely abnormal and that the abnormalities in response to enzymes differ from case to case. There may, therefore, be many different types of glycogen disease.

ALLOXAN DIABETES This type of experimental diabetes was first produced by Dunn, Sheehan and McLetchy (1943) who showed that alloxan has a selective necrosing action on the Islets of Langerhans. In 1937 Jacobs had noted the effect of alloxan in rabbits—an initial hyperglycemia and a subsequent hypoglycemia. No histological studies were made and Jacobs postulated an insulinlike action of alloxan. It has now been shown that the hypoglycemia is due to liver damage or liberation of excess insulin from damaged islets or to both. The diabetic state is caused by a failure of islet cells to produce insulin. The diabetic action of alloxan has been demonstrated in the rabbit, rat, cat, monkey and dog. An unsuccessful attempt has been made to destroy the abnormally active islet cells in advanced cases of hyperinsulinism in man by the administration of alloxan. Lesions in the liver and kidney, less marked than those produced in the islets, are seen in some species after the injection of this chemical.

There is, as yet, no evidence that alloxan has any physiological significance. A substance so it was reported, many years ago, in the

urine and intestinal mucus in certain pathological conditions in man.

Griffiths has produced hyperglycemia and glycosuria but not permanent diabetes with uric acid which is chemically related to alloxan. To secure this effect the glutathione level of blood was depleted by a diet deficient in cystine and methionine and feeding large amounts of ascorbic acid. Lazarow in 1945 was the first to show that glutathione injected just before the diabetogenic dose of alloxan protected the rats. While many other substances such as dehydroascorbic acid exert this effect, glutathione as a normal constituent of cells is of particular physiological interest. Glutathione reacts with alloxan to reduce it to dialuric acid which is not diabetogenic. Leech and Bailey found an extensive fall in blood glutathione after alloxan, and previous investigators had shown similar changes in other tissues. The injection of various pituitary preparations has been found to lower the glutathione content of tissues. Cohn found in his studies of transient diabetes in man produced by injecting ACTH that there is a direct correlation between the blood glutathione level and the diabetogenic effect, i.e., the higher the blood glutathione the less the effect. In animals injected glutathione consistently potentiates steroid diabetes by some unknown mechanism. This protective effect against diabetes may be attributed to the removal of diabetogenic compounds from the blood or β cells. It has been suggested (Hedon-Lazrowsky) that factors which increase in insulin production may exhaust the supply of sulfhydryl groups by appropriating the cysteine for the insulin molecules and thus decrease the available glutathione and in this way mask the β cells particularly susceptible to alloxan or naturally occurring damaging factors.

THE ORAL HYPOGLYCEMIC AGENTS In 1918, Watanabe noted that guanidine poisoning was accompanied by hypoglycemia. In 1926, Frank, Nothman and Wagner found a derivative of guanidine which produced a lowering of blood sugar, and which they felt was not as toxic as guanidine. This material was synthalin, a decamethylene guanidine. Very soon, however, clinicians noted disturbing side reactions, primarily in the gastrointestinal tract, and in 1929 Karr reported fatty degeneration and necrosis of the livers of patients receiving this material. The use of synthalin was followed by that of a great variety of oral preparations: Glukhorment, Antico-man, etc. These were various mixtures of guanidine derivatives. Eventually they all proved to be dangerously toxic for human use. In 1942, Janbon and co-workers accidentally observed that a new sulfonamide, para-aminobenzene sulfamido-

isopropyl-thio-diazol, a drug that was originally synthesized by von Kimmel and Kimmig, produced severe hypoglycemia in patients who had been treated for typhoid fever. Loubatières investigated the mode of action of this drug in animal experiments and suggested that it stimulated the Islands of Langerhans. Clinical application of this substance was not made, however, until December 1955, and in the meantime a group of German workers carried out experimental and clinical studies with another sulfonamide, N_1 -sulfamyl N_2 -N-butyl-carbamide (BZ-55). This drug soon became widely used for oral treatment of obese elderly diabetics. Prolonged experiments in animals, however, revealed disturbing bleeding tendencies (Swek et al., 1957) as well as hepatic damage (Schambye, 1957). A few accidents in human patients were also reported and the drug was withdrawn from the market in North America. Almost at the same time another sulfonylurea derivative was made available, the N-(4-methyl-benzene-sulfonyl)-N-butyl-urea (DS60 or tolbutamide). This substance has now been widely used in the obese elderly type of diabetes, and the incidence of disturbing side effects in man has remained negligible. Liver damage is produced in dogs by doses of the drug which are well tolerated by man.

In addition to these derivatives of sulfonylureas, which do not act in the absence of the pancreas or in cases of juvenile diabetes, derivatives of guanide have also been tried. Phenylbiguanide (DBI) has been reported to be effective in certain cases of juvenile diabetes. But the incidence of side effects is high although liver and kidney function tests have not as yet revealed any damage.

Various new sulfonylurea derivatives are now in the stage of experimental or clinical trial.

FAT METABOLISM

Classification of the Fats and Fatty Substances Occurring in the Body

When a tissue is thoroughly extracted with a mixture of ether and alcohol almost all of the fatty substances are removed

The amount of fatty acids combined in the cerebrosides and phospholipids may be determined by taking advantage of the insolubility of these materials in acetone to which some magnesium chloride has been added. The fatty acids may then be liberated and estimated by one of a variety of procedures. An estimate of the amount of the phosphorus-containing substances can be obtained by determining the phosphorus content of the extract, and similarly with those containing carbohydrate by estimating the sugar. The free cholesterol is removed by precipitation with digitonin and estimated gravimetrically or by colorimetric means. In another sample of the extract the bound cholesterol is liberated by saponification as with sodium ethylate and the total cholesterol determined. The difference between the free and the total is the amount of cholesterol combined with fatty acid and thus can be calculated from the known combining weight of fatty acids with cholesterol. The result is an estimate of the amount of cholesterol ester. The difference between the total fatty acid content and the sum of the amounts combined with carbohydrate, phosphoric acid and cholesterol, gives us an estimate of the amount combined with glycerol. The fatty materials or lipids may therefore be classified as follows

- (1) *Fats* Esters of fatty acids and glycerol
- (2) *Lipoids*¹

(a) *Phospholipids* (phosphatides) Fatty substances containing fatty acids, phosphoric acid and some of the following constituents, glycerol, inositol, choline, eth-

anolamine, serine and sphingosine. Examples are—lecithin, cephalin and sphingomyelin

(b) *Cerebrosides* (glycolipids) Combinations of fatty acid sugar and sphingosine (phrenosin, kersasin, etc.)

(c) *Waxes* Esters of fatty acids and certain alcohols (but not glycerol) (cholesterol esters, beeswax, etc.)

(3) *Sterols* Hydrogenated phenanthrene derivatives (free cholesterol, ergosterol, etc.)

(4) *Hydrocarbons* (squalene, carotene, etc.)

THE TRIGLYCERIDES

CHEMICAL STRUCTURE In the members of the first group, the fats one molecule of glycerol is combined with three of fatty acid: oleic acid $C_{18}H_{34}O_2$, stearic acid $C_{18}H_{36}O_2$, and palmitic acid $C_{16}H_{32}O_2$, are the three which account for the bulk of the fatty acids of the neutral fat fraction of body tissues. The latter two are saturated, while oleic acid has a double bond in the middle of its fatty acid chain. This renders it less stable and more easily oxidized. Oleic acid is liquid at low temperatures while stearic and palmitic are solid even at body temperature. It is now thought that the glycerides are usually mixed, i.e., they contain two or more different fatty acids in their molecule. Fatty acids more unsaturated than oleic (linoleic and arachidonic) are also found in the triglycerides. The naturally occurring fatty acids in tissues usually have 12 to 20 carbon atoms and one terminal carboxyl group.

The neutral fats obtained from animal tissues contain fatty acids which have an even number of carbon atoms. The characteristic fatty acids in the depot fat vary with different animals. Hilditch and Lovern have shown that certain fatty acid mixtures are characteristic of marine animals, others of fresh water fish and others of land animals. The fat of the fish, for example, contains large quantities of higher unsaturated fatty acids C_{20} and C_{22} , but in the depots of ox and pig these are almost absent.

¹ The phospholipids, cerebrosides and waxes which resemble fats may be termed lipoids or fat-like substances. The sterols and hydrocarbons while associated with fats are chemically quite distinct.

TABLE 49 I

Distribution of tissue lipids

Column (1) (after Campbell and Lucas) gives the distribution of the total lipids of the mouse in the various tissues

Column (2) shows the distribution of adipose tissue in the rat (after Mendel) as per cent of total adipose tissue

	(1)		(2)
Carcass	34	Subcutaneous	50
Adipose tissues	32	Genital	20
Skin	18	Perirenal	12
Liver	5	Mesenteric	10
Intestine and spleen	3	Inter muscular	5
Genital organs	3	Omental	3
Kidneys and adrenals	2		
Brain	2		
Lungs and thymus	1		

DISTRIBUTION. It is evident from gross inspection of tissues that reserve fat is laid down in large quantities subcutaneously in the omentum, the mesentery, retroperitoneally and at other sites. Reserve fat is also contained in the interstitial tissues of most other organs. Exceptions include the brain and the cornea (see table 49 I). The distribution of fat is largely independent of the type of diet but the amount and kind of fat deposited are influenced by the food intake and the type of diet.

PHYSIOLOGY. The main function of the glycerides is undoubtedly to provide a source of energy. Fat not only furnishes more energy per gram (9.3 Calories) than carbohydrate and protein but it is the only food material stored in the dry state. The total fat content of a well nourished animal may be between 10 and 12 per cent and under unusual conditions much higher. A very large proportion of the total energy store of the body is in the form of fat.

While animals grow normally when diets containing only very small amounts of fat are provided, several investigators have reported that growth is seriously retarded on a diet free of fat (McAmis, Anderson and Mendel). Palmitic, stearic and oleic acids are not essential but Burr and Burr have provided evidence that certain of the unsaturated fatty acids are necessary. Growth is favorably affected by linoleic, linolenic and arachidonic acids and the development of skin lesions (similar to acrodynia) is prevented. These acids should be considered separately in

dietary studies since there are definite differences in the magnitude of their effects on growth and on the skin lesions. There is an interesting interrelationship of the actions of the unsaturated fatty acids and those of pyridoxine, pantothenic acid and other accessory food factors (see also p 945).

In some species, of course, the layers of fat in the subcutaneous spaces serve as an insulating mechanism against extreme cold. Thus in cold climates the fat deposited just under the skin contains a relatively large amount of oleic acid. It is therefore more liquid than the material which is found in the less superficial subcutaneous reserves. Henriques and Hanson have pointed out that since the temperature of the outermost subcutaneous fat is appreciably lower than that of the deeper parts, the body requires a less congealable type of fat at this place. In a somewhat similar investigation of fat in different parts of the body, Anderson and Mendel could find no difference in saturation of the fat from the superficial subcutaneous region and that of deeper and warmer parts of the body. These latter workers used animals which are not normally subjected to extremely low temperatures.

Recovery from the depot fat of a particular dietary fatty acid has been repeatedly demonstrated. This deposition is however limited to the higher fatty acids (above C_{16}). Interconversion of the fatty acids within the body is well established. Schoenheimer and Rittenberg have shown that the length of the carbon chain of fatty acids can be increased or decreased by two carbon atoms at a time and further that desaturation or hydrogenation of unsaturated acids can take place in the body. While one double bond can be formed, the body appears unable to introduce more than one. Thus the highly unsaturated fatty acids such as linoleic and linolenic are not found in fat which has been synthesized in the body. They must be provided in the food.

Conversion of Carbohydrate And Protein to Fat

The formation of body fat from carbohydrate of the diet was established by the classical work of Liebig (1852) and Lawes and Gilbert (1853). The rate at which the fatty acids are formed has now been studied by the use of isotopes. These studies have shown that conversion of carbohydrate to fat proceeds continuously and does not occur only (as was formerly believed) when there is excessive intake of carbohydrate.

The formation of carbohydrate from protein is

well established. It has been assumed that this newly formed carbohydrate is available for fat synthesis and good evidence for this assumption has been secured by Longenecker and by Hoagland and Snider. On an almost exclusively protein diet the fat formed was similar in composition to that synthesized from dietary carbohydrate.

Many of these recent additions to our knowledge establish the fact that the fat depots are not essentially inert storehouses of energy as was previously thought, but are centers of continuous metabolic activity. Glycogen and fat formation take place in adipose tissue and there is a brisk uptake of dextrose the rate of which is controlled, in part, by the presence of insulin.

THE PHOSPHOLIPIDS

CHEMICAL STRUCTURE. The phospholipids probably occur mainly in combination with tissue proteins. They are divided into the monoaminophospholipids in which the ratio of nitrogen to phosphorus is 1:1 and the diaminophospholipids in which the ratio of nitrogen to phosphorus is 2:1. The identified monoaminophospholipids are lecithin (phosphatidyl choline), phosphatidylethanolamine and phosphatidylserine. These two latter compounds with some inositol containing substances and uncharacterized basic materials have been referred to as the "cephalin" complex.

Lecithin and the members of the cephalin complex are composed of glycerol and fatty acids as are the *triglycerides*, but one fatty acid may be considered to be replaced by the phosphoric acid nitrogenous base complex. There may be one saturated and one unsaturated fatty acid but in some cases two saturated or two unsaturated fatty acids occur. Oleic and either palmitic or stearic acids are commonly found but more highly unsaturated fatty acids such as *linoleic* and *linolenic* have been identified. In recent years pure synthetic lecithins identical in every respect with the natural substances have been made by Baer and his associates. Their work indicates that the naturally occurring lecithins are of the alpha type. Sphingomyelin is a diaminophospholipid and contains two bases—choline and sphingosine, and one fatty acid radical but no glycerol. Different sphingomyelins containing respectively, stearic, lignoceric and nervonic acids have been found.

DISTRIBUTION. The phospholipids are widely distributed in the body and it is thought that all cells contain one or more of these compounds.

* May be esterified with fatty acid

Sphingomyelin is present in much larger amounts in the brain and nerve tissues than elsewhere and is usually associated with the cerebrosides.

The "cephalin" content of the brain is considerably higher than the lecithin concentration. In the liver and spleen they occur in almost equal

amounts while in the kidney, heart and lung, lecithin predominates in a proportion of about two to one. "Cephalin" and lecithin have been isolated from the gastric mucosa of pigs but sphingomyelin could not be demonstrated.

The evidence of the French workers Mayer and Schaeffer, and Terroino showed that the amount of phospholipid in a particular organ in a given species remains relatively constant under a variety of conditions including extreme starvation. As a result, they have called this fraction the "élément constant". This evidence strongly suggests that the lipids are structural components of the cell. Their rapid rate of turnover like that of many other structural elements has been established. In table 49.2 the phospholipid content of various human tissues is given.

PHYSIOLOGY The exact role of the phospholipids is not yet understood but their metabolic importance is widely accepted. As noted above the phospholipid content of the various tissues is much more constant than that of neutral fat. Significant variations in phospholipids may, however, be induced by changing the nature of the diet or by alterations in the hormonal balance.

Insulin decreases the plasma phospholipid. Repeated injections of thyroid substance increase the amount in liver while removal of the thyroid causes a decrease. With the onset of pregnancy in the human subject the plasma phospholipids show a rise which continues to term (the other lipids also increase). The work of Aten and Hevesy indicates that milk phospholipids are synthesized in the mammary gland.

Bloor has suggested that the phospholipid content of a tissue may be considered an index of the

extent and variety of its physiological functions. Thus, the phospholipid content is increased with physiological activity and decreased when the cells become less active. A secreting salivary gland of the dog (Camunade, Mayer and Vallée) has a higher phospholipid content than the resting one on the other side. The development of the corpus luteum is accompanied by a very significant increase in its phospholipid content (Bloor, Okey and Corner). When the body temperature of rabbits and dogs was greatly reduced by immersion in very cold water, Mayer and Schaeffer found a decrease in the phospholipid content of the liver and a compensatory rise when the animal had recovered from the experience. The phospholipid content of rapidly growing malignant tumor cells is higher than in normal tissue or in benign tumors of the same tissue.

The metabolic function of the phospholipids is most readily studied experimentally. The injection or feeding of synthetic compounds containing labelled atoms such as deuterium or radioactive tritium in place of hydrogen, heavy carbon C^{13} , radioactive carbon C^{14} , heavy nitrogen N^{15} , and radioactive phosphorus P^{32} has made it possible to study the synthesis of the phospholipids. Schoenheimer, Bloch, Rittenberg, Hevesy, Arton, Chaikoff, Stetten and many others have used these techniques to increase our knowledge of phospholipid metabolism. Sinclair used elaidic acid, the unnatural trans-isomer of oleic acid, as a labelled compound in similar studies. The assumption that the body is unable to distinguish between the cis and trans isomer may not be justified. Indeed recent reports of studies with compounds doubly or trebly labelled have shown that sometimes the different tracers have given different answers. Caution is necessary in the interpretation of data obtained with isotopes.

These methods have shown that the turnover of phospholipids is most rapid in the mucosa of the small intestine during fat absorption, somewhat slower in the liver and much slower in the muscles and kidneys. In the brain the incorporation into phospholipids of P^{32} (given as inorganic phosphate) is a slow process. The correspondingly slow loss of P^{32} from the brain confirms the sluggish turnover of phospholipids in nervous tissue. The limited data on the turnover rates of sphingomyelins in liver and muscle indicate that they are of about the same order of magnitude as that of lecithin although the latter always has the fastest regeneration rate.

A close relationship between liver and plasma

in regard to phospholipids has been established. Chaikoff and his associates have shown that virtually all the plasma phospholipids are derived from the liver. Thus was demonstrated by administering phosphate labelled with P^{32} and palmitic acid labelled with C^{14} to normal and hepatectomized dogs. Only traces of isotope were recovered from the plasma of hepatectomized dogs although other tissues (kidney, intestine, etc.) were able to synthesize phospholipids at the same rate as in the control dogs. The liver appears also to be the tissue principally concerned in the utilization of plasma phospholipids since their concentration changes but slowly in the absence of the liver. The incorporation of administered P^{32} into phospholipids of the corpuscles is a much slower process than into those of the plasma.

THE CEREBROSIDES (GLICOLIPIDS)

In cerebroside the base sphingosine is combined with a sugar (galactose or glucose) and a fatty acid. Thus the cerebroside differ from one another in the nature of their fatty acids or carbohydrate. They can be distinguished from the phospholipids by the absence of phosphorus. The only individual cerebroside that have been isolated in a pure condition contain galactose, they differ in their fatty acid component. Kerasin contains a characteristic saturated acid (lignoceric, $C_{24}H_{48}O_2$), phrenonin (also called cerebrin) contains the corresponding α hydroxy acid (cerebronic, $C_{24}H_{46}O_3$), nervone contains the corresponding Δ_{11} unsaturated acid (nervonic, $C_{24}H_{44}O_2$), hydroxynervone contains the corresponding unsaturated α hydroxy acid (hydroxynervonic, $C_{24}H_{44}O_3$). They are found particularly in nervous tissue, only minute amounts occur elsewhere in the normal body.

CHOLESTEROL

Chemical nature. Cholesterol is found associated with the fats but chemically it is not related to them. Cholesterol, a white waxy solid, is the principal sterol found in animal organism. The sterols are crystalline saturated or unsaturated complex alcohols derived from cyclopentanoperhydrophenanthrene. They occur both free and combined as esters or glycosides. Very minor changes in their structure sometimes produce extraordinary differences in physiological activity. The term steroid is applied to a group of closely related compounds containing the same complex nucleus. These substances include the sex

hormones, bile acids, cardiac glycosides, toad poisons and vitamin D. Cholesterol has been known since the eighteenth century as the chief component of human gall stones. It is an unsaturated secondary alcohol. Most of the cholesterol occurs in the body as the so-called free form (the unesterified alcohol) which is precipitable by digitonin. A much smaller portion is present as the ester of long chain fatty acids (the so-called bound cholesterol). Recent studies indicate that both forms of cholesterol are present in some loose combination with protein. These complex materials of very high molecular weight, referred to as lipoproteins, have been studied by Chargaff, Gofman and others.

DISTRIBUTION. Cholesterol is found in all cells and fluids of the body. The free and bound forms are not equally distributed. The free cholesterol content of any particular tissue is characteristic and normally remains relatively constant, the esters, on the contrary, vary considerably in amount with changes in dietary, hormonal and other factors. The brain and suprarenals have the richest supply of cholesterol. In the former it is found mainly in the free form and in the latter about 90 per cent as ester. In bile it occurs only in the free state. In the corpuscles of human blood cholesterol exists chiefly in the free state while in the plasma more than half is present as the ester. In most other tissues the ester makes up a small fraction of the total. Table 49.3 shows the average total cholesterol content of normal tissues of rabbit and man.

ABSORPTION, TRANSPORT AND EXCRETION OF CHOLESTEROL. Crystalline cholesterol administered orally is absorbed in only small amounts unless some fatty material is also present in the intestine. Bile and pancreatic juice are said to aid in its absorption. Colloidal or amorphous cholesterol may be absorbed in the absence of dietary fat. Combination with the bile acids increases the solubility of cholesterol in intestinal fluids. The experiments of Mueller in 1915 on the absorption of cholesterol have been confirmed and extended by the tracer studies of Chaikoff and his associates using cholesterol labelled with C^{14} at carbon atom 4. When free cholesterol is fed a portion is esterified and about half appears in the chyle in the bound form, on the other hand when cholesterol esters are fed some hydrolysis occurs and again about half appears in the lymph in the free form. Thus, the processes of esterification or of hydrolysis (either before, during or after absorption) lead to essentially the same pro-

† After Cook

portions of free to bound cholesterol in the lymph. The exact site of this esterification, whether in the lumen or intestinal wall, is at present undecided. The increased cholesterol of the blood during fat absorption is probably due in large part to absorption of cholesterol contained in the pancreatic and intestinal juices and the bile. The increase in cholesterol ester has been taken to indicate that the sterol may play a part in the transport of fatty acids. It is very interesting that closely related sterols (phytosterol, coprosterol) are absorbed only in very small amounts (Schoenheimer and Sperry). The blood contains an enzyme which will split the esters and presumably, under other conditions, will cause synthesis (Shope, Sperry and Schoenheimer). Part of the absorbed free cholesterol, but not the ester, is excreted in the bile and part is changed to coprosterol by hydrogenation and eliminated in the feces. Some unchanged cholesterol is also excreted. The cholesterol plus coprosterol in the feces is usually greater than the cholesterol content of the diet. Some of the biliary cholesterol is reabsorbed in the small intestine. Gardner and Gumsborough state that cholesterol can be found in normal urine and that the amount is increased by cholesterol

feeding and in certain diseases. Under these circumstances cholesterol deposits may be found in the kidney tubules.

THE PHYSIOLOGY OF CHOLESTEROL SYNTHESIS and degradation of cholesterol go on simultaneously in the animal body. Herbivorous animals do not get any cholesterol in their food yet their tissues contain essentially the same levels of cholesterol as do those of omnivores and carnivores. Synthesis of cholesterol has been shown to occur in many tissues (adrenal, kidney, testis, ovary, small intestine, skin, etc.) but the liver is the most important site. Plasma cholesterol comes chiefly from the liver. The 'two-carbon fragment', now identified as acetyl coenzyme A, has been recognized for some years as a metabolic intermediate in the synthesis of cholesterol in the body. Attempts have been made to measure the rate of synthesis of cholesterol by feeding acetate labelled with deuterium or C^{14} . The time required to synthesize an amount of cholesterol equal to the amount present in the body is called the regeneration time. Schoenheimer and Rittenberg suggested the term "regeneration" to denote replacement by synthesized molecules, since 'turn-over' implies only replacement without regard to source. Turnover could, for example, be applied to the replacement of tissue cholesterol by labelled dietary cholesterol. The regeneration time can be shown mathematically to be $1.44 \times$ the "half life regeneration time" as determined by standard techniques.

Rittenberg and Schoenheimer found the regeneration time for total body cholesterol in the mouse to be about 25 to 30 days. The regeneration time of cholesterol in the liver has been estimated to be about 4 to 5 days in the rabbit (Popjak) and in the rat about 9 days (Bloch). Regeneration in the carcass is very much slower, about 43 days being required in the rat. The regeneration time for plasma cholesterol has been found to be about 12 days in both man and dog. The rate of synthesis of plasma cholesterol in normal man appears to be about 500 to 600 mg. per day (Rittenberg). The nature and caloric value of the diet affect the rate of synthesis of cholesterol; during fasting the process is much retarded. The amount synthesized per day in man is probably about ten times the average daily intake. An increase in the dietary intake decreases the amount formed in the body.

Hormonal factors also affect the metabolism of cholesterol. A single injection of an anterior pituitary extract containing the adrenocorticotrophic

hormone (ACTH) causes a definite fall in adrenal cholesterol within a few hours (Sayers, Long). When the thyroid is overactive, the concentration of cholesterol in the blood is decreased, drugs such as thiouracil, which depress the activity of the thyroid, increase the level of blood cholesterol. In human subjects estrogens depress serum cholesterol. Cyclic variations of serum cholesterol have been described in women during both the menses and pregnancy. On the other hand, there is no convincing evidence for a primary effect of androgens or progesterone upon cholesterol metabolism.

Bloch has demonstrated with the aid of deuterium the conversion of cholesterol to pregnanediol. It appears that cholesterol may also act as a precursor of other steroid hormones.

Ever since Overton's work in 1899, the lipid nature of the cell membrane has aroused interest. The hydrophilic nature of the lecithins, the hydrophobic nature of cholesterol and the peculiar intermediate properties of the cholesterol esters have been invoked to explain the phenomena at membranes. While there are many examples of the physicochemical antagonism of cholesterol and lecithin, little exact information is available as to the physiological role of the cholesterol moiety of the lipoproteins in cell membranes.

The Absorption of Fat

(See also p. 676)

Since the fats and their hydrolytic products, the fatty acids, are very sparingly soluble in water, the explanation of their absorption presents special difficulties. The exact mechanism is still unsolved. There are two main schools of thought concerning the processes involved. One group champions Pfleger's polylytic theory, the other Frazer's partition hypothesis. Nearly 200 years ago Hewson (1774) observed that the milky fluid seen in the lacteals following a meal leaves a grease spot when dried on paper. Under the microscope the milky fluid was seen to contain numerous tiny particles for which Gage in 1920 proposed the name chylomeron. In 1856 Claude Bernard had demonstrated that a fine emulsification of fat occurs in the intestine and showed that this depends upon the presence of bile and pancreatic lipase. Bernard also noted that lipemia was present in the systemic circulation following ingestion of a fat-rich meal. Further study of this phenomenon was made by

Munk and Rosenstein in 1891, utilizing a patient with a lymphatic fistula of the leg.

The mode of transfer of the neutral fat from the epithelial cells to the central lacteals remains a matter for conjecture. The leukocytes have been credited with this function but most of the evidence is against their playing such a role. During fat absorption the central lacteals show rhythmic contractions which evidently serve to pump the chyle contained within them into the lymphatics tributary to the thoracic duct. Thus the absorbed fat is constantly propelled along the lymphatic channels of the mesentery.

According to the classical hydrolytic theory fat is emulsified and split completely to fatty acids and glycerol before absorption. The fatty acids rendered water-soluble by complex formation with bile salts, are believed to enter the epithelial cells of the intestinal villi where they are combined with glycerophosphoric acid or phosphatidic acid to form phospholipids and finally reappear as neutral fat. This is carried largely in the lymph, by way of the lacteals, to the thoracic duct where it enters the systemic circulation.

The partition theory suggests that it is not necessary for all the fats to be completely hydrolyzed. Frazer believes that free fatty acids are absorbed by the blood and pass to the liver by way of the portal vein, while glycerides (tri-, di- or mono-), with particle size below 0.5μ are absorbed through the intestinal mucosa directly into the lymph. Thus absorption of fat is partitioned between portal blood and lymph according to the degree of hydrolysis.

Recently studies have been made with free fatty acids and triglycerides labelled with C^{14} . When these compounds were given by stomach tube to rats, over 90 per cent of the absorbed fatty acids were recovered from the thoracic duct lymph in both cases. Such findings are not consistent with the original partition theory. The main tenet of this theory, i.e., that complete hydrolysis of glycerides is not necessary, is however now well established. By feeding synthetic glycerides labelled with C^{14} in the glycerol part of the molecule, it has been conclusively shown that hydrolysis of long chain glycerides in the intestine is neither rapid nor complete. Other studies indicate that in some cases a large proportion of dietary fat is absorbed in the form of glyceride. Small amounts of monoglyceride, formed in the intestinal lumen by the hydrolytic action of lipases, can exert a powerful emulsifying effect, thus enabling the bulk of the dietary glycerides to be

dispersed to particles of extremely fine size. These particles, as noted above, can be directly absorbed.

Fat is not only transported as chylomicrons which are largely triglycerides but as phospholipids and cholesterol esters, and in lipoproteins. The relative importance of these vehicles and of the nonesterified fatty acids in plasma is a subject for further research.

The Elimination of Fat from the Body

There is no fat or phospholipid in the urine under normal conditions but the latter may appear in disease. There are only traces of fat in the secretion of the skin.

The fat content of the feces is normally between 6 and 12 per cent of the fat which is absorbed but as Sperry has pointed out this bears

no relation to the food fat. In dogs, even after five weeks or more on a fat free diet, there are considerable amounts of fat in the feces. Some 60 per cent of this is neutral fat and 40 per cent fatty acids. A large part of this lipid excretion is derived from bacteria and cellular debris.

When the bile duct is ligated, large, light colored stools are usually observed as this procedure interferes greatly with fat absorption. Digestion is nearly complete, however, as is shown by the fact that the fat is excreted chiefly as fatty acids. Fatty stools are found also when the pancreatic ducts are tied although the absorption of fat is by no means completely prevented. When pancreatic lipase is excluded in this way the excreted fat contains more glyceride and less fatty acid.

Blood Fat

Blood transports not only the fatty materials absorbed from the intestines but also lipids resulting from intermediary metabolism. The amount of lipid material found in the plasma of animals in the postabsorptive state (i.e., at least 12 hours after the last meal) does not vary greatly under normal conditions. Table 49.4 gives typical values for the lipid components in the plasma of several species. If however a sample of blood is withdrawn 3 to 6 hours after the ingestion of a large amount of fat, such as olive oil or thick cream, a distinct milkiness of the plasma will usually be observed. The milkiness is due to the presence of the tiny microscopic fat particles called chylomicrons (fig. 49.1). This is a physiological occurrence which is often associated with the postprandial hyperlipemia following a fatty meal. The extent to which the amount of fat in the blood has increased is sometimes studied by counting these particles under a dark field microscope. Erroneous impressions may be obtained by this method however, since an increased amount of heparin in the blood, and possibly other factors can minimize or prevent the appearance of this milkiness in plasma which by chemical methods, can be demonstrated to contain abnormally large amounts of fatty material. Thus great variations in the degree of milkiness may be observed in a single individual under apparently identical experimental conditions. Part of the discrepancy can be explained in other ways, since the amount of fat present in the blood at any given instant depends on the balance between the rate of absorption and the rate at which it is being utilized or deposited in adipose tissue. It is obvious, there-

FIG. 49.1 Shows chylomicrons (After Gage)

fore, that the degree of alimentary lipemia is not a consistently reliable index of the rate at which fat is being absorbed. The postprandial increase in blood lipids is due chiefly to neutral fat, smaller increases in cholesterol esters and phospholipid are often observed. Besides the transient alimentary hyperlipemia there are the so-called retention and transportation hyperlipemias. As stated above, the cholesterol and phospholipids found in plasma originate chiefly in the liver. The plasma phospholipids consist chiefly of the choline-containing types (lecithin and sphingomyelin). The larger proportion of the lipid components of the plasma appear to be in combination with proteins.

The mechanism of production of the interesting lipemia which follows hemorrhage in certain species requires further study.

Fat Transport

The long held belief that phospholipids are particularly active in fat metabolism and transport, seems now to be disproved. Pihl and Bloch, for example, using acetate labelled with C^{14} , have shown that the rate of regeneration of neutral fat is faster than that of phospholipid, from which they concluded that phospholipids are not obligatory intermediates in the synthesis of neutral fat. Their data on plasma lipids suggest that it is unlikely that phospholipids are a major vehicle for fat transport. Indeed, the data suggest that neutral fat may represent the most important means of lipid transport in the plasma.

It was thought, until recently, that all the fatty acids of the blood and tissues were present in bound forms, as esters. It is now known that small amounts of non-esterified fatty acids occur in plasma, loosely bound to protein, particularly albumin. This unesterified or nonesterified fraction of the plasma lipids (UFA or NEFA) consists chiefly of oleic, linoleic, palmitic and stearic acids. As Gordon and Dole and their colleagues have shown, NEFA arise from the fat of adipose and other tissues, including plasma lipoproteins. An enzyme "lipoprotein lipase," isolated by Korn from heart and adipose tissue, catalyzes the release of fatty acids from lipoprotein in the presence of albumin or other acceptor protein for the fatty acids. Heparin is part of this enzyme complex, which has the same properties as the "clearing factor" of plasma.

Labeled NEFA are very rapidly removed from the blood by the liver, muscle and other organs, and are either incorporated into the lipids of the

tissues or oxidized to carbon dioxide. Little uptake by adipose cells occurs. The half life of NEFA in the blood is very brief (a matter of minutes), indicating that they have great metabolic activity. Calculations indicate that they account for most of the lipid utilized.

In the fasting condition the NEFA are somewhat elevated and are diminished by the ingestion of glucose. Thus their release from the depots appears to be influenced by demands for energy and the availability of other nutrients. In normal individuals given insulin the changes in NEFA parallel those of the blood glucose. In diabetic acidosis the NEFA levels are very high, but may be rapidly lowered by the administration of insulin and glucose. Thus insulin appears to regulate, in part, the release of NEFA from the lipid depots. During lipid mobilization produced by growth hormone in fasting animals, on the other hand, the NEFA rise, indicating increased production.

A relatively unexplored possibility is that the calorie-rich lipids in blood may be used to supply energy to areas of higher metabolic activity. To explain the large amounts of lipids found in plasma was not easy in view of the well known insolubility of neutral fats and free cholesterol in water. It was first suggested that incorporation of fatty acids into phospholipids and cholesterol esters would account for the findings. The more recent discovery that these latter substances and neutral fats occur in the plasma largely in combination with protein, may provide a hypothesis to account for the transport of energy rich compounds in the form of lipids. It is conceivable that the lipoproteins may transport water-soluble lipids in the plasma by some mechanism similar to that in which hemoglobin transports oxygen (Turner).

LIPID MOBILIZATION

Mobilization of lipid at elevated rates from the body depots occurs during fasting, after the administration of certain anterior pituitary gland extracts or hormones to fasting animals, when there is deficiency of insulin. A characteristic pattern of changes can be recognized during lipid mobilization, although there are considerable differences in degree from species to species. During the first phase of fasting the carbohydrate reserves are rapidly depleted. In the second phase fat accounts for about four-fifths of the total energy utilized in man, and protein the remainder. Large amounts of lipid accumulate in the liver of

the mouse, guinea pig and rabbit, but not in that of the rat, while the lipid of the reserves is being depleted. In primates, including man, ketonaemia and ketonuria occur and the non-esterified fatty acids (NEFA) of the serum increase. Incubation of liver tissue from fasting animals *in vitro* reveals that the production of acetoacetate is increased and the synthesis of fatty acids is decreased, while the production of NEFA by incubated adipose tissue is increased.

Certain fractions of the anterior pituitary gland intensify the mobilization of lipid in fasting animals (Best and Campbell). This activity is possessed by the growth, adrenocorticotrophic and thyroid-stimulating hormones, and the possibility of a more specific factor is not yet excluded. Treatment with these factors causes (a) over all increased utilization of fat in the body with depletion of fat reserves, (b) rapid and massive deposition of fat in the liver and, to a lesser extent, in the kidney, (c) increased retention of nitrogen and glycogen in the liver, (d) ketonaemia and ketonuria, (e) increase in NEFA of the serum. The protein and glycogen-sparing effects on the liver may be due to the increased utilization of lipid. A fat-mobilizing fraction, termed 'adipokinin' by Weil and Stetten, occurs in the urine of fasting animals and has been obtained also in the urine of fasting man. This material is possibly of pituitary origin. The liver tissue of the pituitary-treated rats produces acetoacetate and utilizes oxygen, *in vitro*, at greatly increased rates. These effects are due, apparently, to increased concentration of substrate (lipid) and to the stimulation of oxidative activity in the liver tissue.

Lipid mobilization by anterior pituitary administration is inhibited by adrenalectomy. However, the adrenocorticotrophic hormone can induce mobilization in the absence of the adrenals (Engel). The adrenal cortical hormones do not induce mobilization, but sensitize the tissues to the adipokinetic factors. Seifter finds that the administration of cortisone to normal (but not to hypophysectomized) animals causes the appearance in the serum of a dialysable substance that elicits fat mobilization when injected into test animals. This factor appears to come from the posterior pituitary gland. Thyroidectomy causes inhibition and loss of response to adipokinetic factors, and thyroid treatment restores the response (Best and Campbell).

Deficiency of insulin, as in depancreatized dogs, rapidly induces (a) wastage of body tissues, with depletion of carbohydrate, fat and protein re-

serves, (b) rapid and massive accumulation of fat in the liver, with increase in the size and friability of the organ (lipid accumulates also, but to a lesser extent, in the kidney and heart), (c) ketonaemia and ketonuria, (d) increase in the NEFA of the blood serum, and (e) inhibition of synthesis of fat. The conclusion is inescapable that these changes are associated with increased utilization of lipid and mobilization of lipid, with deposition of lipid from the depots in liver and kidney. The administration of insulin prevents or reverses all these alterations. It is well known that all these effects of insulin deficiency and of insulin treatment can be recognized in diabetes mellitus. In insulin added to the medium bathing adipose tissue *in vitro* increases the uptake of labelled glucose, the production of carbon dioxide and the synthesis of fatty acids (Renold) and also decreases the output of NEFA (Gordon and Cherkes).

The pituitary gland may be involved in producing these effects of insulin deficiency. The ketosis and the accumulation of fat in the liver of the depancreatized dog are diminished or abolished by hypophysectomy. Diabetes induced in dogs by the administration of growth hormone for four or five days is accompanied by massive accumulation of fat in the liver, with enlargement and increased friability. Lipid also accumulates in the kidney and the heart, while in the blood the lipids, the NEFA and the ketone bodies, rise.

The Liver and Fat Metabolism

Recent tracer studies have confirmed the importance of the liver in the metabolism of fat. As mentioned earlier, the liver is the main site of formation of plasma phospholipids and of plasma cholesterol. The liver is the major organ for the synthesis of fatty acids from carbohydrate (al though this process has been shown to occur in other tissues, e.g., adipose tissue, kidney, muscle, gastrointestinal mucosa and lung) and it is the principal site for the oxidation of the higher fatty acids. Some of the earlier observations which linked the liver with fat metabolism are as follows: (1) The fatty acids combined as liver phospholipids and glycerides are more unsaturated than the fatty acids found in other tissues. (2) The rate of phospholipid turnover in the liver is more rapid than in any other tissue, with the possible exception of the intestinal mucosa during fat absorption. (3) The liver is the principal site of formation of the ketone bodies which are well-known metabolic intermediates in the metabolism of fat.

(1) The fact that the fatty acids in the liver are more unsaturated than those in other tissues was interpreted by Leathes and Meyer-Wedell as evidence for desaturation of fatty acids (formation of double bonds) in the liver. Raper suggested that the liver cells may selectively retain the more unsaturated fatty acids. Using fatty acids labelled with deuterium Schoenheimer and Rittenberg were able to supply direct evidence for the desaturation of stearic acid to oleic acid; they also showed that degradation of stearic acid to palmitic acid (with two less carbon atoms) occurs in the body. The lipids of the body were shown to be constantly undergoing synthesis, interconversion and degradation and the rate at which these processes occur was found to be much greater in the liver than in other organs. More recent studies using fatty acids and glycerides labelled with C^{14} have emphasized the important role of the liver in the utilization of fat. Experiments on hepatectomized and eviscerated animals have revealed the possible importance of lipids as sources of energy in extrahepatic tissue.

(2) The rate of phospholipid turnover in the liver has been studied by giving radioactive inorganic phosphate (P^{32}), fatty acids labelled with C^{14} and choline labelled with heavy nitrogen (N^{15}). All these experiments have shown that the liver phospholipids are regenerated rapidly. More recent studies indicate that the several parts of the molecule (choline, P and fatty acids) are turning over at about the same rate.

(3) It has been well established that the liver is by far the most important site for the production of ketone bodies (see below).

The liver normally contains about 8 per cent of total lipids. Variations within the range from 5 to 7 per cent are considered normal. About 50 per cent of this lipid material consists of phospholipids, about 3 per cent of free cholesterol, about 1 per cent of cholesterol esters and the remainder (45 to 55 per cent) consists principally of glycerides.

The amount of fat which is present in the liver at any time depends on the following factors:

- 1 The rate at which fat is brought to the liver by the blood
- 2 The rate at which the liver is able to take up fat from the blood
- 3 The rate at which the liver can deal with fat,
 - (a) by direct oxidation in the liver cells
 - (b) by passing it on in the same or in a slightly changed form to other parts of the body

- 4 The rate of synthesis of fat in the liver from other materials

There is an increase in the fat of the liver within a few hours after the ingestion of a meal containing large amounts of fat. Under these conditions the ingested fatty acids appear in the liver lipids thus altering their composition. Under certain conditions the liver may become intensely fatty when no fat is fed; here the fatty acids are derived from the depot fat or from ingested carbohydrate or protein. When ear marked fats are deposited in the tissues and then some poison such as phosphorus or chloroform is administered, the excess of liver fat contains the fatty acids which were present in the depot fat.

FATTY LIVERS Under a variety of conditions neutral fat or cholesterol esters may accumulate in the liver to a very much greater extent than in other tissues. In experimental animals fatty livers have been produced containing over 50 per cent of total lipids but this is an extreme situation and values between 20 and 40 per cent are more frequently encountered. These fatty livers are much larger and paler than normal livers; the greater part of the increase in weight of the liver is due to accumulation of glycerides and water. Phospholipids and free cholesterol remain remarkably constant; cholesterol esters increase significantly whenever glycerides increase.

Some conditions which result in an excessive deposition of fat in the liver are as follows:

1 Starvation—the fatty liver of starvation is clearly seen in some species of animals. It disappears when the fat reserves are exhausted.

2 Injection in fasting animals of a fraction obtained from the anterior pituitary gland—purified growth hormone ACTH and TSH are active and the possibility remains that a more specific unidentified factor is operating.

3 Insufficiency of insulin

4 Dietary deficiency—diets deficient in choline or its precursors; diets rich in fat or containing excessive amounts of cholesterol; diets deficient in protein

5 Environmental changes—reduced atmospheric pressure (e.g., at high altitudes or elevated temperatures)

6 Poisons—phosphorus, chloroform and other chlorinated compounds, benzol, ketene, phloridzin, or bacterial toxins

7 Clinical conditions in which one or more of the above situations are present, e.g., kwashiorkor (world wide malignant undernutrition), diabetes

mellitus, pernicious anemia, yellow fever, pregnancy

THE LIPOTROPIC FACTORS. Choline and its dietary precursors, betaine and methionine, are in the rations of animals so as to prevent the accumulation of excessive amounts of fat in the liver (fig 49.2) Choline, a quaternary ammonium base

occurs widely distributed in nature although it is rarely found in the free condition in more than traces It was first isolated (from bile) by Strecker in 1849 and has long been known as a constituent of lecithin and sphingomyelin Lean meats (muscle) contain about 100 mg choline per 100 grams of fresh meat Kidney contains 200 to 300 mg, brain 350 to 450 mg, liver from 450 to 600 mg, fish muscle 50 to 80 mg, whole eggs 350 to 700 mg, egg yolk about 1400 to 1700 mg, whole wheat 50 to 100 mg, wheat germ 350 to 400 mg, oats, barley, rye, corn and rice contain about 60 to 100 mg, yeast (brewer's dried) 240 to 360 mg per 100 g Vegetables as a group are low in choline and fruits are very low Edible fats as obtained commercially are almost free from choline

The other naturally occurring substances which possess lipotropic activity are betaine (the internally neutralized acid formed by oxidizing the primary alcohol group of choline), methionine and β -propiothetin They have been shown to possess labile methyl groups and it is believed that they possess lipotropic activity by acting as precursors of choline Vitamin B_{12} and folic acid, which are important in hematopoiesis, are also able under some conditions to produce a lipotropic effect The relations between these two substances in lipotropic phenomena are not yet clearly understood but vitamin B_{12} appears to be concerned in the biosynthesis of labile methyl groups and folic acid in transmethylation reactions or in the synthesis of some other part of the choline molecule Inositol exerts a limited lipotropic effect in fat-free diets but this effect is minimized when any fat is in the food The crude pancreatic extract which has been referred to as "lipocaine" was at one time thought to possess some unique lipotropic influence since it was believed to be free from choline While it may contain only traces of free choline its content of bound choline sometimes makes it one of the richest known sources of this base Methionine and vitamin B_{12} are also

present in this extract and if proteolytic enzymes are present they may make methionine available from the dietary protein

In 1924 Allan, Bowie, Macleod and Robinson in Toronto, and Fisher in Chicago, noted that large fatty livers developed in depancreatized dogs maintained for a long time with insulin Inclusion of raw beef pancreas in the diet prevented this fatty change Hershey and Soskin noted a similar protective effect with crude egg lecithin In 1932 Best, Hershey and Huntsman found that they could produce fatty livers in rats by dietary means in about three weeks as contrasted with a period of more than six months required in the depancreatized dog With this more rapid method of investigation they quickly identified choline as the active constituent in the lecithin molecule Betaine was found to exert a similar effect It was soon discovered that casein and certain other proteins possess lipotropic activity This activity of protein was largely accounted for in 1937 when Tucker and Eckstein discovered the lipotropic property of methionine It exerts a lipotropic effect by transferring its methyl group to ethanolamine, thus effecting the biosynthesis of choline (du Vigneaud) When choline, betaine or methionine labelled in the methyl group with deuterium were fed singly to rats, the choline of tissue phospholipids, the methionine of tissue proteins and urinary creatinine were all found to contain labelled methyl groups The enzymatic process involved is known as transmethylation and the particular groups concerned are said to be labile methyl groups Not all methyl groups are labile, a distinction must be made between the processes of demethylation and transmethylation since demethylation does not necessarily give rise to a labile methyl group (e.g., sarcosine)

The original view that the animal body is unable to synthesize methyl groups had to be modified when it was found that rats could survive and grow slowly under certain dietary conditions on rations devoid of any preformed methyl groups (Bennett, Medes and Toennies) Later, the importance of vitamin B_{12} and of folic acid in the biosynthesis of methyl groups and in the metabolism of the "one carbon fragment" became apparent

A labile methyl group is not necessary for lipotropic action Tracer studies have indicated that the methyl groups of choline are not labile and only become so after oxidation to betaine It had been recognized previously that arsenocholine

FIG. 49.2 Section from liver of depancreatized dog fed a diet low in choline. Ether soluble material over 60 per cent of wet weight $\times 200$ (From Best, Huntsman and Young)

(Welch), triethylcholine (Channon, McArthur), and sulfocholine (du Vigneaud) which contain *no labile methyl groups* exert a lipotropic effect. When fed, they are incorporated into liver phospholipids as the intact molecule. These observations suggest that the lipotropic action of choline is exerted by the intact molecule and not by virtue of its methyl groups. Dietary components with labile methyl groups exert their lipotropic effect by favoring biosynthesis of choline.

The physiological test for a labile methyl group is to feed the compound containing the methyl group to a rat being fed a synthetic diet complete in every sense except that methionine is replaced by homocysteine. If growth occurs, which can only happen when methionine is formed, transfer (or synthesis) of methyl groups must have taken place.

When the lipotropic factors² are not available

² The term lipotropic was originally used to describe the action of choline which prevented the deposition of, or accelerated the rate of removal of fat from the liver. It now has a somewhat broader meaning and is used to describe the action of choline and its precursors methionine and betaine on fat deposition in liver and kidney. Only those effects of methionine and betaine which are exerted through formation of choline are included in the

in the diet large amounts of fat accumulate in the liver. In young animals hemorrhagic lesions are seen in the kidneys and other tissues (Griffith and Wade), and these may produce death. The anti-lipotropic factor cholesterol aggravates the liver and kidney changes while choline, betaine and methionine prevent their development. When young rats are subjected for only five days to a diet deficient in choline and its precursors and are then returned to a full normal diet a malignant hypertension of renal origin develops four or five months later, in a considerable proportion of the animals (Hartroft and Best).

In the depancreatized dog, choline has been shown to be one of the active components of beef pancreas which as previously stated prevents the development of fatty livers. The protein of pancreas through its methionine content will pre-

term "lipotropic." Substances such as cholesterol which cause a deposition of liver fat are referred to as antilipotropic and hypothetical diets free of lipotropic factors may be described as alipotropic. Cystine under certain dietary conditions increases the deposition of liver fat and the incidence of hemorrhagic kidneys. This is apparently related to an improvement in the diet, the resulting increased food intake stimulates growth and creates an additional need for the lipotropic factors.

sumably also exert a lipotropic effect. Furthermore, the pancreatic enzymes will help to liberate choline and methionine from the phospholipids and protein of the diet. There are thus three pathways by which the minced pancreas, the study of which initiated these investigations, may have contributed the lipotropic agents.

The mechanism by which choline exerts its lipotropic action is unknown. There is a little evidence suggesting that complex esters of choline may act as coenzymes in the metabolism of the lipids.

CIRRHOSIS Prolonged exposure to certain toxic chemical or infectious agents or dietary deficiencies which cause fatty livers can lead eventually to an excessive production of fibrous connective tissue. The shrunken, distorted liver which results is usually of a peculiar orange to brownish color. It is this aspect which Laennec featured in the name *cirrhosis*. *Kwashiorkor* is a pandemic form of cirrhosis found among severely undernourished infants and children in many parts of the world. It appears to be related to diets in which the protein is both low in quantity and poor in quality. No significant role of the lipotropic factors has, as yet, been detected. Some forms of experimental cirrhosis are attributable to deficiency of the lipotropes. The first lessons of this type, preventable by administration of the lipotropic agents, were noted by Maclean and Best in 1934. In depancreatized and later in normal dogs Chaikoff produced cirrhosis by prolonged feeding of diets which permitted fat to accumulate in the liver. Later the lesion was studied in rats by Gjorgy and Goldblatt, Blumberg and McCollum, by Daft, Sebrell and Lilfo, by Hartroft and by others. Experimental dietary cirrhosis begins by condensation of fibrous stroma supporting centrilobular cells which have been distended by excessive fat to their bursting points. The ruptured cells atrophy and disappear leaving a scar formed by their stromal remnants. By repetition and extension of the process these scars eventually spread through the rest of the liver including some areas around large portal veins. It can be prevented or, in its early stages, cured in animals by the addition of choline or its precursors to the diet.

Alcoholic cirrhosis is probably often of dietary rather than of toxic origin. The excessive consumption of alcohol supplies sufficient calories so that the patient feels no need for other foods which would provide the necessary proteins, vitamins and minerals. The toxic effect of alcohol

in very large doses, on various tissues cannot be doubted.

The acute effects of chloroform poisoning on the liver in protein-depleted dogs are diminished or prevented by the administration of methionine (Müller and Whipple).

Methionine, cystine or α -tocopherol protect rats against a massive necrosis of the liver which appears when these substances are in large part removed from the diet. These protective effects of methionine are not exerted through its lipotropic action. Schwarz has recently established the importance of selenium as a protective agent against necrosis of dietary origin.

FAT AND GLYCOGEN IN LIVER While it is true that very small amounts of glycogen are present in very fatty livers and that the fat content is low when large amounts of glycogen are found, it can also be shown that moderate amounts of glycogen can accumulate in moderately fatty livers.

Intermediary Metabolism of Fat

During the oxidation of fat to carbon dioxide and water a number of intermediary substances are formed. It has been known for a long time that three substances are produced during the oxidation of fatty acids, namely, acetoacetic acid, β -hydroxybutyric acid and acetone. These are collectively known as the ketone bodies. The discovery of coenzyme A by Lipmann in 1945 and the identification of 'active acetate' as acetyl coenzyme A by Lynen and his colleagues (1951) are achievements of historic importance. We shall attempt to correlate these recent studies with the previously known facts.

Under ordinary conditions the ketone bodies are present in the blood in very small amounts (about 1 to 3 mg. of total ketones per 100 ml. blood) and only about 0.3 gram are excreted daily. Ketosis (increased amounts of ketones in blood and urine) may occur when increased amounts of fat are metabolized, for example when the diet is rich in fat, or during fasting when the fat reserves of the body are being rapidly utilized. Certain clinical conditions in which ketosis occurs are diabetes mellitus, fevers, the postoperative state, toxemias of pregnancy, hyperthyroidism, glycogen disease. Ketosis is seen experimentally in pancreatic or phlorhizin diabetes after administration of certain hormones (growth hormone, adrenocorticotrophic, adrenocortical and, in fasting animals, insulin). The amino acids leucine, isoleucine, phenylalanine, tyrosine and hydroxyproline, produce an increased excretion

of ketone bodies in diabetic animals. Other amino acids may give rise to glucose in the body. It has been estimated that protein predominantly forms glucose rather than ketones. Ketones may be produced through the oxidation of pyruvate by liver slices *in vitro* but in the intact animal the effect of pyruvate appears to be antiketogenic. In general, it may be taken that the precursors of the ketone bodies are the fatty acids.

INTERCONVERSION AND EXCRETION OF THE KETONE BODIES

Acetoacetic acid is the ketone body that is produced first by the tissue cells. Acetone arises by decarboxylation of this acid—a spontaneous reaction that does not necessarily require the enzymatic activity of the tissue cells. The acetoacetic acid may be reduced by the tissues to β hydroxybutyric acid. The reaction is reversible. In ketosis the greater part of the total ketones occurs as the hydroxy acid. Since β hydroxybutyric acid is weaker than acetoacetic acid this conversion tends to reduce the unfavorable effects of accumulation of fixed acid.

All three ketone bodies are excreted in the urine. Acetone may also be excreted in the expired air, giving a characteristic odor to the breath of the individual with ketosis. In the days before insulin the diabetic ward could be thus detected at a distance.

SITES OF ORIGIN OF THE KETONE BODIES

It is generally accepted that the liver is by far the most important site of production of ketone bodies. The perfused liver produces abundant quantities of ketones while little comes from other organs such as kidneys, lung and skeletal muscle (Emden, Snapper, Grunbaum and Neuberg). Himwich and his associates found that liver consistently added ketones while striated muscle, heart and the organs drained by the portal vein only occasionally added small amounts of ketones,

and sometimes removed them from the blood. It has been observed repeatedly that liver slices may add ketones to the medium and produce relatively large amounts from added fatty acids, while other tissues are very much less active. The rate of utilization of acetoacetate by liver tissue is practically nil, i.e., acetoacetate appears to be an end product of fatty acid oxidation by the liver. In contrast, acetoacetate and β hydroxybutyrate are readily utilized by muscle and other extrahepatic tissues.

THE MODE OF FORMATION OF KETONES

The higher fatty acids that occur in the body contain an even number of carbon atoms in a straight-chain arrangement. This is not the place to describe the contributions of Knoop, Raper, Schoenheimer and Rittenberg and many others all of which pointed to a fundamental two-carbon unit concerned in the metabolism of fatty acids. Two of these units were assumed by MacKay and associates to condense to form acetoacetic acid. Support for this assumption was provided by Weinhouse, Medes and Floyd by labelling octanoic acid with isotopic carbon in the carboxyl group. The acetoacetate formed when this was incubated with liver slices was found to contain the isotope distributed almost equally between the carbonyl and the carboxyl carbon atoms. This could only have resulted from the condensation of pairs of molecules, each containing two carbon atoms (acetyl groups) arising by β -oxidation of the fatty acid. These experiments establish the principle of beta-oxidation and of condensation of "acetate" molecules in the formation of acetoacetate. Subsequent studies have shown that when carboxyl labelled fatty acids are utilized to form acetoacetate the ratio of the label in the carbonyl label in the carboxyl carbon varies in a regular manner with chain length, rising from about 0.3 for butyrate to 0.8 for octanoate and to 1.0 for higher fatty acids. The reasons for this

Scheme showing the metabolism and routes of excretion of the ketone bodies

inequality have been explained by Lynen and by Mahler

THE ROLE OF THE COENZYME OF ACETYLATION (CoA) IN FATTY ACID METABOLISM

While studying "active acetate", Lipmann investigated the acetylation of aromatic amines such as sulfanilamide by tissues and tissue enzymes and discovered that a heat-stable co-factor, the coenzyme of acetylation (CoA) is required

Coenzyme A has been isolated from liver, which is a rich source, and also from yeast and other microorganisms. It is a dinucleotide consisting of 2-thiol-ethylamine (I) and pantothenic acid (II) linked by a pyrophosphate bridge (III) to adenosine (IV) which has a phosphoryl radical at position 3 of its ribose moiety.

Observations in several laboratories suggested that "active acetate" might be an acetylated derivative of this coenzyme (Lipmann, Stadtman, Ochoa). The brilliant studies of Lynen and his colleagues led to the isolation from yeast of a substance able to acetylate without the intervention of ATP. This substance proved to be identical with "active acetate". Chemical investigations showed it to be acetyl-coenzyme A, in which the labile acetyl group (i.e., the "active two-carbon unit") is linked to the sulfur atom. To emphasize the presence and importance of sulfur in this high-energy bond the abbreviated

formula is often written Ac-SCoA instead of Ac-CoA .

The substrates involved in the enzymic degradation or synthesis of the fats are not the free fatty acids but the activated conjugates with CoA. Coenzyme A acts as an acceptor of the two-carbon units (acetyl groups) formed in the β -oxidation of the fatty acids. The coenzyme combines also with many other organic acids, fatty and otherwise, e.g., propionic, butyric, β -hydroxybutyric, acetoacetic, crotonic, succinic, etc. Thus

it may be described as an acyl $\left(\text{R}-\overset{\text{O}}{\parallel}{\text{C}} \right)$ acceptor.

The sulfur linkage whereby the acyl groups are united to coenzyme A is a new type of high-energy bond. Acetyl-SCoA may be regarded as analogous in some respects to a mixed acid anhydride and in others to an ester. In spite of the high energy of the thiol-ester bond, these compounds are relatively stable in neutral aqueous solutions at room temperature, a property which fits them for utilization in cellular metabolism. The bond is split and the energy is released in tissues by the activity of specific enzymes. In tissues (e.g., liver, heart, yeast) these fatty acid oxidizing enzymes are bound to the mitochondria of the cells. Ways have been devised to prepare them in soluble form and to separate those involved at each step. The *in vitro* studies were thus made possible.

FIG. 49.3 Helical scheme to represent the oxidative degradation and synthesis of fatty acids (Bruno Rosenfeld and C. C. Lucas. With acknowledgement of Lynen's suggestion.)

Each complete cycle involves four reactions. In oxidative degradation these are (1) dehydrogenation, (2) hydration, (3) a second dehydrogenation, and (4) thiolytic degradation, i.e., elimination of 2 carbon atoms as acetyl coenzyme A following addition of coenzyme A. The synthetic reactions occur in the reverse order and in the opposite direction: (1) addition of an active 2 carbon unit (acetyl coenzyme A), (2) hydrogenation, (3) dehydration, and (4) a second hydrogenation. Before the oxidation or synthesis can take place, the fatty acid must be activated (Reaction A) by condensation with coenzyme A. These steps are explained more fully on following pages.

OXIDATIVE DEGRADATION (after Mahler)

Reaction A Activation Reaction

e.g.

Reaction 1 Dehydrogenation

Enzymatic removal of two hydrogen atoms gives $\alpha\beta$ unsaturated "activated fatty acid"

Reaction 2 Hydration

Addition of water at the double bond gives β hydroxy "activated fatty acid"

* FAD represents an enzyme derived from flavin adenine dinucleotide

Reaction 3 Second Dehydrogenation

Removal of two hydrogen atoms from the β carbon atom gives the β keto activated fatty acid[†]

*Reaction 4 Thiolytic Degradation*

Coenzyme A adds on at the β keto position from this unstable compound an active two carbon fragment (acetyl coenzyme A) is eliminated from the activated end of the fatty acid to give a new activated fatty acid with 2 less carbon atoms. The molecule of acetyl SCoA thus formed is available to add on at Reaction 4 in the next cycle of the degradation process[‡]

then rearrangement occurs with splitting as shown

THE IS

Reaction A Activation Reaction

e.g.

*Step 1 (Reverse of Reaction 4) This condensation*

The activated fatty acid condenses with an active two carbon fragment (= active acetate = acetyl coenzyme A) to give the activated β keto acid with 2 more carbon atoms. One molecule of coenzyme A is released to effect this condensation.

*Step 2 (Reverse of Reaction 3) Hydrogenation*

Addition of 2 hydrogen atoms to the β keto activated acid gives the β hydroxy activated acid

[†] DPN represents diphosphopyridine dinucleotide

[‡] The coenzyme A does not add on as shown in the simplified scheme above. Most likely it first adds on to the carbonyl group

Step 3 (Reverse of Reaction 2) DehydrationRemoval of water gives the $\alpha\beta$ unsaturated activated acid**Step 4 (Reverse of Reaction 1) Second Hydrogenation**

Addition of 2 hydrogen atoms to the unsaturated acid finally gives an activated (saturated) fatty acid with 2 more carbon atoms than the acid which entered the cycle

Energy is required for the first step in the metabolism of the fatty acids, i.e., for the formation of the "activated fatty acid" (CoA Thio-ester, Reaction A). This energy is provided by a co-mitant oxidation of a member of the citric acid cycle. This is the so-called "sparking reaction" that initiates the oxidation of the fatty acid. Once the degradation has been "primed" it proceeds without further addition of energy, two carbon atoms being spit off (as acetyl-S-CoA) until the acid has been entirely broken down to 2-carbon units. The "active acetate" so formed either enters the citric acid cycle, to be burned to CO_2 and water, or is used in biosynthetic processes. Fatty acid catabolism produces energy, their anabolism requires energy. In both cases the free energy is provided by "active acetate", or more specifically by the bond energy in the acetyl-S-CoA linkage.

From a comparison of the turnover number of the individual enzymes, it has been concluded that the β ketoacyl derivatives, e.g., acetoacetyl-S-CoA, may be expected to occur at a much higher steady state concentration than any other intermediate in the whole enzymatic sequence. Liver, in contrast to kidney and heart, contains a very active deacylase enzyme catalyzing the reaction²

acetoacetyl-S-CoA $\rightleftharpoons$ acetoacetate + HS-CoA
and a very weak transfer enzyme catalyzing the

reaction

Acetoacetate + succinyl-S-CoA $\rightleftharpoons$

acetoacetyl-S-CoA + succinate

Thus we are able to explain why liver tissue gives rise to the formation of acetoacetate as distinct from kidney, heart and muscle tissue (relatively good sources of the transfer enzyme) by which fatty acids are conducted to the catabolic cycle and thus via oxaloacetate and citrate to CO_2 and H_2O .

If processes similar to these enzymatic reactions occur in the living organism, active acetate would become available to the cells of the liver and other tissues by oxidations of fatty acids, amino acids and carbohydrates. The active acetate would be utilized by several alternative routes (fig. 49.4). The relative rates of utilization through these various pathways must be determined by the inherent characteristics of the cells, and by chemical, hormonal and nervous influences.

Ketosis

As mentioned above certain experimental and clinical conditions are characterized by the accumulation of ketone bodies in the blood. Ketosis, in experimental animals, can be attributed largely to increased rate of production rather than diminished utilization of ketones. The ketosis is apparently due to the increased proportion of fatty acids being used by the organism. These are presented to the liver in excessive amounts, causing an accumulation of fat. In both experimental and clinical experience it has been found that when ketosis occurs there is a relative lack of carbohydrate available for use by the liver cells. The administration of carbohydrate produces an antiketogenic effect as do the intermediates of

² An alternative mode of formation of acetoacetate by the liver has been shown by Lynen and his colleagues. Condensation of acetyl-S-CoA with acetoacetyl-S-CoA yields CoASH and β hydroxy β methylglutaryl-S-CoA. Cleavage of this compound yields acetyl-S-CoA and free acetoacetate. The β hydroxy β methylglutaryl-S-CoA is also utilized in the formation of cholesterol. It is interesting that acetoacetate and cholesterol which are both produced in increased amounts by the liver of the diabetic organism, should have this common precursor.

FIG. 49.4 Outline of the routes of formation and of utilization of active acetate (acetyl coenzyme A) by liver cells

carbohydrate oxidation *in vitro*. Leninger has shown that addition of oxalacetate or succinate to the medium in which liver slices were oxidizing fatty acids decreased the rate of production of acetoacetate and increased that of citrate and other components of the Krebs' cycle. Acetoacetate is an alternative but not an obligatory product of the oxidation of fatty acids by the liver.

There are indications that kidney and other organs may produce acetoacetate, but only in small amounts (Medes, Floyd, and Weinhouse). The enzymatic constitution of kidney and heart provides an explanation for the difference between the ketogenic activity of these tissues and that of liver. The ketone bodies are rapidly utilized by extrahepatic tissues. The rate of utilization is not influenced by the amount of carbohydrate or of insulin present.

Drury and Wick (1953) using C¹⁴ glucose, have studied the relative rates of oxidation of glucose and β -hydroxybutyrate and of glucose and acetate. Insulin increases the oxidation of glucose but not that of the other compounds in exsanguinated rabbits. When insulin activity is maximal the administration of hydroxybutyrate or acetate causes a sharp decline in glucose oxidation but has no effect on the rate of its disappearance from the blood. These findings indicate that the cells burn acetate preferentially under these conditions and glucose is displaced from the oxidative sites.

Effects of Ketosis

Ketone bodies in small or moderate amounts provide a source of energy for tissues when the supply of carbohydrate is restricted or its utiliza-

tion is impaired. Acetoacetic and β -hydroxybutyric acids formed in liver cells are nonvolatile and moderately strong acids which must be neutralized by base as soon as they enter the blood stream. In severe ketosis, i.e., when the rate of formation greatly exceeds that of utilization, there may be a dangerous disturbance in acid-base equilibrium. These acids are excreted by the kidney and tend to carry base out of the body with them. The kidney attempts to minimize this loss of base by holding it back and thus produces a highly acid urine. A further process to conserve fixed base (K, Na, etc.) is by increasing the formation of ammonia in the kidney. The urine volume is usually high in ketosis. The excretion of these organic acids represents a loss of potential energy. Thus ketosis results in a loss of base, water, nitrogen and energy and leads to acidosis and dehydration.

The Metabolism of Adipose Tissue

Metabolic changes in the adipose tissue itself had, until recently, only infrequently been studied. Wertheimer and his colleagues have reported that the adipose tissues of well fed or fasted rats contain little or no glycogen. If, however, after fasting the animals are fed a diet rich in sugars glycogen appears in the adipose tissue. It is not yet established that the glycogen is a step on the road to fat synthesis. The so-called "brown fat" present in the rat and some other mammals is said to be more active in glycogen synthesis than white adipose tissue. Mirsky found that adipose tissue from certain mammals can both synthesize glycogen from glucose-1-

phosphate and promote the reverse reaction. The enzyme amylase is also present in adipose tissue. In adipose tissue *in vivo*, insulin promotes the formation of glycogen (Wertheimer and Shapiro, 1948), of fat (Chernick and Chaikoff, 1951, Wick, Drury et al., 1951) and the uptake and oxidation of dextrose (Winegrad and Renold, 1955).

Abnormalities of Fat Metabolism

The problems of starvation and obesity (ch 50), abnormalities of fat metabolism associated with endocrine disturbances (p 865), and the conditions in which there is an excessive deposition of fat in the liver are discussed elsewhere. A profound disturbance of phospholipid metabolism occurs in Niemann Pick's disease, a condition which is seen in infancy and in early childhood and is invariably fatal. The spleen and liver are enormously enlarged and contain very large amounts of phospholipids. The cholesterol content of these tissues is also increased but not to nearly the same degree. The blood phospholipid is also definitely raised. Histologically there is a great hypertrophy of the reticuloendothelial system. Very little is known about this disease but it has been suggested that there is some interference with the activity of the enzymes which are responsible for various stages of fat metabolism in the tissues.

In the rare clinical condition involving a disorder of lipid metabolism, Tay Sachs disease, there is an abnormally high proportion of cerebroside in the brain. Liver, normally, contains little or no cerebroside but in Gaucher's disease the cerebroside content of both liver and spleen is high. The physiological significance of the cerebroside is not known.

Retention hyperlipemia appears to be caused by the sluggish removal of fat from the blood stream. The mechanism underlying the disorder is not clear. Its clinical designation is "idiopathic hyperlipemia." The neutral fat may be increased from 20 to 100 times the normal concentration, and total cholesterol may be about double the normal value. It sometimes occurs as an inherited disorder. This retention type of hyperlipemia does not respond to insulin but does to a diet low in fat. The diabetic (transportation) type of lipemia does respond to insulin. The effect of insulin on the experimental lipemia following hemorrhage or that produced by protamine and decreased by heparin has not been adequately studied.

In 1893 Hand described a condition in children which was characterized at autopsy by yellow

nodules in the cranial bones and in other situations. Since it will become increasingly difficult to add more names when further cases are described it may be expedient to call the syndrome Hand's disease (Hand Schuller Christiaao, etc.) While these nodules show a predilection for the tissues of the head, i.e., cranial bones, orbit, tuber cinereum, they have been noted in most portions of the skeleton (Chester and Kugel). The signs and symptoms depend on the areas affected. Diabetes insipidus and exophthalmos are common disturbances, i.e., due to lesions near the pituitary gland and in the orbit. Rowland believes that the condition is due to an osseous form of xanthomatosis. These xanthomatous nodules contain large amounts of cholesterol and cholesterol esters, which together may account for a large proportion of their total fat. There is no alteration in the fat content of the unaffected parts of the body. The etiology of the disease is unknown. The generalized xanthomatosis which is sometimes seen in diabetes mellitus, may disappear when the blood fats are reduced to normal values by appropriate treatment of the diabetic condition.

A great deal of attention is being paid at the present time to the metabolism of fat in tumor tissue but no review will be attempted here. The important part played by cholesterol in the formation of gall stones has been dealt with (p 651).

Familial hypercholesterolemia is an inherited condition in which there is an abnormally high total serum cholesterol with a normal proportion of free and bound cholesterol. There is frequently an increase in plasma phospholipids. The disease is inherited as an incomplete dominant. The increase in blood cholesterol is not due to dietary intake but to increased production or diminished utilization within the body. There are many reports which indicate that the condition is characterized by a raised incidence of vascular disease.

ATHEROSCLEROSIS

There is now considerable statistical evidence that prolonged hypercholesterolemia and atherosclerosis are associated in some way. The characteristic, but by no means the earliest, lesion of an atherosclerotic artery is the cholesterol rich plaque (containing up to 70 per cent of cholesterol). It is probable that this cholesterol comes from the blood, but this is not proven. The cholesterol in the blood is not present in simple solution, but is carried as lipoprotein complexes, the so-called "giant molecules" (S₁ 10-20) of Gofman. While the total serum cholesterol values, or the concentration of the "giant" lipoprotein molecules afford a significant differentiation between groups of men who are clinically healthy

and groups of men who have (or may develop) coronary heart disease, the forecasting efficiency of the values for individual diagnosis or prognosis is very low. Ancel Keys and others have shown convincingly that the serum cholesterol level is not readily altered even by large changes in the cholesterol content of the diet. There is, however, a relationship between total serum cholesterol and the total fat content of the diet. Excessive intake of fat or of calories in any form rather than of cholesterol or that indefinite process called "ageing *per se*" may be concerned in the causation of degenerative vascular disease.

Serum cholesterol levels can be reduced, in man, through control of the diet in three ways (a) by reducing excess calorie intake, (b) by reducing the intake of animal fats (Keys), and (c) by increasing the intake of vegetable oils (Kinsell, Sinclair, and others). These oils are rich in unsaturated fatty acids. Beveridge and others have shown that certain steroid fractions from these oils, containing for example sitosterol, also reduce cholesterol levels in man. The relative efficiencies of the unsaturated fatty acids, the mechanism of action of which is unknown, and of the steroids, which decrease the absorption of cholesterol and may have other effects, is still unsettled.

Fat metabolism is undoubtedly concerned in the production of atherosclerosis but in the search for the initial causative factor protein which is associated with all fat fractions in blood may be equally important. Abnormalities in the metabolism of the cells of the vessel wall or in their permeability are also obvious possibilities. All of these factors and their integration are being actively investigated.

Diets rich in fat given to dogs in which kidney damage had been produced may result in cardiovascular lesions (McCormick and Holman, 1949). In rats aortic sclerosis may be produced by diets rich in fat when kidneys have been injured by drugs (Lehr and Churg, 1952). Rations extremely low in choline and its precursors may produce severe kidney and cardiovascular lesions in young rats fed diets rich in certain synthetic or natural fats (Stetten, Wilgram and Hartroft). There is a possibility that deficiency of Vitamin E may be important in the production of some of these experimental lesions. The bearing of these experimental findings on human atherosclerosis remains unsettled. The arguments implicating dietary cholesterol as a causative factor in human atherosclerosis have been well presented by Katz,

Stamler and Pick (1958) and discussed by Keys (1956).

THE METABOLISM IN STARVATION, SEMISTARVATION AND OBESITY

Starvation

An animal deprived of food derives energy first from the combustion of its own carbohydrate stores (glycogen). Next the fat reserves mainly are drawn upon and finally after these have been exhausted tissue protein is broken down, the fatty acid part of the molecule is burned while the nitrogen is excreted in the urine mainly as urea. The metabolism of several professional fasters has been investigated. Among the most famous of these are Succi whose metabolism was studied by Luciani and others, Cotte investigated by Munk and Zuntz, Levanzi by Benedict and Beauté by Cathcart. One of the longest of such fasts upon record is that of Merlatte of Paris which lasted for 50 days. A dog has been starved for 117 days. By the end of this time it had lost 63 per cent of its weight but was fairly active. Succi on the 40th day of his fast had lost about 25 per cent of his weight. The length of time a man could survive would depend largely upon his physical condition (fat stores etc.) at the commencement of the fast but it would probably not exceed 9 or 10 weeks in any event. Terence MacSwiney, Mayor of Cork after his arrest during the Irish troubles in 1920 went upon a hunger strike which lasted 74 days, it was terminated by his death in coma.

During starvation the loss of weight is not distributed evenly throughout the body, some organs and tissues losing a much greater proportion of their weight than others (fig. 50 1). During the first few days the subcutaneous tissues and other fat depots bear the brunt of the effect of the fast. Large quantities of extracellular water are also lost at this time. Later, dissolution of muscular tissue occurs as indicated by the N/S ratio of the urine (about 14/1). The water lost during this period is derived mainly from intracellular sources. Later dissolution of protoplasmic structure occurs. The central nervous system, even in prolonged starvation, loses only about 5 per cent

of its weight (as estimated from normal standards) whereas the muscles lose about 35 per cent or more. The weight losses of muscular tissue, liver, gastrointestinal tract and spleen run approximately parallel with that of the body as a whole. The muscle fibers are reduced in size and many are destroyed. Contrary to general belief, the percentile weight loss of the heart is only a little less than that of the skeletal muscles. The kidney loses only 20 per cent or less of its weight, and the gonads, adrenals and thyroid only from 2 to 8 per cent. Some of the small weight losses reported e.g. of the central nervous system may be due to the replacement of solid substance by fluid (see fig. 50 1).¹

NITROGEN EXCRETION. *The total output of nitrogen in the urine falls for the first day or two of the fast when the body is subsisting chiefly upon its carbohydrate supplies. The length of this period varies of course with the size of the carbohydrate stores at the commencement of the fast. A steady rise in nitrogen excretion follows and usually reaches a maximum about the third or fourth day but from then on it shows a progressive decline and may reach a value of less than 6 grams per day. The nitrogen excreted during the earlier part of the fast is apparently derived largely from the mobilization of reserve protein (p. 779). The urea nitrogen excretion at first rises then falls its percentage of the total nitrogen excretion also diminishes. The ammonia excretion rises. The creatinine output shows a steady decline but this is largely compensated for by the appearance of creatine (p. 781) so that the creatinine + creatine excretion remains fairly constant. As a result of some experiments of Voit many years ago it is very often stated that a pro-*

¹ There does not appear to be any definite level of emaciation that is of weight loss of the body as a whole as a percentage of the normal body weight at which death is inevitable. Recoveries with judicious feeding and transfusions of plasma have been recorded after losses of body weight up to 50 or even 60 per cent of the normal weight.

nounced rise in nitrogen excretion occurs shortly before death from starvation, which is attributed to an accelerated breakdown of tissue protein. But this so-called *premortal rise* in nitrogen excretion is a very inconstant phenomenon, and of very doubtful significance, for death very often occurs in starved animals in its absence. The total quantity of body protein catabolized may be determined by calculation from the total nitrogen excretion on the assumption that tissue protein contains 16 per cent of nitrogen and that practically all the nitrogen derived from the breakdown of body protein appears in the urine. That is, each gram of urinary nitrogen represents the deamination of 6.25 grams of protein, so the quantity of protein broken down is calculated by multiplying the figure for the nitrogen excretion by 6.25. On this basis the average daily loss of body protein of an average sized man during starvation is about 50 grams or about 0.4 per cent of the total amount in his body. For a few days following the termination of a prolonged fast the nitrogen excretion shows a pronounced fall—nitrogen is retained for the reconstruction of tissue protein.²

MINERAL METABOLISM The urinary excretion of phosphorus and sulfur shows an initial rise, and then a gradual decline, thus showing a curve which roughly parallels that of the total nitrogen excretion. Toward the latter part of the fast the N:P and N:S ratios are around 5:3:1 and 14:1 respectively. The excretion of P in relation to N is greater than one would expect were it all derived from the soft tissues, the same is true for Ca, which indicates that the skeleton contributes to the quantities of these minerals in the urine. The calcium excretion above that which the soft tissues can account for is much greater (10 times) than that of phosphorus, from which it is deduced that calcium carbonate rather than calcium phosphate is liberated from the bones. The ratio of N to S is a little higher than that of the bulk of the soft tissues, which suggests that the sulfur-con-

taining amino-acids are conserved or excreted in only minimal amounts.

The urinary excretion of chloride, sodium, potassium and magnesium is reduced from the beginning of the fast. This is to be expected since the intake of minerals is restricted to that provided by the water which is drunk. The concentrations of these minerals in the blood shows little change, but the sodium bicarbonate is reduced when ketosis supervenes.

KETOSIS The increase in urinary ammonia (p 563) is a result of the production of excessive amounts of acid metabolites, especially β -hydroxybutyric and acetoacetic acids. The latter are formed as a result of the carbohydrate deprivation and the consequent excess combustion of fat. Succin toward the end of his fast excreted, daily, from 7 to 13 grams of acetone bodies. In a fasting female subject reported by Folin and Denis the acidosis was extreme, some 18 grams of β -hydroxybutyric acid being excreted upon the fourth day of the fast. Fasting ketosis is much more pronounced in women than in men. This sex difference is not related to the usually greater adipose tissue of females, for a very lean woman excretes larger amounts of ketone bodies than

² The loss of protein varies widely among different organs and tissues. Addis and his colleagues found that in rats fasted for 7 days the several tissues contributed to the total protein loss in the following proportions: muscles and skin 62 per cent, liver 16 per cent, alimentary tract, spleen and pancreas 14 per cent, blood 6 per cent, kidneys 1 per cent, heart 0.5 per cent and the remaining organs 0.5 per cent. Or put in percentages of the protein contents of individual normal organs, the brain loses about 4 per cent of its protein, the muscles skin and bones about 8 per cent, the heart 18 per cent, the kidneys 20 per cent, the gastrointestinal tract 28 per cent, and the liver 40 per cent.

TABLE 50 1

Subject L Height, 170.7 cm Only distilled water was taken during this fast
(Abridged after Benedict)

	Day of Fasting			
	1st	11th	21st	31st

* Previous day = 1025

† Previous day = 661

does a man of overweight. Nor, generally speaking, is ketosis (p. 875) during fasting greater in an overweight person than in one of normal weight.

CARBOHYDRATE METABOLISM Even in the later stages of the fast glycogen is found in the liver, and the blood sugar is little depressed. Sugar is apparently synthesized from protein. In the earlier stages there may be a temporary hypoglycemia.

The basal metabolic rate, the body temperature, pulse rate and the blood pressure all show a progressive fall throughout the fasting period. See table 50.1.

Semistarvation, Undernutrition¹

If a diet possessing a caloric value considerably below the energy requirements of the individual is

¹ Comprehensive reports of studies on undernutrition have been published within recent years,

persisted in, as during famine, war blockade, extreme poverty, disease (e.g., stricture of the esophagus or pylorus) or improper feeding of infants, serious nutritional effects result. It must also be remembered that just as an intake of calories over the output will cause obesity so an energy expenditure in excess of the caloric intake will result in a loss of weight. Consequently a man who performs heavy work upon a diet which is adequate only for a sedentary worker will suffer from undernutrition. The economic or other conditions which lead to extreme reductions in the total caloric value of the diet obviously must also cause, as a rule, a reduction in the intake of vitamins, essential minerals and first class proteins. As a consequence, the incidence of specific de-

e.g., *Malnutrition and Starvation in the Western Netherlands*, Netherlands Government 1944-1945, and the two volume monograph by Ancel Keys and his associates, *The Biology of Human Starvation*, Univ. of Minnesota Press, 1950.

iciency disorders, e.g., stunting, xerophthalmia, rickets, osteomalacia, scurvy, etc., is also high when the caloric value of the diet is markedly lowered. These special aspects of undernutrition are dealt with in other chapters.

The most pronounced instances of undernutrition and emaciation are met with most commonly in anorexia nervosa, pituitary cachexia, the later stages of malignant disease, and in prolonged and severe infections.

The following is a summary of the main effects of severe undernutrition.

(1) Reduction in body weight—emaciation. The body attempts to make up the caloric deficiency by burning its own tissues. The loss of weight is due chiefly to loss of fat but also in severe instances to a loss of protein. The nitrogen balance is negative. In children growth is retarded. The positive nitrogen balance is smaller than normal, it may even be negative. In the less severe grades of undernutrition in children the growth impulse continues to cause an increase in height of the skeleton but the muscles and the breadth of the body are poorly developed.

(2) Reduction in basal metabolic rate. The total basal metabolism, i.e., the heat production as related to surface area, is as one would expect owing to the reduction in the mass of active tissue, diminished in semistarvation, but the metabolism per unit (kilogram) of body weight is reduced as well. The total metabolism is diminished by nearly 40 per cent, and the heat production per unit of body weight by nearly 20 per cent. The cause of the reduction per kilogram has not been fully explained, but it can be accounted for in part by the decline in cardiac work (by about 50 per cent), the lowered tone of the skeletal muscles and the subnormal body temperature, which would tend to slow the rate of all chemical reactions in the tissues. The subject is abnormally sensitive to cold, due to the fact that the skin vessels are constricted in an attempt to reduce the dissipation of heat through radiation and convection (ch. 52). The skin temperature upon which our thermal sensations depend is therefore lowered. The specific dynamic response to food may be increased.

(3) The subject is readily fatigued and shows a lack of a zest for physical exertion. Work is performed with the same expenditure of energy as normally, so though energy is economized in the carrying on of the vital processes as shown by the reduced B.M.R. and cold skin, no economy is effected in the execution of muscular work.

(4) The loss of internal fat which normally serves to support the organs—stomach, kidneys, uterus, etc.—against the effect of gravity, results in their displacement (visceroptosis). The lost body fat is partially replaced by water.

(5) Susceptibility to infections. "Fever and plague dog the footsteps of famine." This is an old adage, but with the exception of tuberculosis (in which resistance is definitely lowered) and certain specific effects of vitamin deficiencies there is really little evidence that undernutrition increases the susceptibility to infection.

It is natural to suppose that the production of γ globulin which is so closely associated with immune bodies would be depressed by undernutrition, especially if involving severe protein deficiency. The investigations of Cannon and his colleagues have gone far to show that this, indeed, does occur. In the Minnesota experiment the concentration of γ globulin in the plasma of the subjects was moderately reduced but this was not accompanied by any apparent increase in susceptibility to infections, the semistarved subjects of the experiment had slightly fewer colds over a comparable period than the controls. On the other hand, there is a considerable body of evidence to support the conception that undernutrition actually reduces the susceptibility to certain infections. It has been reported for example, by McCay that underfed rats were surprisingly free from the usual laboratory infections, others have concluded from their experiments and observations of naturally occurring disease that well nourished animals are more susceptible to infection than are undernourished ones. When a severe infection is established, however, the undernourished animal is at a disadvantage and is more likely to succumb.

It is recognized that some noninfectious conditions such as hypertension, neoplastic diseases, and diabetes are benefited by undernutrition. In animals, very severe undernutrition definitely inhibits tumor growth, but whether less severe caloric deficiency has such an effect in man is uncertain. The evidence for the incidence of hypertension being reduced is mainly statistical.

(6) Edema not uncommonly (see ch. 4).

(7) Psychological changes. Mental apathy, moral deterioration, depression, tendency toward introversion and other changes in personality, and lowered intellectual capacity are common effects. "The brain is in some sort of custody of the stomach and relief of malnutrition gives relief of mental dullness" (Roger Bacon). An unresponsive, complaining and uncooperative attitude in semi-starved persons of Western Europe receiving relief after World War II was very frequently observed. Drummond remarked upon this and stated that it disappeared completely when the food intake was raised above 1500 to 1800 Calories per day.

Obesity

Some forms of obesity are quite definitely due to a hypothalamic lesion or to a disorder of an endocrine organ, pituitary (ch. 36), adrenal cor-

tex (ch 58), thyroid or gonads, they will not concern us here. Such origins of obesity are rare and associated with other manifestations of hypothalamic or endocrine dysfunction. Ordinary obesity—the so-called *simple obesity*—is very common and afflicts persons showing no other abnormality.

In many cases of simple obesity there appears to be a genetic element, a conclusion borne out by statistical studies. In surveys of a large number of obese persons, one or both parents were obese, whereas the incidence of obesity in persons both of whose parents are of normal weight is only about 10 per cent. The hereditary obesity of a strain of yellow mice is well known. A Mendelian dominant gene carries the characters for yellowness and obesity, nonyellow mice of the same litter are not obese. The basal metabolic rate of the obese animals is said to be reduced and the body temperature subnormal, an hereditary hypothalamic origin of the obesity has been suggested. Another form of obesity in mice which is accompanied by hyperglycemia has been described. The food consumption of these animals is much greater than nonobese controls. An inherent tendency to fatness seems to be illustrated by the common observation that of two persons who appear to eat about the same amount of food, and exercise to the same extent, one may remain thin or of normal weight while the other grows fat. Furthermore, the "spare" person may have a large appetite and remain underweight while the obese may diet himself and still be fat. In order to explain such cases it has been suggested that they are due to an inherited endocrine characteristic. Yet if this were so, some evidence of it should be forthcoming from metabolic studies. On the contrary, the basal metabolic rate per unit of body surface of the subject of the common or simple type of obesity is within normal limits—that is, his energy expenditure at rest is not less than the normal. Nor is work performed more economically than usual by the obese, the reverse is probably true on account of the greater amount of inert adipose tissue.⁴ His greater storage of energy cannot therefore be explained upon this basis. It has been claimed that the specific dynamic action of food (p 787) is reduced in cases of simple obesity, and it has

been suggested that such a reduction, by conserving energy, may play a causative role. The smaller specific dynamic action which has been observed could, however, account for no more than a 3 per cent reduction in the total daily metabolism, and is quite inadequate as an explanation. An almost inappreciable increase in the caloric intake or a slightly reduced bodily activity would produce a rough greater effect upon the energy exchange. For example, 10 grams of extra fat daily in the diet (e.g., a teaspoonful of butter) yielding 90 Calories, or 23 grams of sugar (about 2 teaspoonsful) would increase the caloric intake of a person of ordinary activity by 3 per cent or so, while a slow walk of a mile would increase the metabolism to a corresponding extent.

Other possibilities have been explored, namely, that the obese person may absorb his food more efficiently, that there exists an inborn peculiarity of the tissue cells, whereby they accumulate fat in excess, or that they release the fat less freely into the circulation for use as fuel. None of these factors has been found to play a significant part.

It is probable that a hereditary or constitutional factor, in the great majority of instances of ordinary obesity, is more apparent than real, and that a careful investigation of these cases with respect to food intake and muscular activity would reveal a positive energy balance. It is therefore likely that when obesity shows a familial tendency, the inclination of members of the same family to follow similar habits with respect to diet and exercise, rather than that some inherited endocrine peculiarity, is responsible. Or again, traits which lead to obesity—overindulgence of the appetite, or a distaste for muscular exertion—may be inherited. Also, the obese person often, though not a "big eater," indulges in highly concentrated food.

The possibility of a hypothalamic or an endocrine element in the development of obesity is very difficult to prove or disprove. From what is known of the role played by the hypothalamus and the endocrines in the control of food intake and in fat metabolism, it is tempting to look in this direction for an explanation of obesity. Obesity might conceivably be due to some hypothalamic or endocrine idiosyncrasy. There is experimental evidence that the hypothalamus exerts an influence upon the hunger sensation (ch 43), but endocrine effects are more often exerted upon the distribution of fat rather than upon the total body weight. There is no substantial evidence that obesity is due to any other cause than overindulgence

⁴ Newburgh states that obese persons as compared with the normal produce more heat in the basal state and expend more energy for the performance of a given amount of work. Their total metabolism measured over 24 hour periods is also considerably greater than the normal.

in food in relation to the body's energy requirements

It must be remembered that the law of the conservation of energy holds for the animal body (ch 44) Energy taken in the food is either expended or stored as fat and carbohydrate, and to some extent as protein Whatever the primary cause may be, whether hypothalamic or endocrine disease, or whether it is due simply to over-eating, obesity is the result of an energy intake in excess of the energy output Theoretically, an energy balance could be struck by increasing the exercise of an obese subject But increasing the energy output by exercise is much less effective than dietary restriction, physical exertion increases the appetite and the subject finds it difficult to resist satisfying it

The basic problem in obesity is the cause of the increased appetite Many psychological aspects of this question are obvious but they will not be discussed here Endocrine factors have been considered elsewhere Mayer and his colleagues have suggested a general distinction between "regulatory" obesities where the primary impairment is one of the central mechanisms regulating food intake (psychological disturbances, hypothalamic injury and "metabolic" obesities where the primary lesion leading to overeating is in tissues other than the regulating centers, i.e., pancreatic or sex gland disturbances) The prolonged effects of one type of lesion may induce the other

The "cost" of OBESITY (See table 502) (1) Owing to the increased weight, muscular exertion places a greater load upon the heart and circulatory system The incidence of arterial hypertension is relatively high in persons who are overweight (2) Dissipation of heat by conduction and radiation (ch 52) is reduced through the heat-insulating effect of the mantle of subcutaneous fat Sweating is in consequence more profuse (3) Diabetes is more common in the obese than in persons of normal weight Joslin refers to diabetes as "the fat man's folly," and to obesity as "the open door to diabetes" Reducing the weight of an obese diabetic has been found to diminish the sugar excretion by as much as 75 per cent (4) Persons who are grossly obese are said to be less resistant to infections and poorer surgical risks than those of normal weight (5) The incidence of gallstones is relatively high in the obese according to Baumann, 88 per cent of persons with gallstones are overweight (6) *Life expectancy* Insurance statistics show that overweight after the age of 35 years is associated with a death rate much higher than that of lean persons or of those

TABLE 502*

* After Newburgh

FIG 502 Showing the delay in the loss of weight on a reducing diet owing to the retention of the water (After Newburgh modified) This subject lost as much weight in 6 days as it was predicted would be lost in about three weeks as a result of the destruction of body tissue and without water retention

of normal weight, a fact which has been pithily expressed in the phrase, 'the longer the belt the shorter the life'

GENERAL PRINCIPLES IN THE TREATMENT OF OBESITY The basis of treatment should be as already indicated, (a) reduction in the caloric in

take and (b) increase in the energy expenditure through moderate exercise. The dietary restrictions should not be extreme and should be made gradually. The extent to which the caloric intake should be reduced will depend upon the degree of obesity and the amount of exercise prescribed, but it should never be pushed to the point where the protein of the subject's tissues is drawn upon for energy purposes, nitrogen equilibrium should be maintained. Above all things a properly balanced diet should be devised and an adequate supply of vitamins and minerals provided. When the obesity is pronounced (body weight 25 per cent or more above normal), weight reduction is brought about by placing the subject upon a diet possessing a caloric value 40 or even 60 per cent below his energy requirement, he is thus forced to consume his own fat. The caloric value of human adipose tissue is about 3500 Calories per pound.* The total requirement of the average obese subject is around 2500 Calories per day. A reduction in the energy intake by 40 per cent of the requirement, that is, to 1500 Calories, will therefore entail a weight loss of nearly a third of a pound per day. The subject is kept upon the restricted diet until the desired weight has been reached, his caloric intake is then adjusted to his requirement (see ch. 55).

The failure of an overweight person to lose weight after having been placed upon a "reducing" diet has been a mystifying observation which appeared to refute the conclusion that obesity is due simply to a balance of energy intake over energy output. But the original weight is maintained for only two or three weeks, and is due to the retention of water which replaces the tissue broken down for energy purposes. At the end of this period water excretion increases above the normal and the weight falls rapidly (Fig. 50.2).

In planning a weight reducing diet, it is toward the restriction of the more concentrated forms of food that attention is particularly directed. It will be recalled that the caloric value of fat is more than twice that of carbohydrate. Also fatty foods, since they contain little or no water, are more concentrated than starchy materials. Lard, dripping, olive oil, etc., are 100 per cent fat, whereas the protein and carbohydrate of white bread amount together to only about 60 per cent of its fresh weight. Ordinary fats and oils should therefore be restricted. Emphasis should again be placed on the provision of essential food factors commonly contained in foods which are denied to the obese subject. Sugar in the form of sweetening for beverages, in jams, honey or chocolate is a highly concentrated food. By curtailing its consumption a large reduction in

the caloric value of the diet can be effected without the disadvantages attending the reduction of some of the other foods. Bulky foods, e.g., green vegetables and salads of low caloric value but satisfying to the appetite may be substituted. Undue restriction of the water intake is sometimes practiced but this measure appears to be of no benefit and may be a detriment to health. Alcohol has a high caloric value and is therefore, except in minimal amounts, excluded from the diet. *Thyroid extract* is sometimes employed to raise the metabolic rate and so reduce the obesity. The hormone is clearly indicated as a means of raising a low metabolic rate to normal, otherwise its use is not to be advocated except in exceptional cases and only when the subject's basal metabolic rate can be followed by frequent determinations. *Dinitrophenol* is another agent which raises the metabolic rate and has been employed in the treatment of obesity. It is a dangerous drug unless given under the strictest supervision. Cataract has been reported following its use, liver injury may also result.

While the above well established facts should continue to be the basis of the treatment of obesity some new ones are struggling for acceptance. The work of Kekwick and his colleagues indicates that some aspects of metabolism in the obese differ from that of those who are not overweight. Alteration in the composition as distinct from the total caloric value of a diet may induce changes in the energy output of the obese individual. In some obese cases the rate of weight loss was greatest when fat provided 90 per cent and least when carbohydrate supplied 90 per cent of the caloric value. A striking resistance to ketosis was found in the obese. The treatment of obesity is so a 'dynamic state'.

METABOLISM IN MUSCULAR ACTIVITY

The Structure of Skeletal Muscle

A typical skeletal muscle such as the gastrocnemius or biceps is composed of large numbers of elongated cells, usually referred to as muscle fibers. The fibers are bound together into bundles or fasciculi of different sizes which are grouped again into larger masses to form the whole muscle. A connective tissue sheath of reticulated fibers, called the *perimysium*, encloses each fasciculus and separates it from its neighbors. The connective tissue sheath enveloping the whole muscle is called the *epimysium*. The muscle fibers of different muscles range in length from 1 mm, in a minute muscle such as the stapedius, to about 4 cm in a long muscle such as the sartorius. The cells traverse the entire length of the shorter fasciculi but in the longer muscles they are joined together by tapering ends the tips of which are applied side to side, to form elongated chains. This is the commonest arrangement, but in some muscles designed for maximum contractile force with a minimum of shortening the fibers are disposed in parallel in a series or they may run diagonally to a central tendon. The muscle fibers also vary widely in diameter, which measures about 10 microns in the small muscles to 100 microns in the larger.

The body of the cell contains a limited and variable amount of material which corresponds to the cytoplasm of other cells, and is called the *sarcomplasm*. The latter surrounds large numbers of fine threads packed closely together and running from end to end of the cell. These are the *myofibrils*, they have a diameter of from 1 to 2 μ . Under the high power of the microscope they appear as a faint pattern of parallel lines. At the insertion of the muscle they become continuous with the fibrils in the tendon. This longitudinal striation is also seen in smooth muscle. But the most striking and characteristic microscopical appearance of skeletal muscle fibers is their *cross striation* or *stripes*. These are alternating light and dark bands which run across the width of the fiber. When the myofibrils are separated by microdissection, the cross striations are seen to be a feature of the fibrils themselves: the cross stripes of the whole fiber are the result of the accurate alignment of the dark and light bands from fibril to fibril across the breadth of the cell. The dark and light sections

of the fibers are known as the A (or Q) and I (or J) bands, respectively. The A band in the relaxed fibers is from 3 to 6 μ long, and is a little broader than the I band. It stains deeply with the usual stains while the I band remains pale, but even in unstained sections of muscle the A band is dark compared with the adjacent I band. When the fresh muscle fiber is viewed by polarized light the A band appears bright and the I band dark. This is due to the former being doubly refractive (DR). The I band has a single refractive index. On account of its birefringent property the A band is also known as the *anisotropic* band or disc, while the I band is termed *isotropic*. Both the A and the I bands are bisected by narrow cross lines. The line in the A band is bright and known as the H line (or Henson's line), that in the I band is called the Z line, Dobie's line or Kreuse's membrane. The Z line is not confined to the myofibrils but in teased specimens can be seen to pass through the sarcomplasm between them, and appears to be of a membranous nature. It extends to the sarcolemma to which it becomes attached. The Z line is probably of importance in the linkage between the changes in electrical potential across the sarcolemma which accompany excitation and the contraction of the myofibrils. Local depolarizations which cause no effect elsewhere may bring about a local contraction of a single sarcomere if they occur opposite a Z line.

Each muscle cell contains several hundred nuclei which in vertebrate skeletal muscle are situated, for the most part, superficially just beneath the sarcolemma. The latter is a delicate, transparent, but tough membrane which envelops the entire cell. It is composed of interlacing collagenous fibrils embedded in a clear matrix of colloidal material. The fibrils are continuous with those in the endomysium. Lying in intimate association with the myofibrils are the *sarcomeres* or *muscle mitochondria*. These particles contain the very active respiratory enzymes of the cell and are the principal sites of synthesis of the phosphate anhydrides which are believed to provide the immediate source of energy for contraction.

When as a result of growth or athletic training the muscles enlarge and become more powerful, they do so not by increasing the number of their

FIG 51.1 Schematic representation of the ultrastructure of muscle as revealed by the electron microscope. The dimensions shown are those which remain constant when a fiber is stretched while the width of the H zone and the distance between adjacent Z lines are both increased. (After H. E. Huxley and A. F. Huxley.)

constituent fibers but by an increase in size of the individual fibers. The fibers are also larger in persons who are well nourished as compared with those in states of malnutrition. The difference in size of the fibers in the two instances is due to the amounts of sarcoplasm which they contain.

The foregoing is a description of the muscle fibers as seen under as high a magnification as is possible with the ordinary microscope. But, when observed with the electron microscope, it is found that the myofibrils are themselves made up of still finer longitudinal filaments. These filaments, which are the ultimate contractile structures, are composed of two proteins (see below) and have a diameter ranging from 50 to 100 Ångström units ($1 \text{ Å} = 10^{-8} \text{ cm}$).

Recent electronmicroscopic studies by H. E. Huxley have shown that two types of filament exist in the myofibril. The thicker ones have a diameter of about 100 Å and are found in the A band extending from one end to the other of this region. On the other hand, the thinner filaments are seen not only in the I bands, where they occur alone, but also in the A bands where they interdigitate with the thicker filaments. In an orderly fashion, each thick filament being surrounded by an array of six thin filaments. It has been shown by differential extraction and subsequent examination in the electron microscope that the thick filaments are composed of myosin, and similar evidence suggests that the other important structural protein, actin, must be localized in the thin filaments.

This new picture of muscle ultrastructure is complemented by recent observations of A. F. Huxley using the interference microscope. With

this instrument it was possible to show, in contradistinction to older views, that when an isolated muscle fiber is stimulated to contract, the length of the A bands remains constant (1.5μ). This dimension is also unchanged on stretching, when it is observed that the Z lines separate while the H band increases in width. These observations strongly suggest that the interdigitating filaments seen in the electron microscope are able to slide past each other, and that muscular contraction is brought about by just such a sliding motion.

The Chemical Constitution of Muscle

Muscle is composed mainly of protein (18 to 20 per cent). The remainder of its substance is made up of various minerals and a large number of organic compounds some of which are found exclusively in muscular tissue. The chief electrolyte is potassium which is present in a concentration of about 400 mg per 100 grams. Magnesium, calcium and sodium are found in much smaller amounts. Muscle contains a great variety of substances generally grouped under the heading of nitrogenous extractives such as creatine, phosphocreatine, alanine, histidine, adenosinetriphosphate, creatinine, purine bases, carnosine, anserine (bird and fish muscle).

Muscle contains between 0.5 and 1.5 per cent of glycogen, from 0.02 to 0.04 per cent of glucose and about 0.01 per cent of lactic acid. Phospholipids (1.0 per cent), cholesterol (0.07 to 0.18 per cent), vitamins, enzymes and a host of other organic materials are present, many of which will be mentioned later.

Reference has already been made to the chief proteins of the myofibrils, myosin and actin. Myosin has a molecular weight of about 500,000 while that of actin is about 80,000. Under certain conditions actin and myosin may be extracted from the muscle fiber as a complex which is known as actomyosin, containing three parts of myosin to one of actin. A third protein of the myofibril, tropomyosin, is present only to the extent of about 5 per cent, but this is probably the best characterized of the fibrillar proteins, its molecular weight being between 52,000 and 55,000. The oxygen holding pigment myoglobin (ch. 6) in red muscle is about 1 per cent and is free in the cytoplasm of the myofibril. The sarcoplasm also contains the soluble enzymes of the glycolytic sequence while the "insoluble" enzymes of the respiratory sequence (cytochromes, flavoproteins) are present in the sarcosomes.

The Chemical Physiology of Muscular Contraction

The mechanical response of an isolated muscle to stimulation is not accompanied by an increased consumption of oxygen, extra oxygen is not con-

sumed until after contraction and relaxation are over. So, there are two phases in the contraction cycle, an *anaerobic (anoxidative) phase* and an *aerobic (oxidative) or recovery phase*, during which the muscle is restored to its previous state. If the muscle be stimulated repeatedly in an atmosphere of nitrogen it contracts forcibly at first, but soon becomes fatigued, since it cannot obtain the oxygen necessary for its recuperation between the individual contractions. Lactic acid accumulates and the muscle enters into rigor. If, at the onset of fatigue, oxygen is readmitted, the lactic acid disappears, and the muscle recovers its original power to contract. The lactic acid concentration at which complete fatigue of skeletal muscle ensues (lactic acid maximum) is from 0.3 to 0.6 per cent. The lactic acid is derived from the breakdown of glycogen (ch 48). As the lactic acid concentration rises the carbohydrate stores diminish. Yet, the onset of fatigue is not due to the exhaustion of the glycogen stores, for the muscle fails to contract before the latter have disappeared. It may be that the high acidity inhibits the enzymes through whose action glycogen breakdown is brought about. Inorganic phosphate also accumulates in a muscle contracting in the absence of oxygen. The phosphate production rises rapidly during the earlier contractions, soon reaches a maximum and then ceases.

That a muscle can contract anaerobically has been known for many years. It has also long been known that lactic acid and CO_2 are produced by a muscle contracting in nitrogen. Spallanzani over 150 years ago observed that snails placed in nitrogen evolved CO_2 . In spite of these earlier observations it was thought, nevertheless, that a muscle derived its energy from oxidative processes—for how otherwise was the CO_2 produced? In order to explain the phenomenon it was supposed (Hermann, Pfleger) that an oxygen store was contained in some giant molecule (termed 'inogen' by Hermann) within the muscle substance itself. So 'intramolecular' oxygen was spoken of as the hidden oxygen reserve from which the muscle drew for its anaerobic contraction. Lactic acid also, it was thought, was derived from the breakdown of this hypothetical molecule. This theory was disproved by the classical experiments of Fletcher and Hopkins in 1907. These observers showed that the CO_2 , which appeared during the anaerobic contraction was not the result of oxidation but was preexisting CO_2 —i.e., simply CO_2 which had been liberated by the action of lactic acid upon sodium bicarbonate in the muscle fluids. They showed that the oxidative processes occurred after the contraction was over, that lactic acid then disappeared and

CO_2 was formed. It was erroneously supposed at this time, that the lactic acid which disappeared had been completely oxidized to CO_2 and water. That glycogen was the lactic acid precursor was indicated by the fact that the appearance of lactic acid in muscle fatigued in nitrogen was proportional to the glycogen loss. Also, an R.Q. of around unity, found later by Meyerhof, for the recovery phase of isolated muscle, indicated that its fuel was carbohydrate.

Meyerhof also showed that when oxygen was admitted to a fatigued frog's muscle, the amount of gas consumed was only one fifth of that expected if the disappearance of the lactic acid were due to its oxidation to CO_2 and water. The heat produced during the oxidative phase was also much less than it should be, were all the lactic acid burned. It was found, further, that glycogen increased in the fatigued muscle recovering in oxygen.

Emden had previously shown the importance of phosphate in the activity of muscle. Increased excretion of phosphate in the urine occurs as a result of muscular exercise, and Emden found that when muscle juice was incubated with a solution of bicarbonate, lactic acid and free phosphoric acid appeared in nearly equimolecular amounts. He suggested that the immediate precursor of lactic acid was a hexose phosphate. This he termed *lactacidogen*. A hexose phosphate had been shown by Harden and Young to be formed as an intermediary in the fermentation of sugar by yeast. When Emden added this ester to muscle juice an increased formation of lactic and phosphoric acids occurred. He also claimed to have demonstrated an increased production of phosphoric acid in a muscle during its contraction. The phosphoric acid as well as the lactic acid was believed to be derived from the breakdown of *lactacidogen* (i.e. hexose phosphate).

The Chemical Changes Occurring in Muscle Contracting in the Absence of Oxygen; Phosphorylation, Glycogenolysis and Glycolysis

(See also chapters 32 and 48)

Muscle does not depend upon immediate oxidative processes to liberate the energy necessary for its contraction. It will continue to contract for some time in the complete absence of oxygen. The energy stored in glycogen is thus liberated anaerobically. But for the recovery of the muscle, that is, for the reaccumulation of its energy stores, oxygen is required. The chemical changes involved in the entire contractile process are thus divided into two phases, the *anaerobic or contraction phase* and the *aerobic, oxidative or recovery*

phase. The muscle is comparable to a machine, such as a submarine engine which runs when submerged upon stored energy supplied in electric batteries. The batteries are recharged when the submarine comes to the surface. Expressed in another way, the muscle when it contracts runs up an oxygen debt (p. 879) which it pays when the contraction is over.

Evidence for the anaerobic chemical changes about to be outlined has been obtained very largely from studies of the enzyme systems in aqueous extracts of muscle and in yeast juice during alcoholic fermentation.

One of the first steps in the liberation of energy for contraction is the breakdown of glycogen stored in the muscle fiber. The glycogen reacts with inorganic phosphate and splits off glucose 1-phosphate (Cori ester) molecules in stepwise fashion. This reaction is catalyzed by phosphorylase. It is known that phosphorylase of muscle can exist in an active (a) and an inactive form (b), although the activation process is quite different from that of liver phosphorylase (see p. 811). It is possible that there is a production of phosphorylase a from phosphorylase b during muscular activity, thus making the glycogen stores of muscle available for metabolic processes. Muscle phosphorylase contains pyridoxal phosphate as a tightly bound cofactor (see table 51 f). The cleavage of the glycogen molecule occurs successively at the 1,4 C—O—C linkages between the glucose units. In the separation of the latter, an H atom of the phosphate group becomes attached to the 4 carbon atom, while the 1 carbon atom of the adjacent glucose unit holds the —O—P₃O₄H₂ group. The uptake of phosphate and its cleavage into glucose phosphate units has been aptly called *phosphorolysis* by Parnas, since, obviously, it is analogous to hydrolysis in which water (H₂O) instead of phosphate is taken up, the H atom and OH atoms becoming attached, respectively, to the adjacent groups of the larger molecule (protein disaccharides, polysaccharides, etc.) when they separate (see table 51 f).

The glucose 1-phosphate formed in the phosphorylatic reaction undergoes an intramolecular transference of its phosphate group to the 6 carbon atom, being thus converted to *glucose-6-phosphate* (Robison ester). This reaction is catalyzed by the enzyme *phosphoglucomutase*. The glucose-6-phosphate, through the action of *phosphohexose isomerase*, gives rise to *fructose-6-phosphate* (Neuberg ester), which then receives a phosphate group from adenosine triphosphate (ATP), to

form *fructose-1,6-diphosphate* and adenosine diphosphate (ADP).

The *fructose-1,6-diphosphate* is acted upon by *aldolase* and split into the triosephosphates, *dihydroxyacetone phosphate* and *3-phosphoglycer aldehyde* (Fischer-Baer ester). The 3-phosphoglycer aldehyde reacts with inorganic phosphorus, and in the presence of *triosephosphate dehydrogenase* and DPN (diphosphopyridine nucleotide or Coenzyme I) is converted to *1,3-diphosphoglyceric acid*. DPN accepts H₂ and is reduced to DPNH₂. As rapidly as dihydroxyacetone phosphate is produced it is transformed to 3-glyceraldehyde phosphate (called the "reactive form" of the sugar) which in the presence of triosephosphate dehydrogenase is rapidly removed. The reaction is thus 'drawn to the right'.

The 1,3-diphosphoglyceric acid undergoes dephosphorylation to form *3-phosphoglyceric acid*, the released phosphate group converting ADP to ATP. By intramolecular transfer of the phosphate group 3-phosphoglyceric acid is converted to *2-phosphoglyceric acid*, the reaction being catalyzed by *phosphoglyceric mutase*. 2-Phosphoglyceric acid is converted by dehydration to *phosphoenolpyruvic acid* through the action of *enolase*.

The phosphoenolpyruvic acid reacts with ADP to form *pyruvic acid* and ATP. This reaction is catalyzed by a *transphosphorylase* in the presence of magnesium and potassium ions.

Pyruvic acid in the absence of oxygen is reduced to *lactic acid* by the reduced coenzyme (DPNH₂) in the presence of *lactic dehydrogenase*, the coenzyme being restored to the oxidized form (DPN).

Under aerobic conditions the reduced coenzyme is not oxidized by pyruvic acid as shown in the last reaction but by molecular oxygen through the combined action of a specific flavo-protein and the cytochrome system (ch. 32). The result is that with an adequate supply of oxygen no lactic acid is formed and of that produced anaerobically one-fifth is oxidized through pyruvic acid to carbon dioxide and water, and the remainder resynthesized to glycogen. In the intact animal synthesis occurs in the liver.¹ The oxidation of lactic acid to pyruvic acid is brought about through the action of lactic dehydrogenase in the presence of DPN. In the presence of oxygen the pyruvic acid is oxidized in a series of steps called the *tricarboxylic acid cycle*. Although there is not

¹ According to Meyerhof resynthesis of glycogen from lactic acid occurs in the isolated frog muscle but this probably does not occur in intact mammalian muscle.

TABLE 51 1

unanimity as to the details of the chemical changes involved in the dissimilation of pyruvic acid, the researches of a number of workers, especially Szent Gyorgyi, Krebs, Werkman and Wood and Evans and Slotin, permit the scheme to be drawn as in table 51 2, p 875 Thus oxaloacetic acid and acetylcoenzyme A undergo condensation to form citric acid. The citric acid loses a molecule of water and is converted to cisaconitic acid, this then regains a molecule of water to produce isocitric acid which is oxidized to oxalosuccinic acid. The latter is decarboxylated to yield α ketoglutaric acid which is oxidized to succinic acid, carbon dioxide and water. The succinic acid is oxidized through fumaric and maleic acids to oxaloacetic acid. With the regeneration of oxaloacetic acid the cycle repeats. At each turn of the cycle an acetyl group derived from pyruvate is oxidized, each molecule of pyruvic acid, therefore, yields two molecules of water and three molecules of carbon dioxide, while a molecule of oxaloacetic is reformed. A single molecule of oxaloacetic acid can be used in this way repeatedly in the oxidation of acetyl groups to carbon dioxide and water, it, therefore, acts in the manner of a catalyst.

The energy which the anaerobic production of lactic acid from glycogen yields for the performance of work is only a small fraction of that which results from the oxidation of lactic acid. For each gram molecule of lactic acid produced the free energy amounts to about 23 000 calories, whereas some 325,000 calories are liberated by the oxidation of a corresponding amount of lactic acid to carbon dioxide and water.

THE ROLE PLAYED BY PHOSPHATE ANHYDRIDES (CREATINE PHOSPHATE AND THE ADENYLIC ACID SYSTEM)

In 1927 Eggleton and Eggleton obtained a creatine phosphorus compound from muscle which they named *phosphagen*. About the same time Fisk and Subbarow isolated the same substance and called it *phosphocreatine*, it is also known as *creatine phosphate*, or briefly CP. It has the following formula

Phosphoarginine is the corresponding phosphagen in invertebrate muscle. In the muscles of some species both compounds are present.

CONTRACTION WITHOUT LACTIC ACID PRODUCTION

An experiment of Lundsgaard (1929) revealed the essential importance of phosphocreatine in the contractile process. He found that after the injection of sodium iodoacetate into the dorsal lymph sac of a frog, violent contractions of the muscles occurred followed by rigor. When a muscle of the poisoned animal was isolated and stimulated electrically in nitrogen, it responded, but *no lactic acid was produced*. After about 100 contractions, it became fatigued. This is much sooner than the onset of fatigue in normal muscle, and, unlike the latter, the poisoned muscle became slightly *alkaline* in reaction. About 0.5 mg of lactic acid per gram of tissue is formed in a normal muscle after a similar number of contractions.

Upon analysis the poisoned muscle shows a loss of glycogen and of phosphocreatine, and an increased content of hexose phosphate. The lactic acid and phosphocreatine phosphorus values of normal and poisoned muscles after 150 contractions each are shown in the following table (after Lundsgaard)

		Lactic acid mg per cent	Phosphagen phosphorus mg per cent
Normal	Resting	25	61
	Working	84	40
Poisoned	Resting	16	57
	Working	15	0

It was concluded that the disappearance of CP was not due to its being used up more rapidly, but to its failure to be resynthesized. The energy for resynthesis was presumably derived from glycogen—lactic acid breakdown (glycolysis). Iodoacetate reacts with sulphhydryl groups of triose phosphate dehydrogenase which are essential to its action. This inhibition arrests glycolysis at the stage where 3-phosphoglyceric aldehyde is converted to 1,3-phosphoglyceric acid. Thus, iodoacetate inactivates the glycolytic system which is essential for the resynthesis of phosphocreatine.

Such observations led to the concept that the energy for contraction is derived from the breakdown of phosphocreatine, the role of carbohydrate dissimilation being to provide the energy for the resynthesis of this compound. However, in 1934, Lohmann showed that dialyzed muscle extracts are incapable of hydrolyzing CP, and that its breakdown occurs in a series of two reactions, the first of which, known as the Lohmann reaction after its discoverer, may be written as follows: $\text{CP} + \text{adenosine diphosphate (ADP)} \rightarrow \text{C} +$

adenosine triphosphate (ATP), the latter compound being broken down by adenosine triphosphatase to form ADP and inorganic phosphate. This work suggested that the breakdown of ATP must precede that of CP and that this reaction is closer to the primary processes of contraction. The nucleotide ATP (also called adenylypyrophos

phate) is a compound of adenine, D-ribose, and three molecules of orthophosphate. Both CP and ATP possess energy rich phosphate bonds, indicated by the symbol $\sim$ in their formulas. The free energy of hydrolysis of such a bond is about 10,000 calories per gram molecule of phosphate liberated.

Adenosine triphosphate [Adeny] pyrophosphoric acid ATP

The terminal phosphate group of ATP may be split off by the action of the enzyme adenosine triphosphatase (ATPase) or the phosphate bond energy may be transferred to other compounds, ADP is formed. Phosphate is given up for example in the conversion of fructose 6-phosphate to fructose 1,6 diphosphate in the course of glycolysis. There are three main pathways for the resynthesis of ATP in muscle, the Lohmann reaction, discussed above, glycolysis, and respiration. In the glycolytic sequence, the energy rich phosphate bonds are generated at the triosephosphate dehydrogenase and enolase levels, while during respiration as many as three molecules of inorganic phosphate may be incorporated into such bonds for every atom of oxygen consumed, in a process known as oxidative phosphorylation, the detailed mechanism of which remains a major gap in our knowledge of metabolism. This process takes place within the muscle mitochondria (sarcosomes) which lie among the myofibrils, while glycolysis occurs in the "soluble" sarcoplasm. These recovery processes are activated very rapidly after a muscle twitch, indeed Millikan has found that the desoxygenation of myoglobin commences within 0.2 sec of stimulation indicating that the respiratory system has been activated in that time.

The resynthesis of phosphagen is effected by a reversal of the Lohmann reaction, i.e., ATP yields phosphorus to creatine, CP and ADP being formed. The equilibrium of this reaction is, however, markedly in favor of creatine and adenosine triphosphate. Phosphocreatine can, therefore, function as a reserve of phosphate bond energy which will bring about a rapid resynthesis of ATP, even in the iodoacetate poisoned muscle although the normal resynthesis of energy rich bonds, which is a concomitant of carbohydrate break-

down, cannot take place in the presence of the inhibitor and after a series of contractions the supply of CP will be exhausted.

THE RELATIONSHIP BETWEEN ADENOSINE TRIPHOSPHATE BREAKDOWN AND MUSCULAR CONTRACTION

There are many experimental facts which suggest that the breakdown of ATP is in some way associated with the contraction of muscle. Three main pieces of evidence have led to this belief that the ATP/ADP system is the immediate source of energy for contraction. Firstly, the work of Lundsgaard and Lohmann, considered above, leads clearly to the idea that contraction may occur at the expense of phosphate bond energy, with the breakdown of ATP preceding that of phosphocreatine and therefore being more intimately related to the contraction process.

Secondly, it was discovered by Engelhardt and Lyubunova that myosin, the chief protein of muscle and long recognized as an element of the contractile apparatus, possessed ATPase activity. This identity or, at least, close relationship of myosin with ATPase appears to bring the breakdown of ATP into intimate association with the mechanical effects, i.e., with the actual contraction of muscle. Myosin has been obtained by Szent Gyorgyi in the form of minute needle shaped crystals. Upon repeated recrystallization no loss in ATPase activity but rather an increase, occurs. From this fact and the following observations, myosin and ATPase are generally assumed to be identical, although absolute proof has not been secured. They are at least very closely associated. (a) Crude preparations of myosin contain several other enzymes, but these can be removed completely by successive precipitations. (b) The thermolability of myosin and of ATPase are closely similar, the protein undergoing denaturation, and enzyme activity is abolished at about the same temperature, which is relatively quite low. (c) Electrophoretic studies show that myosin possesses a high degree of homogeneity, the large rapidly moving fraction which constitutes over 90 per cent of the protein of the preparation has been found to have double the ATPase activity of the smaller slowly moving fraction which possesses a low protein content.

Only one phosphate group is split from ATP by myosin. ADP is not attacked. It shows a high degree of specificity in this regard. Inosine triphosphate and inorganic triphosphate are split in a similar manner. Calcium ions activate

ATPase, whereas magnesium, copper and silver are inhibitory, the enzyme activity is unaffected by cyanide.

The third line of evidence relating ATP to contraction, and perhaps the most dramatic, is that certain preparations can be made from muscle which undergo mechanical deformation on the addition of ATP. Thin strips of rabbit psoas muscle may be extracted with 50 per cent (volume per volume) aqueous glycerol at -10°C for several days. During this extraction, the soluble proteins of the muscle fiber are leached out but the myofibrils retain their structure and orientation. When adenosine triphosphate in low concentration is added to such a preparation it will shorten by as much as 70 to 75 per cent and may exert tensions which compare well with those exerted by living muscle. Even simpler systems will display contractile properties, the proteins actin and myosin form a complex called actomyosin which may be precipitated in threadlike form. Such threads will shorten in the presence of ATP.

These findings provide strong circumstantial evidence for the view that ATP breakdown is intimately associated with the contraction process. However, the attempt to provide experimental evidence of a direct nature, i.e., a demonstration of the dephosphorylation of ATP during contraction by a living muscle has so far failed. The expected breakdown of ATP would be of the order of $0.25 \mu\text{mole per gram muscle per twitch}$, but the values found are considerably lower than this estimate. Indeed it appears that at least one twitch and possibly a short tetanic contraction (1 to 2 sec) may take place without any significant breakdown of either ATP or creatine phosphate. There is, however, some evidence in favor of a liberation of inorganic phosphate under these circumstances which may provide the key to a resolution of this apparent discrepancy, since it may mean that some presently unknown phosphate compound is breaking down and either bringing about a very rapid rephosphorylation of ADP or is itself providing the immediate energy for contraction.

Whatever may issue from this controversy, a fundamental problem will remain, namely, how is the energy of hydrolytic reaction, if such it be, linked to the physical changes in the muscle—the shortening and thickening which we call contraction. An earlier view of the molecular basis of contraction regarded it as a reflection on the macroscopic scale of a folding of the polypeptide chains of myosin but the newer knowledge of the ultra-

structure of the myofibril (p 869) suggests that contraction represents a change of intermolecular orientation rather than of intramolecular configuration, a suggestion which is confirmed by recent studies of X ray diffraction by muscle. The nature of the forces which bring about the sliding motion of the two types of filament relative to one another is unknown but it may be assumed that this structural interaction is related to the biochemical interaction between actin and myosin. A scheme has recently been proposed by A. F. Huxley in which active side groups on the myosin filament react with sites on adjacent actin filaments, the rates of association and dissociation depending on the relative position of the filaments. The reaction is blocked by ATP (or some other high-energy phosphate compound) and the splitting of ATP would bring about activation of the contraction mechanism. This model is remarkably successful in providing an exact relationship between parameters having the form of the rate constants of a cycle of chemical reactions and the over all mechanical and thermodynamic constants of muscle. This and other schemes suggest that the resting state of muscle will be characterized by a low ATPase activity and that the electrical changes in the sarcolemma which initiate the contraction process must bring about a rapid activation of ATPase. This may coarsely be effected by an alteration in the free concentration of Mg^{++} , Ca^{++} or other changes in the ionic environment of the active site of the myofibrillar ATPase but the detailed nature of these steps remains a central problem of muscle physiology.

HEAT PRODUCTION IN MUSCLE

Our present knowledge of the relationships between the activity of muscle and the energy set free is very largely due to A. V. Hill. During muscular activity, energy is liberated in two forms, as mechanical work and as heat. The heat production associated with a muscle twitch occurs in two stages, a very rapid outburst of heat which occurs during the twitch itself and a slow, prolonged production of heat following the contraction. This latter is called the *recovery heat* (to be sharply distinguished from the so-called heat of relaxation) and is identical in time course with the extra oxygen consumption which follows activity. Both then reflect the increased metabolism which restores the energy supplies of the muscle (ATP, phosphocreatine, etc.) to their resting levels. It is of interest that the recovery heat is about equal to the total energy set free during

FIG 51.2 A comparison of the kinetics of shortening and heat production during an isotonic twitch (frog sartorius). The liberation of the heat of activation precedes shortening and is succeeded by a phase in which the curves are approximately parallel and heat production is proportional to shortening (From Hill Proc Roy Soc 136B, 242 1949 by kind permission of the author and of the Royal Society)

contraction. During recovery the chemical changes which are associated with this initial liberation of energy are reversed and since an equivalent amount of energy is wasted as heat the efficiency of the recovery process is about 50 per cent.

The initial energy itself may be divided into three forms. Firstly, the *heat of activation* (A) which is associated with the process whereby the muscle passes from the resting to the active state e.g. the hydrolysis of phosphate anhydrides. In frog muscle at 0°C this heat production commences about 10 msec after electrical stimulus at 35°C the latent period of the activation heat would be much shorter. At about 20 msec after shock shortening commences and a second phase of heat liberation is associated with this process, and indeed this *heat of shortening* is directly proportional to the amount of shortening i.e. heat of shortening $= ax$ where x is the shortening in cm and a is a constant, having the dimensions of a force if the heat is expressed in mechanical units. These two processes of heat liberation may be clearly observed in figure 51.2. The magnitudes of these effects are also indicated here, $A + ax = 3$ mecal per gram muscle, A is about one half of ax , for maximum values of x .

The third form of energy liberation is performance of work. In an isotonic contraction under load P , this will be equal to Px . If the muscle is allowed to relax under load, an amount of heat equal to this work will appear, this may be conceived as having its molecular basis in the return

of contractile and elastic elements in the fiber to their resting orientation. It is however of prime theoretical importance that *there is no true heat of relaxation*, i.e. if a muscle is allowed to relax under zero tension (a condition which may only be attained under ingenious experimental conditions) no measurable heat appears. It is therefore highly improbable that there are any chemical changes such as ATP breakdown associated to the relaxation process.

The total initial energy of a twitch E may therefore be written,

$$E = A + (P + a)x$$

In a tetanic contraction activation heat is produced in response to each of the series of shocks and is summated. It is then referred to as the maintenance heat and is proportional to the duration of the contraction (t).

$$E = kt + (Px + a)x$$

Since the work done is Px it will be seen that during contraction the efficiency of the muscular machine,

$$\frac{\text{work performed}}{\text{energy expenditure}} = \frac{Px}{kt + (P + a)x}$$

In order to relate the efficiency to velocity of contraction the numerator and denominator are divided by t . Thus allowing v to stand for the speed of shortening (x/t) we obtain

$$\text{efficiency} = \frac{Pv}{k + (P + a)v}$$

The efficiency of the muscular machine is, therefore a function of the speed of contraction itself a function of the load. The maximal efficiency is reached at about a fifth of the maximal speed of shortening i.e. under zero load and is equal to about 40 per cent though when the heat of recovery is added to the total initial energy (to which it is approximately equal see above) the efficiency falls to 20 per cent.

It has been shown by Hill that the sum of the rate of work and the rate of production of shortening heat (i.e. the rate of energy liberation in excess of the heat of activation) is linearly related to the tension, in the following manner

$$(P + a)v = b(P_0 - P)$$

where P_0 is the isometric tension and b is a constant. On rearrangement this becomes

$$(P + a)(t + b) = \text{constant}$$

This equation relates the velocity of shortening in an isometric contraction to load, and is of considerable importance, since it is possible to derive the constants a and b quite independently from thermal data or by purely mechanical measurements, with very good agreement. The physical basis for this very simple and fundamental relationship is unknown although it is one of the very noteworthy features of the model proposed by A. F. Huxley that it does in fact yield a mathematical formulation which is consonant with Hill's equation.

MUSCULAR CONTRACTION IN THE INTACT ANIMAL

Oxygen Debt

We have seen that an isolated muscle is able to contract when stimulated in an atmosphere of nitrogen but its recovery phase is postponed until oxygen is re-admitted. During strenuous exercise the muscles of the intact animal behave similarly. While working strenuously, the circulatory and respiratory systems are incapable of supplying adequate amounts of oxygen for the removal (by oxidation and resynthesis to glycogen) of the large quantities of lactic acid produced. Complete recovery must be postponed until the exercise is over, when the accumulated lactic acid is gradually removed. The muscles of the intact animal during strenuous exertion are comparable, therefore, to the isolated muscle contracting anaerobically. It was shown by A. V. Hill and his associates that an athlete during great muscular effort such as sprinting cannot possibly inhale more than a fraction of the oxygen required. That is the body works its muscles but does not furnish them with the total oxygen required for the work until some time after this has been completed—it "goes into debt for oxygen" paying up during the recovery period (see fig. 51.3). In a 100 yard sprint, for example, the oxygen requirement may be over 6 liters. It is obviously impossible to deliver this amount to the muscle in the few seconds in which the race is run. The maximum consumption possible is not more than 4 liters of oxygen per minute. Furthermore, a sprinter can dash 100 yards with the breath held. The great value of the anaerobic phase of muscular contraction is thus revealed. Through the ability of the muscles to contract when deprived of oxygen and to replenish their stores of energy during the phase of oxidative recovery, they are enabled to perform for short periods an amount of work which otherwise would be impossible, that is, were they as in the

FIG. 51.3. Illustrating the increase in O_2 consumption above the resting level following exercise—"oxygen debt" (From Hill, *Muscular Movement in Man*).

case of a motor engine, dependent entirely upon a contemporaneous oxygen supply.

The oxygen debt is determined by measuring the oxygen used during the period of recovery, i.e., from the termination of the exercise to the time when the oxygen consumption has returned to normal, and subtracting from it the quantity of oxygen used during a corresponding resting period. The length of the recovery period may be 80 minutes or more. In very severe exertion the oxygen debt amounts to over 10 liters (or about 0.3 cc. per gram of muscle tissue). The maximum recorded in man is over 18 liters. During less strenuous exercise the discrepancy between lactic acid production and lactic acid removal is less pronounced, and the oxygen debt is correspondingly smaller. In light exercise the lactic acid is removed during the work—the body "pays as it goes"—and no oxygen debt is incurred. This is called the *steady state*. In other words, anaerobic and aerobic processes are balanced. The average man cannot maintain the steady state unless the oxygen requirement of the work does not exceed about 2 liters per minute. After severe exercise the normal level of lactic acid in the blood may not be reached until an hour or more after the exercise has ceased.

Lactic Acid Production during Exercise

The lactic acid produced in a short bout of strenuous exercise may amount to as much as 3 grams per second and its concentration in the blood rise as high as 0.2 per cent. The lactic acid though buffered by the muscle protein thus

lactic acid	potassium proteinate	potassium lactate	acid pro- teinate undis- sociated
----------------	-------------------------	----------------------	---

and to a less extent by phosphates and bicarbonates causes a sufficient change in blood reaction

to stimulate powerfully the respiratory center. Large amounts of carbon dioxide are 'blown off' from the lungs.

Hill and Lupton have taken the excess oxygen consumed during recovery as a basis for calculating the quantity of lactic acid present in the body at the end of exercise. They assumed that the recovery oxygen was used entirely in the oxidative removal of lactic acid, and that the quantity of lactic acid removed by oxidation was, as in the case of isolated muscle, only about one fifth of the total quantity which disappeared. Thus,

That is, for every 3 molecules of oxygen consumed during recovery 1 molecule of lactic acid has been oxidized, and for every molecule of lactic acid oxidized 4 have disappeared through synthesis to glycogen. Three gram molecules of oxygen consumed therefore represent the disappearance of 5 gram molecules ($90 \times 5 =$) 450 grams of lactic acid. Or 1 gram molecule (22.4 liters) of oxygen represents the disappearance of $\frac{1}{3}$ gram molecules (150 grams) of lactic acid. Each liter of oxygen consumed during recovery would therefore indicate the disappearance of $(150/22.4 =)$ 7 grams approximately of lactic acid.

Nonmuscular tissues, liver, heart, brain and muscles not actually engaged in the exercise, share in the removal of any lactic acid carried to them in the general circulation. Barr and Himwich showed this in animal experiments. From the results of their experiments upon rabbit muscle with intact nerve and blood supply, Sacks and Sacks conclude that, contrary to what is believed to occur in isolated frog muscle, lactic acid is not resynthesized to glycogen in the mammalian muscle during recovery, but diffuses into the circulation to be mainly converted in the liver to glycogen. A smaller part is oxidized by brain, heart and probably by other tissues as well. If produced in large amounts, as in strenuous exercise, an appreciable amount finds its way into the urine.

The Fuel of Exercise

We have seen that in the case of isolated frog muscle the respiratory quotient is around unity, which indicates that the ultimate source of the energy for the contractile process is mainly, if not entirely, carbohydrate. That is, the energy required to restore the muscle to its pre-contraction state is derived from the oxidation of this food material. Though the glycogen of the isolated muscle is reduced by activity, no diminution of its fat content has been demonstrated. It has also been shown that if an isolated muscle be stimu-

lated while suspended in Ringer's solution so that the lactic acid as it forms may diffuse away, fatigue sets in only when the glycogen stores have been exhausted (see p. 871). If glucose be added to the Ringer's, something like 10,000 twitches can be evoked and a total tension of 6 tons per square centimeter of cross section of the muscle developed. It cannot, however, be concluded from experiments upon the isolated frog muscle, which for one thing is poorly supplied with oxygen, that the muscles of the intact mammal can use only carbohydrate fuel. Himwich and Rose, for example, by determinations of CO_2 and of O_2 of venous and arterial bloods of intact muscles obtained an average respiration quotient (R.Q.) of only 0.80. Attempts to decide the question for the intact body have been made by determinations of the respiratory quotient of the *excess metabolism of exercise* in man. The results are, however, difficult to interpret and no definite conclusion can be drawn from them.

The excess metabolism of exercise is determined from the oxygen consumed (or of the CO_2 eliminated) during the work and recovery periods less the amount of oxygen used (or CO_2 eliminated) during a corresponding period preceding the exercise. The ratio between the excess quantities of the two respiratory gases will, of course, be the R.Q. of the excess gaseous exchange. But certain precautions must be taken in order to obtain the true R.Q., i.e., the R.Q. of the oxidative processes, for as already mentioned a large proportion of the CO_2 which is eliminated following exercise is not oxidative in origin but is simply gas which has been liberated from chemical combination (p. 871). The period of increased CO_2 elimination and high R.Q. immediately following the exercise is followed by one in which the output of the gas is reduced and the R.Q. is well below the normal level of 0.85— CO_2 is being retained to replenish the bicarbonate stores (fig. 51.4). During a period of sufficient length, therefore, one effect (retention) will just balance the other (blowing off) and the quantity of CO_2 eliminated during this time in excess of the output during a pre-exercise period will be the extra quantity actually produced by oxidative processes. This value is used in calculating the R.Q. of the excess metabolism resulting from the exercise.

In experiments on man involving short periods of strenuous exercise, the R.Q. of the excess metabolism has been found by several observers to rise above that of the resting period and to reach or exceed unity. Best, Furusawa and Ridout ob-

FIG. 51.4 Curve of the R.Q. of the excess metabolism caused by muscular exercise (From Hill *Muscular Movement in Man*)

tained a R.Q. of between 1.18 and 1.68 for very arduous exercise. For less strenuous work the R.Q. was around unity and for mild exercise it was considerably lower—little above that for the rest period. The degree of exercise required to raise the quotient to unity varied in different subjects. The very high quotients (above unity) which these observers obtained have since been observed by others, but Gemmill in more rigidly controlled experiments in which the subject was kept under basal conditions for a period of several hours preceding the exercise, obtained an average R.Q. for the excess metabolism of a little less than unity. Determinations of the oxygen consumption and carbon dioxide elimination were made over a recovery (post exercise) period of 3 hours.

The R.Q. of the excess metabolism has also been determined by a number of workers upon diets high, respectively, in fat or carbohydrate. Benedict and Cathcart for example found an R.Q. of 0.90 on a carbohydrate rich diet and one of 0.82 (indicating the utilization of fat) on the fat-rich diet. They concluded that the fuel of exercise was not exclusively carbohydrate but depended largely upon the previous diet. Krogh and Landhard decided that the food material oxidized during work was the same as that during rest and that in either case the relative quantities of fat and carbohydrate oxidized varied with their proportions in the diet. Work, however, was performed less economically (by 10 per cent) upon fat than upon carbohydrate. Others have observed an increase in efficiency upon high carbohydrate diets though, as a rule, the increase was not as great as that found by Krogh and Landhard.

Carpenter and Fox carried out two comparable groups of experiments. In one group 50 grams of glucose were given just prior to the commencement of the exercise. In the other group the subjects were fasting. The R.Q. of the excess metabolism of those which had received the glucose was considerably higher than those of the other group.

Anderson and Lusk obtained in a starving dog working a treadmill respiratory quotients suggestive of the combustion of fat namely from 0.71 to 0.73. Also in prolonged severe exercise in man Talbot and associates observed a fall in the R.Q. following an earlier rise.

Other lines of approach have yielded more important evidence for carbohydrate being the main fuel though not necessarily the only one used in muscular work. Other food stuffs especially fat can serve under certain circumstances the proportion of each which undergoes oxidation varying with the amount available and the severity of the exercise. In short periods of light exercise it is probable that the energy is derived from the oxidation of materials of the same nature as those which furnish energy during rest. These are small molecules of carbohydrate, fat and protein material already present in the circulation (Carpenter). Such materials are soon exhausted however, by heavier work when the glycogen reserves are drawn upon. There is general agreement that in strenuous exercise the fuel used by the muscles is mainly if not entirely carbohydrate. If the exercise is long continued as in a marathon race hypoglycemia results. The administration of glucose at the commencement of the race prevents the fall in blood sugar and exerts a definitely beneficial effect upon the athlete's performance. The

production of large quantities of lactic acid in strenuous muscular exercise also points to carbohydrate material as the source of energy. In short but strenuous bouts of work a rise in blood sugar up to a concentration of nearly 200 mg per cent has been observed. The mechanism governing this mobilization of the carbohydrate reserves has not been definitely determined. It does not appear to have an emotional basis (liberation of adrenaline or stimulation of the sympathetic). Gemmill suggests that the high blood lactate stimulates the production of glucose by the liver.

In prolonged and exhausting exercise the carbohydrate stores become depleted. Fat and, to some extent, protein are then utilized to drive the muscular machine. Both these materials are used in directly, i.e., after their conversion to carbohydrate.² As the carbohydrate stores are used up physical exhaustion ensues. Dogs can be worked for 17 hours or so before they are completely fatigued if fed carbohydrate, but become exhausted in less than 5 hours if worked without food (Dill and associates). The fatigued animals are capable of further work if then given carbohydrate.

The use of protein as fuel has been a subject of controversy for a number of years. It has been common teaching that this food material except in minimal quantities when fat and carbohydrate are unavailable is not a source of energy for muscular work, but served merely to repair tissue "wear and tear." This conclusion was arrived at chiefly from studies of the nitrogen excretion. Ordinary exercise, for example, does not increase appreciably the output of nitrogen in the urine nor does it increase the non-protein nitrogen of the blood. More strenuous work causes a slight rise in the blood non-protein nitrogen and a moderate increase in the urinary nitrogen in man and in animals. In work experiments upon fasting dogs it has been calculated that at the most not more than 7 per cent of the energy required for the exercise could have been derived from protein, the great part of the energy had apparently been ob-

tained from the combustion of fat. In prolonged starvation after exhaustion of the stores of carbohydrate and fat, protein (carbon part of the amino acids) must then, serve as the sole source of energy.

It has been pointed out by Cathcart, however, that the nitrogen excretion during short periods of exercise may not be a true criterion of protein metabolism since the nitrogen released in the breakdown of protein may be utilized in synthetic processes and consequently not appear in the urine. Or, muscle protein may be catabolized and its nitrogen excreted, yet if, as is quite possible, an equivalent amount of nitrogen derived from the food were diverted to the muscles to replace that which had been lost, the total nitrogen excretion would remain unchanged. This observer also considers that, in the long run, muscular work exerts a very definite influence upon protein metabolism and cites the familiar observation that persons engaged in heavy muscular work demand a diet rich in protein particularly meat. It has also been shown by several investigators that a retention of nitrogen occurs during a period of training—apparently for the manufacture of muscular tissue.

Such views are in harmony with modern conceptions of protein metabolism (p. 779). Since catabolism and anthesis may go hand in hand the total quantity of nitrogen excreted gives no indication of the interchanges which are taking place between food and tissue nitrogen. It is scarcely reasonable to assume that after deamination the non-protein portions of the amino acids can not serve as a source of oxidative energy. A carnivorous animal, for example, can subsist upon a diet composed almost exclusively of protein. Cantanelli and Rapoport also draw attention to the irrelevancy of the nitrogen excretion and insist that it can give no information respecting the non-nitrogenous part of the catabolized protein. From a study of the respiratory quotient of the excess metabolism of exercise performed by a dog on a high protein diet they conclude that oxidative energy for muscular exercise can be supplied quite as readily by protein as by carbohydrate or fat.

The question whether or not alcohol can furnish energy for muscular work has been investigated repeatedly. The results obtained by different workers are not entirely in agreement. Some have reported that muscular exercise hastened the disappearance of alcohol from the blood, presumably by increasing combustion (see Mellanby). On the other hand Carpenter and his associates in a recent careful study did not find that work exerted such an effect. They conclude that alcohol disappears from the human body at a uniform rate whether the subject is at rest or performing muscular exercise. Nor did muscular work alter the concentration of alcohol in the expired air (i.e.,

² This statement may have to be modified in the light of recent experiments by K. L. Zierler and I. B. Fritz. It now seems clear from the results of the former author (*J. Clin. Invest.*, 35, 671, 1956) that the oxygen uptake of the resting human forearm is greatly in excess of that suggested by the arteriovenous difference in glucose concentration. That some of this discrepancy may be accounted for by the oxidation of fatty acids is suggested by the experiments of Fritz and his collaborators (*Am. J. Physiol.* 191, 379, 1958) who show that C^{14} labeled fatty acids are oxidized by isolated skeletal muscle and that the rate of oxidation is increased on faradic stimulation. The quantitative aspects of the role of nonesterified fatty acids as fuel for muscular exercise remain to be examined.

the amount eliminated per liter of CO_2 remained unchanged), in the urine or in the blood

THE BODY TEMPERATURE

The normal body temperature, recorded from the mouth, is usually given as 98.6°F (37.0°C). The rectal temperature averages $\frac{1}{16}$ of a degree F higher than this and the axillary temperature at least 1 degree F lower. No absolute figure can be given, for there is a wide variation between individuals. The oral temperatures of a large group of normal persons range from 96.6° to 100.0°F (35.8° to 37.8°C), the average being around 98.4°F (36.9°C). Ivy, in a study of nearly 300 medical students, obtained a mean oral temperature of 98.1°F (36.7°C). Variations in the body temperature also occur in the same individual throughout the day—a difference of 2.0° or even 3.0°F occurring between the maximum in the late afternoon or early evening, and the minimum between 3 and 5 o'clock in the morning. In night workers the times of the maximal and minimal temperatures may be reversed. The temperature of the internal organs is higher by several degrees than the temperature of the skin. The temperature of the liver, for example, is about 100°F (37.8°C), whereas that of the skin covered with clothes is from 85° to 93°F (29.5° to 33.9°C). The temperature of the bare skin varies widely, of course, with the environmental temperature. The influence of the latter upon the temperature of the covered skin will depend upon the heat-insulating properties of the clothing, air movement (breeze, wind), atmospheric moisture, etc. Strenuous muscular exercise causes a temporary rise in body temperature of 1.0° to 4.0°F or more, a temperature of over 104°F (40.0°C) during exercise has been reported (L. Hdl).

The heat regulating mechanisms are not fully developed at birth. The body temperature of the newborn child, although in general the same as that of the adult, tends to be irregular and unstable. Spontaneous variations of from 1 to 2°F are common during the first year. Excitement or other strong emotion, even in older children, may raise the temperature by as much as 2°F.

The Regulation of Body Temperature

The almost unchanging body temperature of warm blooded animals, living under a variety of

environmental conditions, indicates a remarkably efficient thermostatic control and regulating system. The temperature of a warm blooded (homiothermic) animal remains practically unchanged although the surrounding temperature may vary between 0°F or less and 100°F or upwards. On the contrary, the body temperature of a cold blooded (poikilothermic) animal such as the frog, turtle, etc., is practically that of its environment (fig. 52.1).

Heat is continuously being produced within the body by metabolic activity, the rate of heat production being minimal during sleep and increased by muscular activity. In order to maintain a constant temperature, the rate of heat loss must be adjusted to equal the rate of heat production. This process is complicated by the varying environmental temperatures. A high ambient temperature reduces the rate of heat loss. A low temperature may increase the rate of heat loss to such an extent that metabolism must be increased by means of shivering to maintain the balance. With environmental temperatures in excess of the body temperature, or if heat is being produced rapidly by muscular activity, the evaporation of sweat is necessary to dispose of the excess heat. Shivering and sweating are "emergency" measures. Throughout the range of moderate temperatures the rate of heat loss can be regulated by varying the rate of blood flow through the skin. Heat is produced mainly in the deeper structures (muscles and viscera), which are insulated from the environment by subcutaneous fat and skin. The heat is transported by the blood which is warmed in the deep central structures and cooled at the body surface. Although the temperature of the skin may vary widely, the central or "core" temperature is maintained homeostatically within a very narrow range. The body absorbs heat radiated from surrounding objects with temperatures higher than its own, and from direct or reflected sunshine, a stove or an open fire. Heat is also gained by the ingestion of hot food. Heat production is the result of chemical reactions and was therefore called the "chemical" regulation of body temperature by Rubner. Heat loss is dependent

upon physical (and physiological) factors—"physical" regulation. These terms are redundant and an oversimplification, since the chemical and physical cannot be separated.

Under basal conditions, when no external work is being done, all the metabolic energy ultimately appears as heat. If this heat were not lost to the body, the body temperature would rise. The basal metabolic rate usually produces heat amounting to about one calorie per kilogram of body weight per hour. Since the body is composed chiefly of water, it has a specific heat of a little less than one, so the body temperature would rise about 1°C per hour if no heat were lost.

With strenuous physical exertion more than three quarters of the increased metabolism appears as heat within the body, the remainder appears as external work. Fever increases the metabolic rate, the average increase being 13 per cent to each degree C rise (7.2 per cent per degree F). This change in metabolism corresponds to a temperature coefficient (Q_{10}) of between 2.0 and 3.0. The temperature coefficients of the various metabolic reactions are not, however, identical, consequently, a rise in temperature causes a disturbance in the metabolic pattern of the body. The resulting disorganization of function in the brain is made evident by the delirium induced by high fever and the mental confusion accompanying hypothermia.

The body's heat-regulating mechanism is supposed to be in abeyance below an internal temperature of 75°F , because the activity of the underlying nervous structures is suppressed. The body then gains or loses heat like an inanimate object. The lower lethal temperature for the human is about 79.5°F (26°C), although lower temperatures have been induced with survival during therapeutic hypothermia. Death is due to cardiac failure. The upper lethal limit is not clearly defined, cases are recorded to have recovered after attaining a rectal temperature of 110.8°F (43.5°C). Probably the average upper limit is about 110°F (43°C). (See DuBois)

HEAT LOSS

Although the body temperature is in excess of the ambient temperature in temperate climates, the constant production of heat by metabolism necessitates a constant dissipation of heat. It is only under exceptional circumstances that in such climates the excess heat of the environment must be counteracted in addition to the normal metabolic heat. In cold weather where more heat is lost than can be balanced by that of the resting

FIG. 52.1 Variation of body temperature of different types of animals by sojourn for two hours in an environment of 5° to 35°C (After Martin)

metabolism extra heat is produced by increased muscular activity—increased tension of muscles, shivering, "goose flesh," and shaking. Throughout the range of moderate temperatures, i.e. within the comfort zone, neither shivering nor sweating occurs even while the body is at rest. Heat is lost from the body mainly at the skin surface, although some is lost through the respiratory passages where air comes in contact with the body.

Heat is lost from the body through (a) radiation, conduction and convection from the skin, (b) warming and humidifying inspired air, (c) evaporation of sweat and insensible perspiration, (d) urine and feces.

Of these various routes only (a) and (c) are directly under physiological control. The temperature of the skin determines the rate of heat loss from the body surface. The heat lost in warming and moistening the inspired air, and the rate of evaporation through the skin (insensible perspiration) will depend upon the temperature and humidity of the ambient air. It is only indirectly, by creating a "local climate" by means of clothing or air conditioned dwellings, that these avenues of heat loss can be regulated.

Under the ordinary conditions of every day life over 95 per cent of the total heat loss occurs through (a), (b) and (c). The heat lost in raising the temperature of the inspired air to body temperature (c) will, of course, vary with the air temperature, but at ordinary room temperatures it does not amount to more than 2 or 3 per cent of the total. Air is a very poor conductor, so in terrestrial animals conduction plays a very minor role except under special circumstances, as when

the body is in contact with a cool object, cold ground or immersed in water. Radiation is responsible for about 50 per cent of the total heat loss and convection for about 15 per cent (see table below). The heat lost in the urine and feces accounts for only 2 per cent, or less, of the total heat loss.

The total quantity of heat lost in 24 hours must, of course, just equal the amount produced, otherwise the body temperature would rise or fall. The heat production of an average man doing light work is about 3000 Calories. The proportions of this which are dissipated through the various channels at ordinary room temperature are given in the following table, in approximate figures.

	Calories	Per cent
(a) Radiation, convection and conduction	1950	65
(b) Evaporation of water from skin and lungs and liberation of CO ₂	900	30
(c) Warming inspired air	90	3
(d) Urine and feces (i.e. heat of these excreta over that of the food and water)	60	2
Total daily heat loss	3000	100

RADIATION AND CONVECTION AND THEIR VARIATION BY PHYSIOLOGICAL FACTORS

The rate of cooling of any warm object varies with the temperature of the air and of colder objects in contact with or near it. When a large temperature difference exists between the two, the warm object loses heat rapidly through radiation, convection and conduction. The rate of heat loss, however, becomes gradually less as the temperature of the object approaches that of the environment. The dead human body behaves in a manner similar to that of any inanimate object, taking from 10 to 20 hours on an average to reach the temperature of its surroundings. In the living body, on the other hand, factors operate to encourage or minimize heat loss, respectively, when the environmental temperature is high or low, or corresponding changes in the body's heat production occur.

The factors involved in heat conservation or heat loss are dependent to a large extent upon reactions of the autonomic nervous system. The following are the principal adjustments which take place in the blood vascular system. (a) *Redistribution of blood*. The subcutaneous tissue acts as an insulating layer. The insulating quality of

this layer can be altered by varying the blood flow through it. By the redistribution of blood the temperature of the skin may be adjusted to any temperature from about 15°C (59°F) up to the central body temperature. At a room (ambient) temperature of 34°C (93°F) the quantity of blood circulating through the skin may, according to DuBois, amount to 12 per cent of the cardiac output. Scott, Bazett and Mackie found that the blood flow through the fingers would increase from 1 cc per minute per 100 grams of tissue in a cool environment to 80 or 90 cc per minute upon exposure to heat. These changes may be initiated in one or all of four ways: a change in temperature of the blood supplying the nervous centers, reflexly through centers in the brain and cord in response to changes in skin temperature (stimulation of hot or cold spots, p. 1139), through local avon reflexes, and finally through responses of the vessels to direct stimulation by changes in external temperature. (b) *Variations in blood volume* (see p. 28). A rise in temperature causes an increase in blood volume, the blood is diluted by fluid drawn into the circulation from the tissues, chiefly the skin, muscles and liver. Blood is expelled from the spleen (p. 67). It has been found that an unacclimatized man is capable of increasing the total circulating blood volume by about 10 per cent in 2 or 4 hours on exposure to heat of sufficient severity to cause a diffuse cutaneous vasodilatation. The increased blood volume is chiefly in the plasma although additional cells may be added from the spleen. The initial increase of the blood is brought about by dilution with water drawn from the other cells, so that the hematocrit drops a little and the plasma protein concentration decreases. Associated with the decreased osmotic pressure of the plasma protein a mild edema of the ankles is frequently observed in unacclimatized persons suddenly exposed to heat. The body can manufacture the proteins rapidly so that after two or three days exposure to heat the blood osmotic pressure has been restored and the edema will disappear. At low temperatures the blood volume is reduced, the blood becoming more concentrated as shown by an increase in the percentage of blood solids. The sudden return to a cool environment causes a rapid decrease of blood volume associated with a marked diuresis. This is frequently seen in moving from the tropical plains in India to the temperate hill stations (Powell, personal comment). (c) *Increased circulation rate*. The increased cardiac output ensures a rapid blood flow through the dilated cutaneous vessels.

As already stated, half of the total heat loss is brought about through radiation. The human skin (of whatever color) within the range of the infrared to which it is usually exposed, is an almost perfect 'black body radiator.' That is to say, it radiates nearly all infrared rays¹ (up to 1 or 2 per cent) or absorbs to the same extent such rays as fall upon it (Hardy and Muschenheim).

The skin and the subcutaneous tissues when the vessels are constricted are a little more efficient as insulating material than a layer of cork of the same thickness (DuBois). The subcutaneous layer varies considerably in thickness in different persons and is thicker in women than in men. This accounts for the greater ability of women than of men to withstand cold.

The radiating surface of the standing human body is only about 85 per cent of the total surface area, for apposed surfaces, e.g., axillae, inner surfaces of the thighs and upper arms, do not lose heat to the environment by radiation. It is for this reason that one huddles in the cold and spreads out one's limbs in the heat. Adolph has shown that the nude man sitting in the sun absorbs on an average 143 Calories per hour by radiation; this is reduced by clothing. Molnar *et al* found that clothing by reflecting radiation can diminish the absorption of heat from the sun and sky by about 60 Calories per hour. On the other hand, clothing will reduce heat loss by radiation since the external surface of the clothing has a lower temperature than the skin and consequently radiates less heat. The main factor influencing heat loss through radiation is the temperature of surrounding objects relative to that of the skin. The body, for example, radiates heat to a block of ice but absorbs heat from a hot stove or radiator. It should be remembered that the air intervening between the body and the source of heat is not heated by radiant energy, but only by convection. Another factor, though a very minor one, is the humidity of the atmosphere. Air with a high water vapor content is more opaque to radiant heat than dry air. Heat lost through radiation is therefore slightly reduced when the relative humidity is high.

CONVECTION. The rate of movement of warm air from the neighborhood of a heated object varies, of course, with the temperature of the atmosphere. The clothed body has a layer of warm moist air in contact with the skin which tends to become trapped in this situation and in

the spaces of the clothing. In the absence of a temperature difference between it and the external air or of some movement to cause mixing, this air will remain practically stagnant and little or no heat is lost through convection. However, when the atmosphere is cooler, convection currents are set up which mix the air lying against the skin with fresh air. Convection is essentially dependent upon the relative densities of air at different temperatures, the warmer and lighter air rising, the cooler air falling. Dry air is denser than air possessing a high content of water vapor. One would expect therefore that changes in the humidity of the atmosphere should alter the heat lost by convection, but as a matter of fact, the relative humidity of the external air has little effect upon heat loss through convection. Probably the most important factor influencing heat loss by convection is air movement; the loss in creasing with the square of the wind velocity up to 60 miles per hour, a wind velocity beyond this exerts little or no further effect.

EVAPORATION OF WATER

It is obvious that the nearer the temperature of the environment comes to that of the blood the smaller will be the amount of heat which can be lost by radiation and convection. At an air temperature of about 98.6°F (37°C) heat loss by these means must cease. At higher air temperatures than this the body would actually gain heat if no other means of cooling were available. Large quantities of heat are lost to the body through the secretion and evaporation of sweat and the exhalation of water vapor, expired air being 95 per cent saturated with moisture. Its temperature can for this reason, be maintained constant when the atmosphere (dry) has a temperature about 150°F (65°C) above that of the blood. The heat absorbed in the evaporation of 1 cc of water amounts to 0.58 Calorie. Even at ordinary room temperatures when there is no obvious perspiration the heat lost through evaporation from the lungs and skin amounts to about 17 Calories per hour. About two-thirds of this is from insensible perspiration through the skin; the remainder from the lungs. Newburgh and his associates have found that people, living in a cool environment performing only the routines of life, lost heat by the insensible evaporation of water from the skin and lungs equivalent to about 24 per cent of the metabolic rate, the absolute amount depending upon the metabolic rate. At higher temperatures the increase in the proportion of heat lost by evaporation of water

¹ The wave length of the infrared rays emitted by skin at usual temperature (34°C) is 9.140 μ .

² This has been called the profile area.

FIG. 52.2 Rubner's chart showing the manner of heat loss in the dog at different room temperatures. Stippled area: heat loss in calories through evaporation of water, cross-hatched area: heat loss in calories through radiation and convection. The distance between opposite points on the curved boundary lines represents the total heat production at a particular temperature. (Redrawn and slightly modified from Luck.)

as compared with that lost by radiation and convection is shown in figure 52.2. It will be seen that evaporation plays little part in heat regulation until the air temperature reaches between 28° and 30°C (82° to 84.5°F); the heat loss by this means remaining nearly constant below this level but increasing rapidly above it. At a temperature above 35°C evaporation accounts for all or nearly all the heat lost.

It is to be remembered that evaporation from the body surface occurs quite independently of sweat secretion, for the skin is not entirely impervious to water, fluid extravasated from the cutaneous capillaries seeps into the epidermis. There is a continuous diffusion through the epidermis from the moist deep layers to the dry skin surface. The evaporation of this water that diffuses through the skin has been called insensible perspiration. The speed by which water diffuses through the skin is determined by the diffusion gradient and is greatest in dry atmospheres when the water vapor pressure of the air is low and the skin dries rapidly. It has been shown in persons in whom sweat glands were absent from birth that some 18 grams of water per square meter of body surface may be lost hourly by evaporation. This is about the same as that of a normal man under ordinary conditions, and represents a total daily heat loss of about 450 Calories for a body of average size (surface area 1.8 square meters), which is not far from the normal. At high temperatures, or even during mild exercise, however,

a person without sweat glands is at a great disadvantage, his body temperature is likely to rise.

The respirations are increased by a rise in air temperature or by a greater heat production, the heat loss through warming the inspired air and the vaporization of water from the lungs, and the liberation of CO₂, is thereby increased. Hyperpnea (panting) is the chief means possessed by the dog (in which functioning sweat glands are largely confined to the footpads) for increasing the vaporization of water and combating a rise in body temperature.

The rate of evaporation of water is influenced inversely by the degree to which the atmosphere is already saturated with moisture, i.e., by its relative humidity.² Sweat which is not evaporated but simply drips from the skin, of course does not increase heat loss. For this reason the sweating mechanism for the elimination of heat is badly crippled when the relative humidity is high.⁴ We

² It is dependent essentially upon the difference in the vapor pressure at the skin and of the surrounding air.

⁴ The relative humidity is defined as the ratio of the weight of water vapor contained in a given volume of air to the weight which the same volume of air would contain when saturated. The quantity of water vapor which air can hold when saturated increases with the temperature. The relative humidity is expressed as a percentage. Thus, if a sample of air at a certain temperature contains 20 per cent of the water vapor which it is possible for it to contain at that temperature, it is 20 per cent saturated, and so has a relative humidity of 20 per cent.

are all familiar with the insufferable heat of a hot humid day, and the comparative comfort when the air is simply hot and dry. A man can maintain a normal temperature in an atmosphere of from 210° to 260°F (a temperature that will grill a beefsteak) provided the air is perfectly dry, his ability to sweat profusely is sustained by large draughts of water, and evaporation is facilitated by stripping the greater part of the body's surface. On the other hand, a damp atmosphere with a temperature of 120°F causes the body temperature to rise rapidly, and cannot be endured for more than a few minutes. Evaporation and consequently heat loss by this means is greatly hastened by air movement. The layer of air nearly saturated with water vapor lying next the skin is thus replaced by drier air.

SWEATING

Sweat is a weak solution of sodium chloride in water together with urea and small quantities of potassium and lactic acid. It has a specific gravity of from 1.002 to 1.003. Its pH as reported by different observers varies from 4.2 to 7.5. The percentage of sodium chloride varies between 0.2 and 0.5. Muscular exercise increases the salt concentration, which is also higher in sweat secreted by clothed than by naked skin. The quantity of nonprotein nitrogen ordinarily excreted in the sweat, per day, is, according to Benedict, 0.071 gram; on the other hand, if the sweating is copious from 0.5 to 1.0 gram may be eliminated per hour. The actual concentration of nitrogen in the sweat falls, however, when sweating becomes profuse, whereas the concentrations of sodium chloride and potassium rise. However, when acclimatization has been established the percentage of salt diminishes. About 3 grams of salt daily are required after acclimatization to maintain the salt balance. Nevertheless, even after acclimatization, if strenuous work is performed for a long period in a high temperature and large quantities of water are drunk, depletion of the body's supplies of chloride and a lowered concentration of this element in blood and tissue fluids occurs, producing severe cramps in the muscles of the limbs and abdominal wall (heat or stoker's cramps, see p. 894).

THE CONTROL OF SWEAT SECRETION The sweat glands, which number over two and a half million in a man living in temperate climates, are cholinergic yet under the control of the sympathetic nervous system. These glands are, however, anomalous in their responses to sympathetic and parasympathetic drugs, in that they are stimu-

lated by muscarine, pilocarpine and acetylcholine, and inhibited by atropine (p. 1399). According to Coon and Rothman, the action of acetylcholine is *twofold*—stimulation of the glands directly through a muscarinelike action and through the imitation of axon reflexes (nicotinelike action). In man and most animals they are not excited by adrenaline nor paralyzed by ergotamine. The usual stimulus to sweat secretion is a rise in blood temperature which exerts its effect in two ways—directly upon the nervous centers, which is of more importance, and reflexly by stimulation of heat receptors in the skin. The sweat response to a rise in temperature is abolished by sectioning the nerves to a part and is therefore not due to direct stimulation of the glands. That a rise in temperature of the centers alone will induce the secretion of sweat has been shown by heating the hypothalamus in the cat (whose sweat glands are confined to the paw pads), sweating then occurs although the paws themselves remain cold. The centers may also be stimulated in man by the injection of pituitrin into the lateral ventricle. In the initial stages of muscular exercise sweating is apparently initiated by the discharge of impulses from the motor cortex. It occurs before there is any change in rectal temperature. Later on the effect of a rise in body temperature comes into play. In a man (indoor clothing) at rest, visible sweating usually commences at an air temperature between 27° and 32°C (80 and 90°F). Sweating may be induced by the experimental stimulation of regions of the diencephalon (hypothalamus, p. 1227). *Spinal centers for segmental control of sweating exist, for peripheral sweating occurs in quadriplegic patients who have complete transverse cervical cord lesions.* Such patients have lost temperature control to a large extent, for neither adequate sweating shivering nor changes in cutaneous blood flow can occur for the regulation of body temperature. Destruction of the sympathetic nerve supply to a part completely abolishes the sweating response to a rise in temperature. The sweat glands, however, still respond to pilocarpine and acetylcholine. The former drug, which has been employed in the past for the purpose of demarcating areas deprived of their sympathetic supply, is of no diagnostic value, for it acts peripherally, i.e., directly upon the gland cells. Sweating is not dependent upon the circulation for it occurs after occlusion of the vessels and can even be induced by stimulation of the nerves in an amputated limb. Although usually associated with cutaneous vasodilation it may occur with constricted

sweat." This is usually the result of psychic influences, e.g., nervousness, fear, fatigue or mental work. The sweating occurs most noticeably in these instances on the forehead, the palms of the hands, and the soles of the feet, which do not, as a rule give a pronounced response to heat. In many persons, reflex sweating, confined to the face and neck, is induced by eating spicy or appetizing food (gustatory sweating), or sometimes sweating over a remote part, e.g., the knee occurs. Faradic stimulation of the human skin over the forearm induces local sweating due apparently to direct stimulation of the glands, for it occurs after section and degeneration of the nerve supply.

The few observations that have been made upon the secretion pressure of sweat indicate that it is high, 250 mm. of mercury or more. Sweat is therefore a true secretion and not simply a filtrate. The secretion rate may be enormous, amounting to a liter or more per hour, and may be increased some 80 times over the normal by immersing the body in a bath at 108°F. At ordinary room temperatures the sweat evaporates as quickly as formed so that there is no apparent secretion.

HEAT PRODUCTION

The several factors which stimulate the chemical processes of the body and so increase the heat production have been dealt with in chapter 44. An account of the manner in which chemical and physical factors interact to maintain a constant body temperature remains to be given.

A low environmental temperature is a potent influence in stimulating heat production. At air temperatures below about 28°C (82.4°F) the body (nude) loses heat rapidly. Within the temperature range between 28° and 31°C (82.4°F and 87.8°F), the naked male body is able quite easily to maintain the balance between heat loss and heat production. There is neither sweating nor shivering and a male subject feels comfortable. This range of temperature is therefore called the "comfort zone." For reasons given below the comfort zone is broader (27° to 33°C or 80.6°F to 91.4°F) for women. The external temperature (about 23°C or 73.4°F) below which heat production must be increased in order to maintain a normal body temperature is sometimes called the "critical temperature."

Below the critical temperature heat loss by radiation and convection increases progressively with falling air temperature, but heat loss by vaporization shows little change. The naked body at a temperature below the comfort level (28°C or 82.4°F) loses more heat than it can produce in

the basal state, and at about 23°C (73.4°F) shivering occurs. Heat production is thus increased in an effort to raise the body temperature to the normal level. In the human, heat production is not increased until the onset of shivering and in nude men under basal conditions the metabolism remains constant within the range of air temperature from 35° to 23°C (96° to 73.4°F). It has been shown by Hardy and DuBois that this is not true for women. They show a reduced heat production of from 14 to 20 per cent at temperatures between 30° and 32°C (86° and 89°F). Also, owing to the greater insulation afforded by the thicker layer of subcutaneous fat the heat loss of the female body in a cold environment is some 10 per cent less than that of men. Thus women have the more efficient thermoregulating mechanism, being better able to maintain the heat balance at lower temperatures without shivering, and also to be more comfortable at higher temperatures.

The critical temperature and the temperature of comfort will vary of course with the amount and nature of the clothing. The cooling effect of water by conduction is some 20 times greater than that of air—a cold bath at 4°C (40°F) increasing the heat production some 5 times above the basal level. Few men can survive for long in very cold water, below 4°C (approximately 40°F) which is about the winter temperature of the sea in temperate latitudes. Heat production becomes depressed after immersion for 20 minutes or so, and the body temperature falls. In an experiment in Germany during the last war one man survived a temperature of 5.5°C (42°F) for three hours. His body temperature was then 25.2°C (77.3°F).

It will be seen from figure 52.3 that heat loss increases both above and below the critical temperature. At the lower temperatures heat is lost mainly by radiation and convection, at the higher temperatures mainly by vaporization. It will also be noticed that at the lower temperatures the skin temperatures follow a straight line, but that the curve commences to flatten out at around 30°C (87°F). This is attributed to dilation of the cutaneous vessels and the flooding of the skin with blood.

The muscular tissues (particularly of the extremities) and the liver, wherein numerous chemical reactions are carried out, are the main sources of the body's heat. The rise in metabolism which

* In cold blooded animals the metabolism as measured by the carbon dioxide output falls with the environmental temperature.

FIG 52.3 Showing effect of a rising air temperature on rectal and skin temperatures, heat loss, and vaporization. (Modified from DuBois.)

results from a fall in atmospheric temperature is effected through an increase in activity of the skeletal muscles and in some instances by fine involuntary contractions, e.g., shivering and chattering of the teeth and increased muscular tension. By these means the heat production may be increased approximately three times over the resting level. Contractions of the smooth muscle of the skin, giving rise to "goose flesh" also contribute heat. In some mammals and in birds, the contraction of the cutaneous muscles also curtails heat loss through ruffling of the hair or feathers. In man, too, the smooth muscle of the skin may, when stimulated by cold, cause erection of the fine hair on the body surface, the effect however is rudimentary and without value. After the skeletal muscles are paralyzed by curare, an animal loses the power to maintain a normal body temperature in a cold environment. Its ability to dissipate heat is, however, intact so that it can resist high air temperatures. Isolation of the muscles from control by section of the cord in the lower cervical region (C6) also abolishes the extra heat production. This operation divides as well the vasoconstrictor nerves which travel through the cervical cord to the sympathetic outflow in the thoracic region. A redistribution of blood is not possible, and the body temperature will fall if the animal is exposed to a low air temperature. The rise in body temperature in strenuous muscular effort is apparently due, not to any failure of

the heat-dissipating mechanisms, but because heat is produced more rapidly than it can be dissipated.

Food, especially protein through its specific dynamic action, is an important factor in the regulation of body temperature. At high environmental temperatures the specific dynamic action of food increases the heat production and adds an extra burden upon the heat loss mechanisms. For this reason a low protein diet is more suitable in hot weather. At very low atmospheric temperatures, on the contrary, the specific dynamic effect of food is almost completely masked, since it simply replaces the environmental effect (cold) upon heat production. That is to say, the neuromuscular mechanisms called into play to increase heat production at low temperature are less necessary since the food itself raises the level of metabolism. Protein food in cold climates is therefore a valuable aid to the regulation of body temperature.

The effect of protein ingestion upon the heat production of a dog at different temperatures is shown in table 52.1 (Lusk).

STORAGE OF HEAT The body has a large specific heat (about 0.85), so that a rise in the temperature of a 70 kg man of 1°C may increase the stored heat by about 60 Calories, or 2 per cent of the average daily heat production. A considerable storage of heat may occur in strenuous muscular exercise (140 Calories or so in a 100-yard sprint), and, until the heat-dissipating mechanisms become fully effective, the body temperature may rise 2°C or more. A rise in rectal temperature may also occur in a robust person after a cold plunge. The cold water causes, through vasoconstriction, diminished heat dissipation and through involuntary muscular action increased heat production. The body temperature may rise for a few minutes. After the first effect of the plunge the vessels are released from spasm, the stored heat is eliminated, the surface of the body glows

TABLE 52.1

Atmospheric Temperature	Heat Production in Calories per Kilogram of Body Weight		
	Starved	550 grams of meat fed	Increase
°C			
4 2	128	133	4
14 5	101	111	9
22 1	71	101	43
30 7	62	117	89

and a feeling of comfortable warmth is experienced. This constitutes the "healthy reaction" of a cold shower. A comparable drop in rectal temperature has been observed on suddenly passing from a temperate to a hot environment, or on entering a hot bath.

HEAT REGULATING CENTERS

Section of the neuraxis through the midbrain at the level of the superior colliculi, or at any level posterior to this and anterior to the lower cervical cord, renders an animal poikilothermic (fig. 524). Section of the cord in the upper thoracic region, i.e., above the level of the outflow of the greater part of the sympathetic fibers causes a gross disturbance in the temperature regulation. The muscles of the head, neck and forelimbs remain in communication with the brain, so that shivering in these parts will prevent a fall in body temperature. On the other hand, the hypothalamus has lost control over the temperature regulation of $\frac{2}{3}$ of the skin surface, and no sweat is produced for temperature regulation below the segmental

FIG. 524. Diagram to illustrate the nervous control of the heat regulating mechanisms (Modified from Martin.)

level of the lesion. Consequently, the body temperature tends to rise in warm environments, and may fall in cool environments, for the excess heat from shivering of the arms may be lost from the lower parts of the body. The effect of section through the brain stem indicates that the main center or centers controlling heat regulation must be anterior to the superior colliculi. Removal of the cerebral cortex, thalamus or corpus striatum does not destroy the controlling mechanisms so long as the hypothalamus remains intact. Destruction of this region alone, however, was found by Keller and Hare to abolish the ability to maintain a normal body temperature upon exposure to cold. The heat dissipating mechanisms remained intact and were, in fact, released from restraint by the hypothalamic lesion, as evidenced by pronounced panting, vasodilation, and sweating of the toe pads (of cats).

The thermoregulatory centers have been located more precisely by Ranson and his associates. From the results of their experiments upon cats and monkeys they place the centers controlling heat loss (sweating and panting) in the preoptic and supraoptic regions between the anterior commissure and the optic chiasma. Heating this area causes sweating and panting or rapid breathing and a fall in body temperature. Destructive lesions in this location are followed by hyperthermia when the animal is exposed to a degree of heat that would cause little effect upon the body temperature of a normal animal. Sweating or panting does not occur though the temperature rises to over 41°C (106°F). Such lesions have little effect upon the animal's ability to resist cold. The centers controlling heat production and heat conservation, i.e., the mechanism whereby an animal is enabled to maintain a normal body temperature when exposed to cold is situated according to these investigators, in the caudal part of the lateral hypothalamus, it appears to be identical with the sympathetic center. The existence of a center for shivering (heat production) in the hypothalamus is suggested by the fact that under certain circumstances shivering in animals is accompanied by some of the manifestations of "sham rage" (Barcroft and Izquierdo). That the posterior part of the hypothalamus contains the main shivering center is indicated by the experimental results of Keller and his associates and of Ranson and his colleagues who found that, in cats, shivering was abolished by a destructive lesion in this location. The efferent pathway for shivering is unknown, but an observation upon a patient in whom both spinothalamic tracts had been sec-

tioned and who did not shiver when the legs were immersed in cold water, suggests that the impulses descend the cord by these paths. The impulses are not transmitted by sympathetic nerves, since shivering occurs in sympathetomized parts. Shivering is reduced or abolished by certain drugs, especially calcium chloride and aminopyrine, which most probably act upon the shivering center.

From observations of patients with intracranial lesions involving the base of the brain, it seems most likely that in man the centers are situated as described by Ranson and his associates for animals. Lesions in the supraoptic region are sometimes associated with hyperthermia, hypothermia on the other hand, may accompany lesions involving the posterior part of the hypothalamus.

The main heat-regulating centers are apparently influenced in two ways—reflexly from the skin and by the temperature of the blood flowing through them.

The posterior hypothalamic center apparently exerts its controlling influence upon temperature through the transmission of sympathetic impulses to the cutaneous vessels, sweat glands and pilomotor muscles; removal of the sympathetic renders an animal unduly susceptible to cold (ch 71).

THE ENDOCRINES IN THERMOREGULATION

The thyroid and adrenals also play their roles, probably important ones, in the regulation of body temperature. The calorigenic effects of the secretions of these glands are well known (ch 57 and 58). Cannon observed that exposure to cold caused an increase in the rate of the denervated heart. It has also been reported that the serum taken from an animal exposed to cold raises the metabolism of a second animal into which it has been injected. If the first animal has been thyroidectomized the effect upon the metabolism of the second is not observed. The adrenal secretion exerts a calorigenic effect which is immediate and of short duration. Its liberation follows short periods of exposure to cold. But owing to the delayed action of the thyroid hormone and the persistence of its effects it does not seem possible that the thyroid could play any part in increasing heat production unless the cold stimulus were continued over a long period. Rats exposed over a period of weeks to low temperatures (78° to 122°C or 46° to 52°F) shows thyroid hyperplasia and a rise in metabolic rate of as much as 16 per cent which was not reached

however, until the lapse of from 2 to 4 weeks. Thyroidectomized rats, on the contrary show little rise in metabolic rate under the same conditions. The experiments of Uotila point to the pituitary as being responsible (influenced through the hypothalamus) for the thyroid response to cold; for hypophysectomy causes thyroid atrophy as usual, though the animals are exposed to a low temperature for long periods. It may be mentioned in this connection that the temperature tends to be subnormal in supradrenalectomized or thyroidectomized animals in Addison's disease, and in cretinism.

Disturbances of Heat Regulation (Other Than Fever)

Since the body temperature represents the balance struck between heat production and heat loss, an alteration in the value of one of these factors in relation to the other obviously will be followed by a change in body temperature.

Temporary rises in temperature may occur in health as a result of hot baths which prevent heat loss through convection, radiation and the evaporation of sweat as well as by actually adding heat to the body, or during violent muscular exercise which increases heat production. Since the metabolic rate can be increased easily and rapidly to several times the basal level, a fall in the temperature of a normal person is much more difficult to produce than a rise.

The heat regulating mechanisms are depressed by anesthetics, hypnosis and by general bodily fatigue. During sleep the heat regulating mechanisms continue to function though somewhat sluggishly. The body temperature falls a little reaching a minimum between 3 and 5 a.m.

There are four separate syndromes which result from exposure to excessive heat. These are *Heat exhaustion*, *dehydration exhaustion*, *heat cramps* and *heat stroke*. Although each of these syndromes is encountered in a pure form there is frequently an overlap of the syndromes and difficulty in distinguishing between them.

HEAT EXHAUSTION. Upon sudden exposure to a high temperature there is a dilation of the peripheral vessels greatly increasing the vascular space. The heart rate and cardiac output increase and the blood pressure may fall a little. If in addition physical work is performed the heart may not be able to maintain the blood pressure and the condition known as heat exhaustion ensues. The patient is confused, fatigued to exhaustion and feels hot. The skin is moist and sweating may be profuse. The pulse is rapid, the blood pressure

low The patient feels extremely uncomfortable and may be mildly dyspneic The symptoms are indicative of cardiac insufficiency The patient may collapse and lose consciousness He is very uncomfortable and dyspneic lying flat, and is more comfortable with his head and shoulders propped up (orthopnoea) The condition responds rapidly to rest and fluids by mouth

DEHYDRATION EXHAUSTION Although heat exhaustion may occur any time after exposure to heat it usually occurs when unusual physical demands are made upon an unacclimatized subject Dehydration exhaustion, however, occurs after longer exposure to heat, if the fluid loss is not replaced In a hot environment with extensive sweating the blood volume is reduced, this reduction in the blood volume associated with the larger vascular space again produces cardiac insufficiency and exhaustion to collapse As dehydration progresses the heart rate rises and exertion becomes progressively more difficult Ultimately even standing becomes an intolerable strain This exhaustion occurs when the body has lost about 5 per cent of its weight The patient may suddenly collapse unconscious with an extremely rapid heart rate General discomfort and extreme fatigue are the main symptoms just before collapse Dehydration exhaustion responds to rest restoration of body fluids and cooling of the body Again orthopnoea may be a prominent feature Water may be administered by mouth or intravenously The intravenous fluid provides a rapid recovery, but fluid by mouth is satisfactory Death from dehydration exhaustion occurs suddenly with little warning and may be preceded for some hours by extensive edema of the legs, indicating the cardiac origin of the syndrome (see Rawicz)

HEAT CRAMPS If the sodium chloride content of the body is decreased, as will occur with sweating and a low salt intake, exertion will induce severe painful muscle contractures After exertion these painful cramps will continue until the salt balance is restored The administration of sodium chloride, either by mouth or parenterally, will rapidly cure the cramps In order to maintain the salt balance under desert conditions, 2 grams of salt should be provided for each hour of exercise and $\frac{1}{2}$ gram for each hour of rest This averages about 24 grams per day

HEAT STROKE This is a rare condition compared with heat exhaustion It is characterized by a rising temperature with a dry skin The patient, apparently well, may suddenly become unconscious The rectal temperature is high 41° to 43°C (106° to 110°F) There appears to be a complete breakdown of the heat regulating mechanisms Unless the temperature is promptly reduced, there may be permanent damage to the nervous system Heat stroke often terminates in death The pathogenesis of heat stroke is obscure, its onset usually

occurs with exertion, which may be quite mild It is probable that heat stroke requires an intercurrent infection, the toxins from which disturb the heat regulating centre in the hypothalamus

SUN STROKE is a term applied to those cases of heat stroke that occur during exposure to tropical sun Powerful sunshine itself, however, will not cause sun-stroke provided heat dissipation is adequate to keep pace with heat production, i.e., when the air is dry and cool and strenuous exercise is not undertaken

The frequent occurrence of heat exhaustion and heat stroke among British troops serving in the tropics during the nineteenth century was probably due to lack of understanding of the mechanisms of heat regulation and the use of quite unsuitable uniforms The use of toupées and spinal pads is quite unnecessary if proper clothing and adequate water are provided

Fever—Pyrexia

There are 5 types of fever (1) *Infectious fever*, e.g., sepsis, typhoid pneumonia, etc (2) *Surgical fever* which arises after an extensive aseptic operation and is apparently due to toxic substances liberated by the injured tissues (3) *Neurogenic fever* from injuries to nervous centers, especially lesions in the neighborhood of the third ventricle, internal capsule, medulla or upper part of spinal cord (4) *Fever of dehydration* due to a reduction of blood water (anhydremia, p. 25) This is particularly likely to occur in young children (5) *Fever produced by drugs and other chemical substances*

Body temperatures as high as 45°C (113°F) have occasionally been reported but survival with a hyperpyrexia above 44.5°C (112°F) is rare In the great majority (over 95 per cent) of fevers, from whatever cause, the temperature does not exceed 41°C (106°F) Temperatures higher than 41.6°C (107°F) become harmful or dangerous from the high temperature itself The infrequency of temperatures above 41°C (106°F) suggests that some safety thermostatic mechanism comes into operation around this level

Intravenous injections of concentrated solutions of glucose or salt induce fever by causing anhydremia (p. 25) Drastic cathartics, by drawing water from the blood into the bowel may cause fever in a similar manner Caffeine and cocaine in large doses induce fever by increasing muscular activity (greater heat production) and by causing blood concentration (reduced heat loss) Hemoglobin solutions when injected into the blood stream exert a pyretic action, the hemolysis resulting from the intravenous injection of distilled water acts similarly The manner in which the fever is produced is unknown β Tetra

hydronaphthylamine injected subcutaneously raises the temperature by its action upon the central and peripheral sympathetic mechanisms, causing cutaneous vasoconstriction and consequently a greater conservation of heat. It also, through its action upon the muscles, causes increased heat production. The adrenal medulla is also probably stimulated by this drug and the outpouring of adrenaline may be an added factor in the temperature rise. Ergotamine causes a rise in temperature in some animals (cat), presumably through a direct action upon the heat centers. Dinitrophenol, a drug sometimes used in the treatment of obesity, and injections of foreign protein also raise the body temperature. Dinitrophenol acts by stimulating oxidative processes in the tissues. Adrenaline and thyroxine in large doses may also, through their stimulating effect upon the metabolism, cause a rise in temperature.

INFECTIOUS FEVERS

At the onset of an acute infectious fever the heat regulating center brings into action the mechanisms to conserve heat. It is as if the "thermostat" had been set to a higher level. This is brought about by the action of the bacterial toxins on the heat regulating centers in the hypothalamus. There is a redistribution of the blood flow, with constriction of the skin vessels, producing a cold, pale or slightly cyanotic skin. This reduces the heat loss by radiation and conduction. Since the normal comfortable feeling of warmth depends upon stimuli from temperature sensory endings in the skin and subcutaneous tissues, there is a feeling of cold. This is known as a *chill*. If this heat conserved by the redistribution of the blood flow does not raise the internal temperature fast enough, shivering and the other reactions of a normal person exposed to severe cold, occur. Such violent shivering at the onset of a fever is known as a *rigor*. The involuntary contractions produce heat, which with the constricted skin vessels causes a rapid rise in the internal temperature. The chills and rigors occur as the body temperature rises. When the "new setting of the thermostat" has been reached, and the fever is at its height, an unstable state occurs. Usually the skin is flushed, hot and dry but sweating or chills may supervene rapidly. At the elevated body temperature the basal metabolism is elevated 7 per cent for every $^{\circ}\text{F}$ rise (p. 766). The effect of fever on the basal metabolic rate is shown in figure 52.5.

DuBois, in an experiment upon a normal man and a malarial fever patient, demonstrated the reduced heat elimination which occurs during the

chill. The normal subject imitated as closely as possible for a period of 34 minutes the shivering of the patient and thereby increased his heat production by nearly 200 per cent. Most of the extra heat was eliminated as it was produced, the body temperature showing only a slight rise. In the malarial patient, on the contrary, in whom the heat production during the chill was increased to about the same degree, all the extra heat was retained. The heat retention caused a rise of 2°C in body temperature. After the chill the heat elimination rose and the temperature fell.

The "continued" fever, which usually follows the initial chill of an infectious disease, or which develops in other instances without this preliminary, is due essentially to the raised threshold for heat loss. There is, of course, increased heat production but this is mainly secondary—the velocity of the oxidative processes of the tissues being increased by the rise in temperature induced by the diminished heat elimination. That the latter, rather than increased heat production, is the principal factor in the elevated temperature is indicated by the fact that in fever a temperature of 104°F (40°C) is accompanied by an increased heat production of only about 35 per cent whereas in health the heat production must be increased several fold (as in muscular exercise) in order to raise the body temperature even transiently to this extent. Also, the metabolism may be raised 40 per cent or so in an animal by protein feeding (see specific dynamic action, p. 787) without the occurrence of a temperature rise. Furthermore, the increased metabolism in ordinary fevers occurs simultaneously with the temperature rise. If the latter were the result rather than the cause of the former, it should be possible to demonstrate by indirect calorimetry a period of increased

FIG. 52.5 Relationship between basal metabolism and body temperature in fever. Results in six different fevers grouped in one chart. The continued line shows the average metabolism; the interrupted lines the metabolism 10 per cent above and 10 per cent below the average respectively. (After DuBois.)

metabolism preceding the rise in temperature, this, however, does not occur

When the infection has been overcome, the "thermostat" setting is returned to normal. This may occur rapidly as in malaria or the resolution by crisis in pneumonia, or gradually as in the resolution by lysis. In either case the body must dissipate the excess heat. The skin is flushed, warm and moist. In the crisis there will be profuse sweating. When the temperature regains its proper level, the normal heat regulating mechanisms again come into play.

SPECIAL METABOLISM IN FEVER

Water and salt. At the onset of a high fever there occurs a retention of chloride which apparently is deposited in the tissues, the chloride concentration of the blood being normal or below normal. The urinary chlorides in most fevers are greatly reduced. During the course of the fever there is a pronounced reduction in urine volume. The vaporization of water from the skin is increased owing to the high temperature, and from the lungs for the same reason, but to a more important extent, as a result of the more rapid breathing.

At the termination of the fever the retained water and chloride are eliminated by diuresis and sweating. Chloride retention is especially pronounced in pneumonia.

Protein. The excretion of nitrogen in the urine is greatly increased in most infectious fevers. This is furnished by body protein, the protein minimum, i.e., the wear and tear quota of protein metabolism (p. 786) being much higher than normal. In very severe infections from 300 to 400 grams of body protein may be destroyed daily. It has been found impossible to maintain the fever patient in nitrogen equilibrium (p. 785) by giving liberal allowances of protein combined with supplies of carbohydrate which under ordinary circumstances would be considered quite adequate for energy purposes. It has, therefore, been held that the toxins of the disease were responsible for the protein destruction, the so-called "toxic destruction" of protein. It has been shown, however, by Schaffer and Coleman that if a diet be given possessing a caloric value 50 to 110 per cent in excess of the patient's requirements, as actually determined by calorimetry, and containing a liberal supply of protein (160 to 200 grams), nitrogen equilibrium can be established. The high protein catabolism which has been observed in fever patients on the usual diet is therefore thought to have been due in large measure to the fact that

the caloric intake was far below the requirements, which owing to the higher metabolism in fever are considerably greater than has been supposed. In other words, a fever patient upon a diet which has been considered adequate in the past is actually in a half-starved state, and is, in consequence, forced to consume his own tissues.

Nevertheless, even on a high caloric diet composed of carbohydrate and a small quantity of fat, the nitrogen excretion still remains well above that of a normal person. Moreover, a protein allowance equivalent to that of a healthy man together with carbohydrate somewhat more than sufficient to cover the calculated caloric requirements of the febrile state, will not maintain nitrogen equilibrium. As just mentioned, the caloric allowance must in some instances be double the heat production of the patient. It therefore appears that the toxic process itself must be responsible in part for the increase in protein metabolism. Creatinine, uric acid, purine bases and phosphates also appear in the urine in increased amounts—further evidence of a destruction of body protein. The manner in which the "toxic" effect is produced is not known. It does not seem to be due merely to the high temperature, for raising the temperature of a normal person to 40°C (104°F) by immersion in a hot bath does not increase the nitrogen excretion significantly. In fevers with much destruction of body protein the specific dynamic action of food is absent.

It must be apparent from the foregoing remarks that in order to reduce the waste of body tissue in fever a liberal diet should be given, provided such is not contraindicated by some special feature of the disease. The old adage "feed a fever" holds true. Since the very high protein diet required for the establishment of nitrogen equilibrium in the fever patient has its disadvantages, one must usually be satisfied with reducing the waste of body protein rather than aiming to abolish it. Special attention, therefore, is directed toward furnishing an abundance of protein-sparing food (p. 786), namely carbohydrate, and thus avoiding excessive quantities of protein. The more abundant diet causes a negligible increase in heat production and no elevation of the temperature.

Fats and carbohydrates. The metabolism of body fat or carbohydrate shows no definite abnormality in fever. In patients upon a low food intake body fat and glycogen are utilized as fuel. Acidosis results from the excess combustion of fat only if the available carbohydrate is inadequate in amount.

THE ACTION OF ANTIPYRETIC DRUGS (FEVER REDUCING)

A list of chemical substances which are capable of inducing a rise in body temperature has been given on page 766. Other drugs, e.g., anti-pyrine, acetylsalicylic acid (aspirin), salicylates, quinine, etc., although they exert little effect upon the normal temperature, lower the temperature in fever by increasing heat elimination. According to Barbour they bring about this effect through drawing water from the tissues into the vessels and thus increasing the volume of fluid in the body's heat radiating system. They seem to exert little effect upon heat production. The effect upon the blood volume is possibly brought about indirectly. All these substances raise the blood sugar, the greater sugar concentration may then through osmotic forces attract water into the vascular system.

Morphine and general anesthesia depress cerebral activity, including the regulation of body temperature. During some stages of anesthesia sweating may occur which further disorganizes the regulation of body temperature. The anesthetic reduces metabolic activity, hence less heat is produced. The temperature of an anesthetized patient is liable to shift, either up or down depending upon the room temperature and the coverings. Under the drapes in an operating room body temperature frequently rises, but if left uncovered in a cool room the temperature will fall.

Alcohol causes cutaneous vasodilation. This hastens heat loss, for the skin is warm and often moist. The warm skin gives a sensation of warmth, hence the belief that alcohol will warm a person who is suffering from cold. In fact it increases heat loss and may cause a lowering of body temperature.

THE VALUE OF FEVER. Fever is frequently the herald of serious disease, nevertheless unless of high degree and on this account endangers the functions of vital tissues, it should not be looked upon as a reaction detrimental in itself. On the contrary, there is every indication that its occurrence is an important aid to the body in its combat with the disease. It is well known, for example, that in infections that overwhelm the patient the fever reaction is depressed. But the role played by fever in the defensive process is unknown. It has been suggested that antibodies can be elaborated in adequate amounts only at higher temperatures.

In support of the belief that moderate fever is not injurious in itself but is actually beneficial the following observations upon animals may be cited. (a) The body temperature of rabbits has been maintained by the application of external heat at a level of over 40°C (105°F) for weeks at a time without ill effects. (b) In animals infected with certain microorganisms the disease

runs a milder course when the temperature is raised (to 40°C or 104°F) artificially. High temperature is thought to be favorable for the elaboration of antibodies. (c) It has been reported that with moderate overheating the formation of various antibodies is increased, but at higher temperatures the process, apparently, is depressed. (d) The immunity of fowl to the ordinary pyogenic infections is ascribed to their higher body temperature which is inimical to the growth of pus forming bacteria. (e) Fevers induced artificially by means of foreign proteins or injections of malarial blood are used as therapeutic agents in arthritis and in chronic nervous disease due to the pathogen of syphilis (*Treponema pallidum*). Short wave diathermy has been employed with success in the treatment of certain infections—the high temperature produced in the tissue exerting a lethal action upon the microorganisms. (f) In the past it has been common practice to reduce fever (above 40°C to 104°F) by cold bathing, but it was found that the patients did not do well and the practice except in an extremely high fever which is dangerous in itself has been abandoned.

REFRIGERATION—HYPOTHERMIA. The lowering of the body temperature occurs when the rate of cooling exceeds the rate of the heat production. This can occur with inadequate clothing in freezing weather, but will occur much more rapidly in water. As the temperature of the tissues fall, their metabolic rate falls, the oxygen needs are reduced and the circulation can be interrupted for a much longer time without damage. For these reasons hypothermia is induced artificially to protect the brain during operations on the heart and great vessels, or upon intracranial vessels. The patient is given a sedative and a drug such as chlorpromazine to inhibit shivering. Under minimal anesthesia the patient is placed in ice water. The rectal temperature will fall to 30°C (86°F) in 1½ to 2 hours. Respiratory and heart rates fall, the blood pressure is reduced a little to about 90/70. Urine production is decreased.

THE VITAMINS

HISTORICAL INTRODUCTION

The increasing understanding of metabolic processes has revealed that some of the enzymes catalyzing vital reactions need, as cofactors, minute traces of organic compounds. These cannot be made by the body and, therefore, must be supplied in the food. These compounds, now known as vitamins, posed nutritionists and biochemists with many a complex riddle. The student is referred to textbooks of biochemistry for details of the structure and properties of the vitamins. The present discussion will review their discovery, occurrence and principal functions.

Vitamins have been defined briefly as organic compounds required in minute amounts for normal health. Expanding knowledge of the metabolic roles of the vitamins makes it increasingly difficult to formulate a definition that is concise and yet complete. They occur in natural foods (either as the vitamin itself, or as a precursor) and are neither oxidized to supply energy nor used to build tissue structures.

Some 20-odd growth factors for animals have now been identified, but only about 15 (or fewer) seem to be required by man. For historical reasons they are usually classified and referred to as fat-soluble vitamins (A, D, E and K) and water-soluble ones (B complex and C). More than a dozen components have now been isolated and identified in the water-soluble group: thiamine, riboflavin, nicotinamide, pyridoxine, pantothenic acid, para amino benzoic acid, choline, inositol, biotin, lipoic acid, folic acid, folinic acid and cyanocobalamin, ascorbic acid (vitamin C) and certain flavanoids (vitamin P) are in this same category.

Sir Frederick Gowland Hopkins (1861-1947) of Cambridge University in England is generally credited with the first experimental proof that accessory food factors are necessary to supplement the five well-known dietary essentials: water, minerals, protein, carbohydrate and fat. Many years earlier several clinical and experimental studies had pointed clearly in the same direction but the publication in 1912 of Hopkins' findings

nourished a world-wide interest in this new field. At about the same time Stepp in Germany was reaching similar conclusions.

Historical Review Development of the Vitamin Concept

A brief review of the discovery of the vitamins will serve to acquaint the student with the nature and seriousness of deficiency disease that were in former times the mysterious cause of millions of deaths. It will also show how the vitamin concept had its origins.

SCURVY Scurvy is said to have afflicted the Crusaders. During the 1400s and 1500s it was apparently one of the more prevalent diseases in Europe. It attacked with particular virulence the inmates of besieged garrisons and sailors on long voyages. Vasco da Gama reported the death by scurvy of 100 sailors out of the crew of 160 men, and Jacques Cartier, obliged to winter in Canada in 1535, lost one quarter of his men and the remainder were severely ill with the disease. Strangely enough, in view of its prevalence in Europe, Cartier wrote that "the disease was wholly unknown to us." From the Indians Cartier learned the curative value of a decoction of the leaves and bark of twigs of the 'annedda' tree, apparently the cedar, *arbor vitae*.

Admiral Sir Richard Hawkins mentioned in 1593 that within his own personal experience 10,000 seamen had died of scurvy, and he reported that the juice of oranges and lemons was able to cure the disease. As early as 1601 the ships of the East India Company had adopted the regular use of oranges and lemons to prevent scurvy, apparently upon the recommendation of the English privateer, Sir James Lancaster.

In 1720 a physician to the Austrian army, Kraemer by name, had written of scurvy and reported that a supply of green vegetables, or of oranges, lemons or limes could cure this dreadful disease without other help. Captain Lind of the British navy wrote a celebrated *Treatise on Scurvy* in 1753 in which he reported experiments on sailors which proved beyond doubt that "salads, summer fruits, etc." would prevent the disease and that the severest cases could be so cured within six days.

BERRERI Three other diseases, lagra and rickets, are now known to

origin. The patient suffering from beriberi first notices numbness in his legs. Later pain develops in the calf muscles. Exhaustion, emaciation and paralysis, with increased heart rate and enlarged right heart lead to death from heart failure. One of the most characteristic features, clinically, is peripheral neuritis. Nearly 80 years ago, Admiral Takaki, Director General of the Medical Service of the Japanese navy, had convinced himself that beriberi, which sometimes crippled up to 50 per cent of the sailors on long voyages, was due to some fault in the diet. He arranged in 1852 to have the usual diet (largely of polished rice) on a Japanese training ship augmented with meat, fish and other protein rich items. The improvement in the health of the sailors was so dramatic that the diet throughout the Japanese navy was similarly enriched and beriberi vanished. But in other parts of the world thousands continued to die from the disease which was still commonly believed to be due to poor sanitation, to contaminated rice or to a microbe.

In 1890 Eijkman (1853-1930), a medical investigator in the Dutch East Indies, accidentally made an observation which led him to discover an analogous disease in chickens. Birds fed milled (polished) rice developed polyneuritis and other signs resembling those of patients with beriberi. If they were fed unmilled rice, or if the bran was restored to their ration, the birds recovered. Eijkman soon showed that the curative principle could be extracted from the bran with water or alcohol and that it was dialyzable.

Eijkman thought that he had discovered a pharmacological antidote against the "toxin" or "microbe" in polished rice, but his colleague, Grijns, suggested in 1901 that beriberi was caused by a lack of some substance essential to the metabolism of the nervous system.

THE "VITAMINE" CONCEPT. Attempts to isolate the protective or curative principle from rice bran followed the adoption of Grijns's deficiency theory. Dr. Casimir Funk, of the Lister Institute in London, was among those who were more successful in their efforts to isolate Eijkman's anti-beriberi substance. When he thought he had it in pure form, Funk proposed for the substance a name which has since become famous. At the suggestion of Dr. Max Nierenstein the term *vitamine* was applied because the compound, he thought, was an *amine* that appeared to be essential to life.

Funk was also the originator of the "vitamine theory." He suggested in 1912 that there were four different vitamins: his anti-beriberi vitamin, an anti-scurvy vitamin, and probably also anti-rickets and anti-pellagra vitamins. Funk was led to this conclusion by a careful study of the pertinent medical and experimental literature. Some clinical observations pointing in this direction have already been described. Several other medi-

cal and earlier experimental studies will now be mentioned.

In 1888 Lunin, a student with Professor Bunge at Basle, had reported that mice could not survive on synthetic diets composed of purified proteins, fats and carbohydrates, plus mineral salts and water. Thus Lunin provided proof over 70 years ago that the known components of natural foods are unable to support life, and he drew the logical conclusion that natural foodstuffs (such as milk) must contain small quantities of unknown substances indispensable for normal nutrition. In the next 20 years many other workers confirmed the inability of the known dietary components to support growth.

In 1905 a Dutch physiologist, Pekelhaar, published the results of experiments actually done some years earlier which showed that a very small amount of whole milk added to an artificial food mixture (i.e., made from purified chemicals) was able to transform the mixture to a nutritious food. Pekelhaar wrote "there is still an unknown substance in milk, which, even in very small quantities, is of paramount importance to nutrition." Similar experiments by Hopkins, published in English in 1912, and Funk's vitamin theory published in the same year, finally drew the attention of physiologists and chemists throughout the world to new fields of knowledge—clinically, to a group of affections that came to be recognized as *deficiency diseases*, and chemically, to a class of substances of great potency that would prevent and cure such diseases.

ARE GROWTH FACTORS AND "VITAMINES" THE SAME? For a period there was confusion as to whether only one or more than one factor was needed for growth, and whether the growth factor(s) were the same as the vitamin(s) that cured beriberi and scurvy. In 1915 E. V. McCollum and Margaret Davis showed that there are two growth factors at least: *fat soluble A* found in butter and in egg yolk but not in all fats (e.g., lard and olive oil lack it), *water soluble B* found in the watery part of milk, in watery or alcoholic extracts of egg yolk, in whole wheat or whole rice, but not in polished rice. It was soon found that the water soluble B growth factor could cure polyneuritis in birds, indicating the presence of Funk's anti-beriberi vitamin in the water soluble B factor. Some workers were therefore tempted to assume that the growth factors and Funk's curative vitamins are one and the same.

Over the years, as one after another of the protective compounds was isolated from foodstuffs, and its chemical nature established, it was found that many were not amines. McCollum and Kenedy (1916) had pointed out that the word *vitamine* connoted a vital function, but that such a property had not been demonstrated for the growth factors. They, therefore, rejected Funk's

term and proposed fat soluble A and water soluble B. However, the terminology was cumbersome, and Funk's designation had much popular appeal. In 1920 J. C. Drummond (1891-1952) proposed that the final *e* be dropped to avoid the indication of amine character and that these interesting substances (until fully characterized chemically) be provisionally called vitamin A, B, C, etc.

After McCollum and Davis proved that for the satisfactory growth of rats at least two different factors are required, the question arose as to how many growth factors there were and whether these were really the same as Funk's vitamins.

A few years earlier, Holst and Frolich in Norway, while trying to induce beriberi by feeding purified diets to guinea pigs, had produced instead a condition which they recognized as scurvy. Further work showed, as Funk had suggested, that the specific substance capable of curing scurvy differed from fat soluble A and water-soluble B. Hence it was called vitamin C.

RICKETS The number of recognized accessory food factors increased to four when the studies of Sir Edward Mellanby (1884-1956) in England and of McCollum and of Sherman and their associates in the United States showed that so called fat soluble A was not a unit substance but a complex of at least two factors. Mellanby was seeking the cause and cure of *rickets*, a bone disease known for at least 300 years to afflict especially children living in crowded industrial cities in the northern temperate zone (see also p. 910). Across the Channel A. Trouessart, in 1865, had described cod liver oil as the perfect cure for rickets. Almost 30 years earlier another Frenchman, Jules Guerin, convinced that rickets is caused by faulty diet, had proved his point by producing the disease experimentally in puppies. In France and the Baltic countries the virtues of cod liver oil were quickly recognized. But in England and many other countries rickets continued to deform and cripple thousands of children each year because medical teaching favored lack of lime salts, infection, hypothyroidism or confinement and lack of exercise as causes. The situation was very confused when in 1890 an English physician, T. A. Palm, made a thorough study of a widely held belief that exposure to sunlight prevents rickets and could even cure the disease in children. His data showed that rickets is common in cloudy regions and rather rare wherever sunshine is abundant. In 1919 Huld and Schinsky, in Berlin, had the idea of using artificial sunlight (ultraviolet rays) and was successful in curing rickets by so called actinotherapy. Mellanby at Cambridge (1919, 1921) showed that cod liver oil and other animal fats (e.g., butter and fat of egg yolk) that were known to contain the fat-soluble A of McCollum and Davis protected puppies against rickets. This observation provided experimental proof that a dietary factor is con-

cerned in rickets, and Mellanby at first assumed that it was fat soluble A. In 1921 McCollum and associates showed that certain foods (e.g., carrots and green vegetables) failed to prevent rickets although they are rich in vitamin A activity. Further, it was soon found, both in Britain and the United States that the treatment of cod liver oil with a stream of hot air to destroy vitamin A did not eliminate the rickets preventing effect. The two factors must therefore differ. Since 1923 the antirachitic factor has been called vitamin D.

In 1924 two Americans, Hess, a physician, and Steenbock, a biochemist, independently made a surprising discovery, rickets could be prevented by irradiating the food of the animal with ultraviolet light just as well as by treating the animal itself. The solution to this puzzle proved to be, of course, that in both cases an inert precursor was converted by the ultraviolet light to the biologically active substance, vitamin D.

PELLAGRA Meanwhile evidence had been accumulating that water soluble B was not a single factor but probably a complex mixture. Beriberi is practically unknown in Europe and America but in parts of the United States, in Egypt, Italy, Rumania and other countries where Indian corn (maize) is eaten, largely to the exclusion of other foods, another disease, *pellagra*, was very common. Between 1910 and 1930 pellagra, sometimes called the corn-eaters' disease, was extremely prevalent in the southern regions of the United States. The skin in this disease becomes bronzed and thickened, especially where exposed to sunlight, the tongue is swollen and glossy and mental troubles develop, which progress to dementia in the last stages. It was referred to as the disease of the "three D's"—*dermatitis, diarrhea and dementia*, and although at first its cause was unknown, it came in time to be associated with the use of a diet known as the "three M's"—*maize meal, molasses and meat* (salt pork). Dr. Joseph Goldberger (1874-1929) was put in charge of a study of pellagra sponsored by the United States Public Health Service to determine whether it was caused by an infective agent, a chemical toxin, an amino acid deficiency or lack of a pellagra preventing factor (the P-P factor). Goldberger's associates eliminated the possibility of an infective agent and showed that most foods rich in 'vitamin B' would prevent and cure pellagra. Lack of a suitable experimental animal delayed progress until it was found that dogs fed a certain purified diet developed a sore mouth, called "black tongue," resembling the oral lesions so characteristic of human pellagra. In 1926 Smith and Hendrick showed that the water soluble growth factor B, (which seemed to be the same as the beriberi preventing substance of Funk), contained two different substances, one destroyed by heat, and one heat-stable. The latter was soon found to cure pellagra.

TABLE 53 1

The vitamins

Original Name	Currently Accepted Name	Alternative and Obsolete Names	Effect of Deficiency ^a	Human Daily Requirement ^b
Fat soluble A	Vitamin A ₁	Axerophthol, Bioosterol, Ophthalamin, Anti infective vitamin	Keratization of epithelial structures, night blindness	5000 IU
	Vitamin A ₂ (Carotene)	(Provitamin A)		(7500 IU)
Vitamin D	Vitamin D ₂	Calciferol, irradiated ergosterol, ergocalciferol	Rickets, osteomalacia	(400 IU)
	Vitamin D ₃	Cholecalciferol, activated 7 dehydrocholesterol Antirachitic vitamin		
	Vitamin E	Alpha tocopherol, fertility vitamin, anti sterility vitamin	Sterility, muscular dystrophy	Unknown
	Vitamin K	Methylnaphthoquinone, menadione, antihemorrhagic factor, prothrombin factor	Bleeding	Unknown
	Lipoic acid	Thioctic acid, pyruvate oxidation factor, protogen	Growth failure (microorganisms)	Unknown
Water soluble B	Thiamine	Vitamin B ₁ Aneurin Oryzamin Torulin	Beriberi, polyneuritis	1.8 mg
B ₂ or G (later found to be a mixture of vitamins)	Riboflavin	Vitamin B ₂ Vitamin G, lactoflavin Ovoflavin	Loss of appetite and weight, unspecific lesions, corneal vascularization, (cheilosis, dermatitis)	1.8 mg
	Nicotinic acid Nicotinamide	Niacin (USA) Niacinamide (USA), PP factor	Pellagra	1.8 mg
Vitamin B ₆	Vitamin B ₆ Three active related compounds	Pyridoxine Pyridoxal Pyridoxamine Adernin, yeast eluate factor	Dermatitis in rats, microcytic anemia in dogs, convulsions in infants (?)	2.0 mg (?)
	Pantothenic acid	Antidermatitis factor liver filtrate factor	Dermatitis in chicks, spastic gait in pigs	Unknown
	Biotin	Bios H, Bios HIB, vitamin H, factor W, coenzyme R	Dermatitis, gastrointestinal symptoms, lassitude	Unknown 300 µg (?)
	p Aminobenzoic acid	Anti gray hair factor, bacterial growth factor P, PABA or PAB	Graying of hair	Unknown
	Folic acid	Pteroylglutamic acid (PGA), vitamin M, factor U, vitamin Bc	Macrocytic anemia	0.5 mg
	Foline acid	Citrovorum factor (CF), Leucovorin		

TABLE 53 1—continued

Original Name	Currently Accepted Name	Alternative and Obsolete Names	Effect of Deficiency*	Human Daily Requirement†
	Vitamin B ₁₂	Cyanocobalamin, animal protein factor (APF)	Macrocytic anemia	12 µg
	Choline		Fatty livers, (cirrhosis)	Unknown
	Inositol	Inosite, meso inositol, muscle sugar	Alopecia	Unknown
	Lipothiamide	(see lipoic acid)		
Vitamin C	Ascorbic acid	Hexuronic acid, antiskorbutin	Scurvy	75 mg

* Only the main effects can be shown here. See text for further details and for species concerned.

† The concept of exact nutrient requirements suggested by a single figure in a table is misleading. Great variation is encountered for a number of reasons: (1) biological variation, (2) effects of age, sex and environmental factors, (3) effects of dietary composition, e.g. the nicotinic acid requirement is influenced by the tryptophane content of the diet.

Goldberger called it the P P factor but many Americans referred to it as vitamin G, in honor of Goldberger. The antineuritic factor they continued to call vitamin B. In Britain the antineuritic factor was referred to as vitamin B₁ and the antipellagra factor as vitamin B₂. The latter term became internationally accepted. Later the B₂ fraction was shown to consist of a number of vitamins.

This historical introduction would not be complete without mention being made of other accessory food factors that have subsequently been discovered as the techniques of preparing "purified diets" have been perfected. The isolation of vitamins A, B₁, B₂, C and D in pure form, their chemical identification and eventual availability in crystalline form made possible the recognition of other growth factors: choline, nicotinic acid, pyridoxine, pantothenic acid, biotin, inositol, folic acid, lipoic acid, vitamin B₁₂, lipoic acid, vitamin E, vitamin K and other substances required specifically by certain organisms (see table 53 1).

It should be emphasized that not all organisms, not even all mammals, have the same nutritional requirements. Man, monkeys and guinea pigs require vitamin C, but rats, dogs and many other species are able to manufacture this vitamin. These varying nutritional requirements of different species have led to a great deal of confusion in past experimental studies. Now that the situation is recognized much fruitless work can be avoided by finding which species are suitable for a particular study and using only appropriate test organisms. In the confused period (1930-1940) during which fractionation of the vitamin B complex was being conducted in many laboratories, other vitamins were described whose existence has never been established. Some of the accepted vitamins have not yet been shown to be essential for man, and in some cases they are so ubiquitous that a deficiency is unlikely to arise. Choline, inositol, p- amino benzoic acid, lipoic acid and possibly biotin, belong in this category.

Fat-Soluble Vitamins

VITAMIN A

In 1914 Osborne and Mendel noted that some fats (butter and egg yolk fat) when added to a purified diet caused good growth while other fats (lard and oil of almonds) did not. The eyes of rats fed these latter fats for long periods became red and sore and eventually purulent. The condition was quickly cured by butter fat and cod liver oil. In 1915 McCollum and Davis announced similar findings and proposed the term "fat soluble A." By 1919 Steenbock had shown that carotene iso-

lated from carrots is active (although xanthophyll is not) and had suggested that the vitamin A activity of foods is related to the yellow pigments they contain. It was puzzling to find that fractions rich in vitamin A from animal sources were often practically colorless. Today, we understand the reasons for what was then a baffling mystery.

Chemistry and Occurrence

Vitamin A can be isolated only from animal tissues, but vitamin A activity is found in .

as well. This is due to the occurrence in many yellow-colored and green plant tissues of one or

and egg yolk. Vitamin A in the blood plasma is mainly free, that in the liver is mainly present as

Vitamin A₁ β Carotene

more precursors called provitamins, the most important of which is β -carotene, an orange-yellow-colored hydrocarbon $\text{C}_{40} \text{H}_{56}$. Vitamin A₁ (generally called vitamin A) is an unsaturated alcohol $\text{C}_{20}\text{H}_{30}\text{OH}$.

Attention is drawn to the presence of 5 double bonds one in the ring because *cis trans* isomerism can and does occur around the double bonds in the side-chain. Vitamin A is all *trans* isomer. In many species of animals it is formed in the body (probably in the intestinal tract) by an imperfectly understood hydrolytic and oxidative scission of the provitamins. Some animals (the carnivores) are apparently unable to effect this cleavage and must therefore obtain vitamin A from the flesh of their prey.

The actual vitamin itself is found in animal tissues especially the liver, and in butter, cream

esters. The richest and most important natural sources are the oils from the livers of salt-water fish (cod and especially halibut). A number of isomers are known. Vitamin A₂, possessing one more double bond in the ring, is found in the liver oils of fresh water fish. Its biopotency is about 30 to 40 per cent of that of the all *trans* vitamin A₁. All natural samples of vitamin A₁ and even synthetic vitamin A₁ have been found to contain a stereoisomer, neovitamin A, in which the configuration around the C₇: double bond is believed to be *cis*. It constitutes from 30 to 55 per cent of most commercial samples of vitamin A. Its potency is about 85 per cent of the all *trans* vitamin A. Synthetic vitamin A is on the market in the U.S.A. at a remarkably low price—in 1958 at about 25 cents per million units.

CAROTENE. In Canada and the United States carotene is the principal nutritional source (and also the cheapest) of vitamin A. There are several slightly different forms of carotene. β -Carotene is by far the most important, in many kinds of plants it is the only carotene present in appreciable amount. Other carotenes and cryptoxanthin, which may be present in minor quantities, also can function as provitamin A. The other carotenes display, on a weight basis, only one half or less of the vitamin A activity of β -carotene. This was formerly explained by the symmetrical nature of the β -carotene molecule. Oxidative-hydrolytic cleavage at the central double bond theoretically could give rise to 2 molecules of vitamin A, other carotenes with the characteristic ring (an essential part of the vitamin A molecule) on only one end of the hydrocarbon chain could give rise to only one such structure per molecule. Recent more careful bio-

TABLE 53.2

Comparison of vitamin A and carotene

Vitamin A ($\text{C}_{20}\text{H}_{30}\text{O}$)	β -Carotene ($\text{C}_{40}\text{H}_{56}$)
Stored by animals (conversion of carotene in some animals)	Synthesized by plants
Almost colorless	Reddish yellow
Absorption band at 325 to 328 $\text{m}\mu$	No absorption band at 326 $\text{m}\mu$
Vivid blue color with antimony trichloride (maximal absorption at 620 $\text{m}\mu$)	Greenish blue color with antimony trichloride (maximal absorption at 590 $\text{m}\mu$)
Vitamin A ₂ plus SbCl_3 gives maximal absorption at 696 $\text{m}\mu$	

logical assays indicate that β -carotene itself appears to give rise to only one molecule of vitamin A. The reason for the lesser activity of the other carotenes must be in the lower efficiency of their biological conversion.

Carotene injections are relatively ineffective in correcting vitamin A deficiency. Large amounts of the injected carotene may be stored in the liver while deficiency of vitamin A is present. When carotene is given orally, vitamin A appears in the liver. These and other observations have led to the belief that the conversion of carotene to vitamin A occurs in the intestinal mucosa during absorption. There are great differences in the extent to which this change occurs. Some animals have white body fat (e.g., sheep, goats, pigs and rats) because carotenoids are almost completely absent from their tissues. In these species the conversion is virtually complete. In humans, however, and in hens, cattle and many other animals, considerable amounts of carotenoid pigments are absorbed without conversion to vitamin A. Dairy cattle convert part of the carotene of the fodder (alfalfa is a particularly rich source) into colorless vitamin A. The latter, as well as unchanged carotene, is secreted in the milk. It is thus evident that a pale-colored milk may have a vitamin A content equal to or higher than one that is more richly colored by carotene.

Clinical and experimental observations have shown a relationship between the activity of the thyroid gland and the availability of dietary sources of vitamin A. The earlier belief that thyroxine favored the conversion of carotene to vitamin A has been modified as the data are more consistent with a stimulating effect of the thyroid hormone (and an inhibitory effect of thiouracil, a drug which depresses thyroid activity) on the intestinal absorption of carotene.

Effects of Deficiency

Deficiency of vitamin A may be caused by (a) inadequate amounts in the diet, (b) defective absorption, (c) inadequate conversion of the provitamin (carotene) to vitamin A, or to a combination of these. Absorption of the vitamin and especially of carotene, is favored by the simultaneous uptake of fat. This relationship is of importance when the diet consists largely of vegetables for these provide carotene but often in a medium low in fat. Absorption of vitamin A or its precursor is impaired in diseases (such as sprue and celiac disease) where fat absorption is defective. The chief function of vitamin A ap-

FIG. 53.1 Illustrates a baby which had suffered from an attack of ophthalmia of dietary origin and was cured by administration of fat soluble A as butter and cod liver oil. The disease had however progressed so far that the sight of the left eye was destroyed and the right eye damaged. (After Bloch, from McCollum and Simmons, *The Newer Knowledge of Nutrition*.)

pears to be the maintenance of epithelial tissues but the method by which it operates has not yet been discovered.

Lack of vitamin A causes (1) failure of growth in the young, (2) severe damage to the rods and cones of the retina resulting in night blindness¹, (3) redness and drying of the eye (xerophthalmia) with consequent softening or destruction of the cornea (keratomalacia), (4) drying and altered structure (erosion and metaplasia) of epithelial tissues such as papular eruptions and drying of the skin due to changes in hair follicles, atrophy of sebaceous and sweat glands, (5) secondary infections² due to the epithelial abnormalities, (6) swelling of the gums (gingival hypertrophy), (7) overgrowth of bones especially those of the cranium and vertebral column which may compress or pinch off nerves in their passage through the foramina, (8) stones in the kidney (renal calculi), (9) degeneration of nervous tissue, (10) failure in reproductive function.

¹ Vitamin A deficiency is not the only cause of night blindness. Even when deficiency of vitamin A is the cause there is no proof that defects in regeneration of rhodopsin account fully for the night blindness. Degenerative changes may have occurred in the visual receptors or optical neurons.

² The former term, anti-infective vitamin, is inappropriate and even misleading. Vitamin A does not improve immunological responses nor has it been beneficial in the treatment of infections. By its action in maintaining the epithelial tissues infection is resisted.

The effect of vitamin A in curing night blindness has been explained in part by the discovery of a close chemical relationship between vitamin A and two compounds, rhodopsin and retinene, that have been isolated from dark-adapted eyes. Rhodopsin, (ch 72) is a protein conjugate with a vitamin A derivative.

Units and Requirement of Vitamin A

Vitamin A activity is usually expressed in terms of international units (IU). The unit has had a constant magnitude but it has been expressed or defined in different ways. The original standard of reference for vitamin A activity, adopted in 1931, was 1 μg of crystalline (mixed) carotenes. This was replaced in 1934 by 0.6 μg of pure, crystalline β -carotene. In 1949 the reference standard became 0.344 μg of pure vitamin A acetate (equivalent to 0.300 μg of vitamin A alcohol). For vegetable products, the carotene standard of 1934 has been retained.

TABLE 53.3
Vitamin A activity of various
fresh liver oils and foods

	International Units Vitamin A*	
	per gram	per serving
Fish liver oils		
Cod	2,000	
Hallibut	87,000	
Ling cod	175,000	
Sword fish	250,000	
Liver, beef (cooked 2 oz)		30,000
Carrots (cooked 1 cup)		18,000
Squash (winter, cooked, 1 cup)		12,700
Sweet potatoes (baked, one medium)		11,400
Kale (1 cup)		9,200
Tomato (cooked 1 cup)		2,500
Egg (boiled one medium)		550
Milk (cow, whole, 1 cup)		390
Butter (1 patte, 7 grams)		230
Margarine (1 patte 7 grams)		230

* The values shown are average. The variation is often considerable, sometimes up to fourfold (and in the case of the fish oils even more) depending upon the season of collection, etc. Both vitamin A and carotene are susceptible to oxidative breakdown, especially when heated. Losses during food processing (dehydration and canning) are minimized when the latter are conducted in a vacuum.

The careful biological comparisons upon which these standards are based have shown that one C_{40} molecule of carotene gives rise to but one biologically available C_{20} molecule of vitamin A. A number of factors (e.g., differential absorption, efficiency of conversion) affect the comparison.

The vitamin A requirements of certain species of animals are fairly well established but in man the picture is complicated by dietary variability (i.e., intake of other vitamins) in different regions, differences in activity, etc. Actual data on human requirements are meager. The Food and Nutrition Board of the National Research Council (U.S.A.) recommends (1958) a minimal intake of 5000 IU (from mixed sources) per day for a 70 kg man. An ordinary mixed diet in North America provides about one-third of the total vitamin A activity as preformed vitamin and two-thirds in the form of carotene. Because carotene is often less efficiently absorbed than is vitamin A, it is usual to recommend higher unitage when vegetable sources provide the bulk of the dietary supply of vitamin A activity than when the principal sources are liver, milk, butter, cod liver oil or pharmaceutical concentrates of vitamin A. A study at Sheffield under the auspices of the British Medical Research Council led to the recommendation of 2500 units of vitamin A as such, or an intake of 7500 units per day for adults, when carotene was the only source. In 1950 the Canadian Council on Nutrition reviewed the available data, decided that vitamin A requirements are proportional to body weight and recommended 72 units (43 μg) of carotene per kg of body weight (i.e., 5000 units for a man weighing 70-kg) or one-fourth of this amount if preformed vitamin A is taken.

Although the evidence for an increased requirement during pregnancy and lactation is questionable, it is customary to recommend during the third trimester of pregnancy 6000 units of vitamin A per day and 8000 units per day during lactation.

SOURCES OF VITAMIN A. As mentioned earlier, vitamin A occurs only in the animal kingdom, but several provitamins (principally β -carotene) occur in vegetables and fruits. Vitamin A activity is most reliably assayed biologically, but this method of assay is time-consuming and costly. Values found by chemical or physical methods, especially for carotene, may give quite an erroneous impression of the vitamin available, because inefficient absorption and conversion may limit the amounts reaching the tissues (see table 53.3).

Fig 53.2 Scheme of wave lengths of spectrum, showing the range of those possessing antirachitic properties. Figures refer to millimicrons. The hatched area indicates the ultraviolet part of the spectrum. (Redrawn and modified from Blunt and Cowan.)

HYPERTVITAMINOSIS A (TOXICITY) Vitamin A given in excessive amounts causes toxic reactions. Adults who ingested 300 to 500 grams of polar bear liver became severely ill. Headache, vomiting, diarrhea and giddiness appeared promptly. About a week later desquamation of the skin and some loss of hair occurred. The intake may have been about seven million IU since the vitamin A content of polar bear liver may be as high as 18000 IU per gram. Numerous instances of poisoning have been described in infants and children given excessive dosage of vitamin A in the form of fish liver oil concentrates. Scaly dermatitis, patchy loss of hair, fissured lips, skeletal pain, irritability and anorexia were common to all these patients. The insidious onset of the symptoms and prompt response to cessation of overdosage are characteristic. Permanent sequelae are unusual. More cases of vitamin A overdosage than of deficiency have been reported in the medical journals in recent years. The condition has been studied in a human volunteer. Nothing is known of the biological properties of vitamin A that will account for these reactions.

VITAMIN D

The curative value of cod liver oil in the treatment of rickets had been noted as early as 1782. Largely due to the efforts of Hulschinsky in Berlin and of Harriet Chuck in Britain and in Vienna the curative effect of sunlight (and artificial sunlight, produced by mercury vapor lamps) on rickets was established (1919). The discovery by Hess and by Steenbock in the United States (1924) that irradiation of some foods generates protective substances led to reconciliation of the cod liver oil and the actinotherapy schools of thought. It is now known that animals and man, under the influence of ultraviolet light (from the sun or elsewhere) can manufacture the antirachitic vitamin from steroid secretions on the surface of the skin (fig 53.2). Ready-made vitamin D is obtained from certain foods, particularly dairy products.

CHEMISTRY The term "vitamin D" refers to several chemically related compounds (steroids) that possess the property of preventing or curing rickets. They differ in the potency with which they are effective in different species. The provitamins of the D group are sterols whose molecules undergo slight rearrangement of structure under the influence of ultraviolet light. The naturally occurring antirachitic vitamin, now called D_2 , arises upon irradiation by the sun of 7-dehydrocholesterol which is present in the oily secretions of the skin. Animals may lick it off the fur, but in man absorption is through the skin. The plant sterol, ergosterol, when irradiated, gives rise to vitamin D_2 . The synthetic product is known as *calciferol* or *mosterol*. In both cases the complex ring system of the sterol nucleus is broken by opening of the B ring between carbon

atoms 9 and 10. The products, no longer sterols in the strict sense, are referred to as steroids. Toxic by products are formed by other rearrangements during artificial irradiation of sterols and these must be removed, or conditions must be arranged to minimize their formation. Ergosterol and vitamin D₂ have similar structural formulas to those of vitamin D₃ and its provitamin, but with a double bond between carbon atoms 22 and 23 of the side chain and an extra methyl group on C-24. Vitamins D₂ and D₃ have equal antirachitic potency in the rat and in man, but in chicks the synthetic product (D₂, calciferol, made from ergosterol) is much less active. There is no vitamin D₁.

Vitamin D is soluble in fats and fat solvents. It is considerably more stable to oxidation than is vitamin A.

Effects of Deficiency

When vitamin D is inadequate, the calcification of bone is defective. The resulting clinical condition is called rickets in children or osteomalacia in adults (figs. 533 and 534). In rickets the intestinal absorption of calcium is reduced, the renal clearance of phosphate is usually elevated. Aminoaciduria occurs as a result of a lowered renal threshold rather than to an increased concentration of amino acids in the blood.

Early signs of vitamin D inadequacy are an increased elimination of phosphate in the urine (elevated renal clearance), a fall in the concentration of inorganic phosphate in the plasma, and an elevation of alkaline phosphatase activity in the blood (reflecting increased osteoblastic activity in the bones). In vitamin D deficiency formation of cartilage continues but no longer in an orderly way, bone formation becomes irregular and calcification may stop entirely.

DEFECTIVE CALCIFICATION OF THE GROWING BONE AND COMPENSATORY HYPERTROPHY OF THE EPiphyseal CARTILAGES ARE CHARACTERISTIC PATHOLOGICAL CHANGES. The band of cartilage at the end of growing long bones may become up to ten times wider than normal, leading to the typical X ray picture (fig. 535). The cartilage expands at the ends of the long bones, especially the distal end of the radius, enlargement of the costochondral junctions leads to a series of small swellings on the thorax commonly referred to as a *rachitic rosary* (beading of ribs). Defective ossification causes the typical deformities (knock knees, bow legs, spinal curvature (*scoliosis*), malformations of the chest and pelvis, and soft depressible areas in the parietal bones (*craniolehes*)).

Animal experiments have confirmed clinical experience that the effects of a diet lacking vitamin D are greatly altered by the composition of the ration. The ratio of calcium to phosphorus is important. Some animals (e.g., rats) do not develop rickets unless this ratio is grossly abnormal. In children (and puppies) the disease develops when vitamin D is inadequate, even without serious disturbance in this ratio. Imbalance increases the susceptibility. Experience suggests that the ideal ratio of Ca/P in the diet is about 1/1, and that the calcium intake of children 3 to 13 years of age should be about 1 gram per day. In man dietary ratios of Ca/P within the limits 2/1 to 1/2 appear to give optimal utilization of both elements.

Increasing the proportion of cereal in the diet, especially of oatmeal, has been found to have an aggravating effect on the tendency to develop rickets. Much of the phosphorus in cereals is present as *phytin* (the calcium magnesium salt of the hexaphosphoric ester of inositol), which is very poorly absorbed; phytin combines with dietary calcium in the intestine and renders it unavailable. The customary use of milk with porridge provides extra calcium needed under these conditions.

Vitamin D favors the absorption of calcium from the intestine, the coincident improvement

FIG. 53.4 A rickety dog. The animal was brought up on a diet deficient in the anti-rachitic vitamin D. (After E. Mellanby)

FIG. 53.5 Left, rickets bone tibia of child 13½ years of age. Right, same bone after the child had received daily doses of cod liver oil for a period of 14 days. (After H. A. Harris)

TABLE 53 4
Vitamin D in common foods

Food	I U per 100 Grams
Cow's milk (raw)	0.3 to 4
Butter	8 to 100
Margarine (vitamins added)	200 to 300
Egg yolk	150 to 500
Liver (ox)	40 to 50
Herring (fresh)	500
Cod liver oil	2000 to 30,000
Halibut liver oil	20,000 to 400,000
Tuna liver oil	2,000,000 to 6,000,000

in tubular reabsorption of phosphate by the kidney may be a secondary effect of the improvement in calcium metabolism. Vitamin D, at least in excessive dosage, mobilizes calcium from the bones, it is possible therefore, that it may have the same action in physiological concentrations. The parathyroid hormone also affects calcium metabolism, this is discussed elsewhere.

Vitamin D is also concerned in the development and maturation of normal teeth. In the absence of vitamin D the structure of the teeth is defective and predisposes to the development of dental caries. Vitamin D can prevent or arrest dental caries, not by a direct action, but indirectly, by maintaining or improving the quality of these structures.

Sources. Foods containing vitamin D are few in number (table 53 4). They all come from the animal kingdom. Fish come first, notably the flesh of those fish that contain much body oil, e.g., salmon, herring and sardine.

The vitamin D content of dairy products varies

greatly depending upon the diet of the cows and hens and on their exposure to sunlight. Natural milk has very little of this vitamin. Today milk is often fortified with vitamin D either by direct addition of the vitamin or by irradiation of the milk. There is some evidence that vitamin D supplied in milk is more readily absorbed, or at least has greater protective effect, than when supplied as an oily concentrate. Different fish liver oils vary tremendously in vitamin D content, oils from different species of tuna contain on the average from 38,000 to 45,000 IU per gram, halibut 1200, cod 100, dog fish 3, sturgeon 0. In any one species, there is considerable seasonal variation in the liver oils. Fish liver oils (especially cod, halibut, tunny), while not natural articles of diet, are important commercial sources of natural vitamin D, i.e., D₂. Because of the relative stability of vitamin D, losses during preparation and storage of foods are usually small.

It is an unfortunate fact that most natural foods are low in vitamin D content. Man should, therefore, endeavor to obtain as much sunlight as possible, so that by the natural irradiation of the sterols in or on the skin an adequate supply of vitamin D may be maintained. In northern regions the short days and low angle of the sun during winter months may not provide enough ultraviolet light to form adequate vitamin D for a rapidly growing child (fig. 53 6). If sunlight is filtered through smoke and dust, its effectiveness is reduced still further, and in industrial areas the antirachitic effect may be almost obliterated. This explains the former high incidence of rickets in large cities where industry was concentrated. Cod or other fish liver oils or commercial concentrates of vitamin D may be taken with ad-

FIG. 53 6. Maximum daily altitude of the sun throughout the year at the latitude of Toronto. (From Tisdall and Brown.)

α -Tocopherol
(5,7,8-trimethyltocol)

γ -Tocopherol
(7,8-dimethyltocol)

β -Tocopherol
(5,8-dimethyltocol)

δ -Tocopherol
(8-methyltocol)

more nearly equal in biological activity. For the cure of muscular dystrophy in rabbits the potencies of natural α , β and γ tocopherols are in the ratio of 100:30:20. The biopotency of the esters is equal to that of the free alcohols or even slightly greater because the esters are not auto-oxidizable.

Wheat germ oil (containing mainly α and β tocopherols), cottonseed oil (α and γ forms in about equal amounts), corn oil (largely γ tocopherol) and soybean oil (α , γ and δ forms) are the main sources of the natural tocopherols. These oils contain from 0.1 to 0.3 per cent of total tocopherols. Today much of the vitamin E available commercially is not the natural d - α tocopherol but a synthetic dl - α tocopheryl acetate.

By definition synthetic α tocopheryl acetate has been assigned a biological potency of 1000 IU per gram. Pure d - α tocopheryl acetate has the highest potency of any vitamin E product with 1360 IU per gram. Other products have the following activity: d - α tocopherol 920 IU, dl - α tocopherol 680 IU per gram.

Effects of Deficiency

The relatively large amounts of vitamin E found stored in all tissues examined (from animals and man) suggest that it possesses an important metabolic role. However, no characteristic biochemical disturbances attributable to lack of vitamin E are known. One property of probable significance is the antioxidative effect of the tocopherols. It has been shown that the vitamin A requirement is partly dependent on the vitamin E content of the diet. The sparing effect of the natural vitamin E on vitamin A is not shared by the synthetic ester dl - α tocopheryl acetate and hence it appears to be concerned with the antioxidant properties of the free tocopherols.

Deprivation of vitamin E in the rat leads to changes in the reproductive organs. In the female a mild deficiency may disturb the estrous cycle, a further deficiency leads to resorption of the fetuses about eight or ten days after normal conception. Prolonged deficiency in the female leads

to loss of ability to conceive. Restoration of vitamin E to the ration permits pregnancies to proceed normally once more, i.e. in females the changes are reversible. In the male rat prolonged deficiency of vitamin E leads to atrophy of the testes and to irreversible changes in the germinal epithelium with complete sterility.

A common finding in mts. guinea pigs and rabbits is the development of degenerative changes in the muscles leading to actual paralysis (nutritional muscular dystrophy). Both sexes and all age groups appear equally susceptible to this effect of vitamin E deficiency.

A characteristic pigment called ceroid probably formed by autooxidation of unsaturated lipids is often found in the muscles, sex glands and liver cells of rats fed E deficient diets.

Necrosis and fibrosis of the heart muscle have also been reported in experimental animals kept for long periods on rations deficient in vitamin E. In chicks vitamin E deficiency leads to *embryonic mortality* (due to disintegration of blood vessels) to the appearance of large patches of subcutaneous edema on the breast, abdomen, neck and legs (*exudative diathesis*) and a nutritional *encephalo malacia* characterized by motor incoordination, head retraction, stupor and death.

Experiments in rats and rabbits have shown that animals given adequate vitamin E survived hypoxia (reduced atmospheric pressure) much better than E deficient ones. They also survived exposure to a high oxygen tension (98 per cent oxygen at 5 atmospheres pressure) much better. They way in which vitamin E protects against changes in oxygen tension is not known.

Although man apparently requires vitamin E much less is known about the role of this vitamin in human nutrition. Beneficial results have been reported from its use in habitual abortion, muscular dystrophies, peripheral vascular disorders (indolent ulcers, early gangrene of the extremities, thrombophlebitis), heart diseases and the menopause. These claims have been denied or minimized by other clinical investigators. Many contend that

it has never been established that the conditions seen in humans (superficially resembling those observed in animals) are due to lack of vitamin E. The literature is decidedly controversial. The high dosage levels of vitamin E often advocated in clinical medicine seem unreasonable. On the basis of animal studies of storage and utilization of fat-soluble vitamins, including E, the possibility seems remote that adults ever suffer from avitaminosis E. Moore (1956) has pointed out that in man the concentration, by weight, of vitamin E in the plasma normally exceeds by about thirty fold that of vitamin A.

In early life the stores of vitamin E may be much less, but even in the case of infants some of the evidence for a beneficial therapeutic effect of vitamin E is unconvincing. There is evidence, however, that the sensitivity to hemolysis of the red cells of newborn and premature infants can be reduced by giving tocopherol.

SOURCES Vitamins E occur so ubiquitously, being found in essentially every article of diet, that consumption of a normal mixed ration provides enough to keep the body stores well supplied. Unmilled cereals, vegetable oils and eggs are the richest sources. The average daily intake of *d*- α tocopherol by an adult man has been estimated to be 14 to 19 mg. Part of this is oxidized in the intestine to quinones and part is excreted in the feces. Possibly only one-third of the intake, or about 5 to 7 mg. per day, are actually absorbed. Nothing definite is known about the human requirement.

Vitamin E is stored in all tissues. Adipose tissue is the major storage site. Hypervitaminosis E has been studied in several species but no toxic effects have been observed even when massive doses have been administered over a prolonged period.

VITAMIN K

(See also ch. 12)

Between 1929 and 1935 several reports appeared of a hemorrhagic condition in chickens raised on purified diets consisting of cereals plus yeast. The disease, due to defective blood clotting, was seemingly of dietary origin. In 1935 Dam proposed the name vitamin K (*koagulation*) for the protective nutritional factor which his experiments, confirmed by Almquist and Stokstad, had shown to be present in the fat-soluble fraction of green leaves. There was no direct relationship of coagulation factor with the chlorophyll, carotene or xanthophyll content of the leaves. When the activity was shown to be in the nonsaponifiable nonsterol fraction it was obviously different from any previously known fat-soluble vitamin. In 1939, two groups

accomplished the isolation, Dam and Karrer and their colleagues from alfalfa, Doisy and his associates from both alfalfa and fishmeal. The fishmeal product proved to have 10 more carbon atoms in a longer side chain and was called vitamin K_2 to distinguish it from the alfalfa product, $C_{20}H_{36}O_2$, which was called K_1 .

CHEMISTRY A number of compounds possessing vitamin K activity are known, all being derivatives of 2-methyl-1,4-naphthoquinone, i.e., all active compounds appear to possess the general formula

Synthetic 2-methyl-1,4-naphthoquinone, ($R=H$) sometimes called *menadione* and sometimes vitamin K_1 , is readily prepared in pure, crystalline form, and apparently possesses all the physiological properties of the natural vitamin. Natural

Menadione
(Vitamin K_1)

vitamin K_1 differs from menadione by having at position 3 a phytyl side chain C_{20} , with 1 double bond) and vitamin K_2 has a difarnesol substituent (C_{30} , with 6 double bonds).

The structure of vitamin K was elucidated fairly rapidly, after its isolation, because of similarities in chemical and physical properties to *phthiol*. This substance had been isolated from tubercle bacilli six years earlier by Anderson and his colleagues, and its structure proven by synthesis to be 2-methyl-3-hydroxy-1,4-naphthoquinone.

Phthiol

K antagonist differs in several ways from the characteristic competition between analogs. Whatever the process by which it acts, dicoumarol(3,3'-methylene-bis-(4-hydroxycoumarin)), when administered by mouth to man or animals causes a marked lowering of the plasma prothrombin level with consequent lengthening of the clotting time. It is used clinically to control thrombus formation (see ch. 12).

TOXICITY OF VITAMIN K. Before dicoumarol came into clinical use, vitamin K and its analogues were given in small doses of a few milligrams per day. Larger doses, of several hundred milligrams per day, are now given to counteract overdosage with synthetic dicoumarins used as anticoagulants. Patients given 150 to 600 mg daily of water soluble synthetic vitamin K analogues intravenously have complained of nausea and of more severe reactions. Some deaths of infants have been attributed to overdosage with a water soluble analogue. The naturally occurring phytyl compound is not toxic when fed or injected in relatively massive amounts.

Sublethal doses of menadione derivatives (but not of phytyl menadione) have induced anemia in rats, rabbits and dogs. Occasionally polycythemia

has been observed in the same animals. In the mouse, the LD₅₀ of menadione (orally) has been reported as 500, 620, 800 and 840 mg per kg, by different workers, in rabbits it is 250 mg per kg.

Lipoic acid. Lipoic acid, formerly known as protogen and as pyruvate oxidation factor, is a fat soluble material which is an essential growth factor for certain bacteria and protozoa. It was isolated in 1951 from yeast and liver. Five different forms, with differing activities, have been described: a bound form, a water soluble complex, and three fat soluble varieties. All are derivatives of an acid containing eight carbon atoms and two sulfur atoms. Because of this it is also known as thioctic acid.

Lipoic acid or its amide appears to function as a further cofactor sometimes necessary, along with thiamine pyrophosphoric ester (TPP), in the decarboxylation reactions (involving pyruvic and ketoglutaric acids) discussed briefly under thiamine and more fully under carbohydrate metabolism. The active agent, lipothiamide pyrophosphoric ester, is referred to briefly as LTPP.

THE VITAMINS (Continued)

Water-Soluble Vitamins

VITAMIN B COMPLEX

Lack of vitamin B leads to loss of appetite with consequent loss of weight (fig 541). Early fractionation studies of "growth factors" in aqueous extracts of yeast, liver and other animal and plant tissues revealed that an antineuritic substance (vitamin B₁ = aneurin = thiamine) could be separated from a pellagra preventing (P-P) factor. Later, other growth factors were found in various fractions. Different names were applied in different laboratories so that a study of the literature of several decades ago may prove baffling to modern readers. Twelve substances are grouped together because of their close association in tissues and because for a long time their separation proved most difficult: *thiamine*, *riboflavin*, *nicotinic acid*, *pyridoxine*, *pantothenic acid*, *biotin*, *para aminobenzoic acid*, *folic acid*, *folinic acid*, *cyanocobalamin*, *choline*, and *inositol*. All have been isolated in pure form, and most of them have been synthesized in the laboratory.

THIAMINE

ISOLATION, IDENTIFICATION AND SYNTHESIS The contributions of Takaki, Eijkman, Grijps, Hopkins and Funk have already been mentioned. McCollum and Davis (1915) had found that young rats grew poorly on a purified diet containing dextrin as the carbohydrate, but that growth improved when lactose was used. The growth stim-

¹ Growth promotion was less, due to loss of Funk's factor, but the factor remaining, designated B₂, (now known as riboflavin) stimulated growth considerably.

² Papers of fundamental importance appeared from other laboratories within a few days of each other, as has frequently happened with studies of other vitamins. Assignment of priority is difficult. Todd and Bergel in England, Wandaus in Germany, and Makino and Imai in Japan made important contributions. Andersag and Westphal of the I G Farbenindustrie may have been the first to accomplish the synthesis but the company policy with respect to patent protection delayed publication of their work until 1937.

ulating principle was destroyed by heating the lactose, and it could be leached away from the milk sugar with alcohol. The substance responsible for growth stimulation was called "water soluble B" by McCollum. Yeast was soon found to be an excellent source of this factor. In 1920 Emmett and Luros provided evidence for the dual nature of water soluble B when they found that autoclaved yeast no longer contained Funk's antiberberi substance but that it still promoted the growth of rats fed certain purified diets.¹ In 1926 the heat sensitive antiberberi substance, vitamin B₁ (in those days often called the antineuritic factor) was isolated in Holland by Jensen and Donath. They proposed the name *aneurin*. The synthesis was accomplished in 1936 by R. R. Williams and his colleagues in the United States.² The presence of a sulfur atom and primary amino group led Williams to propose the name *thiamine*, which is now the term in general use.

FIG 541. Average weight gain curves of rats on vitamin B free diet plus daily supplement of ground whole wheat of 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.8 and 1.0 grams. Negative controls (marked 0.0) received basal diet only. P, point where, on the average, chronic symptoms of polyneuritis appeared. Lines broken from the points at which some individuals died. (After Chase, from Sherman and Smith, *The Vitamins*.)

CHEMISTRY OF THIAMINE (VITAMIN B₁) Thiamine contains two ring systems, the pyrimidine and thiazole, joined by a methylene bridge. It possesses a strongly basic quaternary nitrogen

atom and hence forms chlorides and other salts that dissolve in water and ionize freely, it also possesses a primary amino nitrogen which can form salts such as the hydrochloride Sulphates, nitrates, picrates and other salts have been prepared. The naturally occurring vitamin is thiamine chloride hydrochloride although it is commonly referred to merely as thiamine. Today it is produced synthetically on a large scale and is available commercially at surprisingly low cost.

Thiamine is readily soluble in water and rather insoluble in most organic solvents. Its aqueous solution is strongly acid due to the hydrochloric acid dissociated from the amino group. In acid solution (including acid foods) thiamine is reasonably stable even when heated, but is unstable on the alkaline side. At pH 3.5 boiling causes little destruction. At higher temperatures (autoclaving at 120°, for example) thiamine (in yeast) is stable for short periods, but after 2 to 3 hours most of it is destroyed. Riboflavin (vitamin B₂) is much more stable under these conditions. Near neutrality (pH 5 to 7) thiamine is much less stable to heat and in alkaline foods it is rapidly destroyed by heating. Farrer measured the percentage loss on boiling thiamine at 100° for 1 hour in solutions of pH 3, 4, 5, 6, 7, 8 and 9 as 18, 20, 40, 53, 68, 100 and 100 respectively. Later he found that the buffer used was important: phosphate confers considerable protection and pyrophosphate even more. Storage on the alkaline side even at room temperature should be avoided. Thiamine is readily destroyed by an enzyme found in certain foods as well as by atmospheric oxygen. Thiaminase has been found in some raw fish (herring, carp) raw clams, shrimps and mussels and in certain plants (bracken ferns). Its occurrence was discovered following a study of the paralyses and convulsions seen in foxes and in cats fed rations containing large amounts of raw fish.

Thiamine is believed to act in the metabolic systems of the body as the ester, thiamine pyrophosphate (TPP). This molecule, known as *carboxylase*, is the coenzyme or prosthetic group of the enzyme decarboxylase which decarboxylates α keto acids, especially pyruvic, in the body. Subsequent studies have shown that

most, if not all, vitamins act as coenzymes to facilitate some essential step in intermediate metabolism

Thiamine Deficiency

The effects of thiamine deficiency have already been mentioned beriberi in humans, and polyneuritis in chickens, pigeons, rats, mice, dogs and other species. Two types of beriberi are seen in Japan, Southern China, India, the Philippine islands, Dutch East Indies and other places where the staple is polished rice (1) the wet type, with edema, (2) the dry type, without edema. Multiple peripheral neuritis and muscular atrophy are characteristic in both. Weakening of the muscles accounts for the cardiovascular and gastrointestinal defects (enlarged right heart, peripheral vasodilatation, indigestion, gastric atony, severe constipation). Anorexia (loss of appetite) leads to loss of weight and general debility, tenderness of the feet and legs, lameness, ataxia, paralysis, inflammation of the ocular nerve and heart failure are usual sequelae.

In experimental animals the first signs of thiamine deficiency are loss of appetite, arrested growth, reduced motility of the gastrointestinal tract, and marked slowing of the heart. An extreme degree of bradycardia is seen in rats fed rations deficient in vitamin B₁. In man the opposite effect is produced, i.e., tachycardia.

Thiamine is necessary for the utilization of pyruvic acid, i.e., for the final stages of carbohydrate metabolism. The debility and tissue degeneration in thiamine deficiency are probably due to decreased ability to use carbohydrate. The central nervous system derives its energy mainly from carbohydrate and this doubtless explains the lesions in the central and peripheral nerves.

Function of Thiamine

R. A. Peters at Oxford noted that lactic and pyruvic acids accumulated in the brains of thiamine-deficient pigeons and described the principal effect of vitamin B₁ deficiency as a "biochemical lesion" in which carbohydrate metabolism is impaired by the failure to convert

pyruvate to acetate. The original view that a simple oxidative decarboxylation occurs has had to be modified. A series of decarboxylating enzymes, all with thiamine pyrophosphate (TPP) as coenzyme, are concerned with the decarboxyla-

tion of α ketonic acids. More recent work suggests that (under some conditions, at least) lipoic acid is combined with TPP to form a more complex cofactor (lipothiamide) for the oxidation or dismutation of pyruvic acid. The discoveries leading to this view will be indicated briefly.

In 1929 Evans and Lepkovsky had demonstrated that the vitamin B₁ requirement decreases when the fat content of the diet is increased. Although this effect has been described as a thiamine sparing action of dietary fat, it now appears more accurate to say that the thiamine requirement increases as the proportion of dietary carbohydrate increases.

In 1936 Platt and Lu showed that the blood of patients with beriberi contained pyruvic acid and other ketone bodies and that these increased on exertion. Seven years earlier Kinnersley and Peters had found more lactic acid in the brains of pigeons lacking vitamin B₁ than in normal brains and in 1934 Westenbrink had claimed that either lactic acid or pyruvic acid was the toxic metabolite responsible for at least some of the conditions seen in vitamin B₁ deficiency.

In a paper of fundamental significance Peters (1936) reported that the brains of pigeons deficient in vitamin B₁ had a much lower oxygen uptake (measured on slices in Ringer phosphate solution) than did normal brains when glucose was supplied as energy source. The same result was obtained when sodium pyruvate or lactate was provided as substrate. Addition of vitamin B₁ raised the oxygen uptake to normal in all three cases. The reaction proved to be not only highly specific for vitamin B₁ but extremely sensitive. Peters described it as the *catalatorulin* effect and used it as the basis of a method for determining thiamine. The simultaneous accumulation of lactic acid was puzzling until Shermaa and Elvehjem showed that the accumulating pyruvic acid inhibits the enzyme lactic dehydrogenase. Thiamine facilitates removal of pyruvate and permits the normal metabolism of lactic acid.

Actually as was suggested earlier thiamine itself is not the catalyst. Westenbrink and Pollak observed a ten minute delay after adding thiamine to a polyneuritic brain preparation before oxygen uptake began. About the same time Lohmann and Schuster isolated from yeast the pyrophosphoric ester of thiamine and Weil-Malherbe showed that the vitamin could be transformed into this ester (i.e. into cocarboxylase) by the action of adenosine triphosphate (ATP). Lipmann suggested in 1937, that added thiamine must first be converted to the pyrophosphoric ester which then acts as the coenzyme (cocarboxylase) of a system catalyzing the liberation of CO₂ from pyruvic

acid Neither thiamine nor its monophosphoric ester has any coenzyme activity

UNITS AND REQUIREMENTS The International Unit of vitamin B₁ adopted by the Health Organization of the League of Nations was 3 μ g, i.e., 3 one millionths of a gram, of thiamine chloride hydrochloride. Today values are almost invariably given in μ g or mg

Estimates of human requirements for thiamine are usually expressed in relation to the total daily calorie intake, values ranging from 0.17 to 1.0 mg per 1000 Cal having been advocated. In 1953, after consideration of the available data the United States Food and Nutrition Board recommended that the minimum requirement for adults be 0.23 mg for each 1000 Cal. This value may be compared with those found in a dietary survey by E. G. Young among Canadian families on rather low incomes: 0.20 mg for men, 0.19 mg for women and 0.22 mg per 1000 Calories for children. No evidence of thiamine deficiency could be detected clinically in this group. It is interesting to recall that many years ago Williams and Spies (1938) had suggested a thiamine intake of 0.18 mg per 1000 Cal when fat provided 40 per cent of the total calorie intake, and an increase to 0.3 mg per 1000 Cal when the diet was essentially free from fat. The Canadian Council on Nutrition with this effect of fat in mind, recommends 0.3 mg per 1000 Cal since fats are costly items in the diet, and persons on low incomes will not consume as much fat as their more affluent countrymen.

Some workers in England, the United States and elsewhere are not satisfied that this dosage (0.75 mg per 2500 Cal) is adequate. The latest recommendation of the United States Food and Nutrition Board is 0.5 mg per 1000 Cal (up to 3000 Cal) and 0.2 mg for each 1000 Cal above 3000. They recommend that the total per day should not fall below 1 mg regardless of the calorie intake. No single figure can ever be given as the ideal value because the requirement varies with the composition of the diet as well as with the individual. A constant supply is necessary because the body is unable to store thiamine to any great extent.

These recommendations are generous and are possibly somewhat above the average requirement. They are easily met by the thiamine content of the foodstuffs commonly used in Canada and the United States, and a slight excess can do no harm. On the other hand, there is no evidence that an intake of thiamine in excess of the requirement affords any extra benefits.

Toxicity Tremendous doses of thiamine can be lethal. The acute fatal doses (mg per kg.) by the intravenous route for mouse, rat, rabbit and dog were found to be 125, 250, 300 and 350 mg, respectively. The lethal dose by subcutaneous injection was about six times as great and orally about forty times these values. The toxic signs

observed in dogs were marked but transitory vasodilation with consequent fall in blood pressure, bradycardia and death (due to respiratory arrest). In man, sensitivity to excessive dosage with thiamine (especially when injected) has been observed: nervousness, tremors, tachycardia, sweating, herpes zoster and even anaphylactic shock.

Mills has suggested (1941) that because parenteral injection of even moderate doses of thiamine may sometimes lead to anaphylactic reactions this route should never be used. Untoward reactions to oral administration of reasonable doses are virtually unknown.

SOURCES Thiamine is widely distributed in natural foods of both plant and animal origin. Until man attempted to improve upon nature by refining his food, beriberi was apparently unknown. Plants synthesize thiamine which is found in roots, stems, leaves, flowers, fruits and seeds, e.g., average values (μ g per 100 gram edible portion) in beets 200, carrots 180, turnips 65, onions 120, asparagus 160, watercress 180, lettuce 270 and cauliflower 120 to 330. Peas and beans are rich sources, as are whole cereal grains. Nuts are also good sources of thiamine.

There tends to be more thiamine in the mature dry seed than in other parts of the plant. Unmilled cereal grains are richer in thiamine than the highest recommended dietary allowance (i.e., 0.5 mg per 1000 Cal) since whole wheat averages better than 1.0 mg per 1000 Cal. Whole rice and rye may average somewhat lower than this but whole oats may sometimes contain more thiamine per 1000 Cal than does wheat. The bulk of the thiamine in cereal grains resides in the germ which is removed in conventional milling processes. The refined white wheat flour, polished rice or corn meal (hominy) will keep much better in storage than the unmilled grains but the unfortunate penalty paid for this 'improvement' is that the bulk of the thiamine has been eliminated. In some regions, thiamine (synthetic) is now added to the milled products, with or without other nutrients. Such fortification of white flour and polished rice is technically and legally referred to as enrichment.

Dried yeast is the richest of all known sources, containing from 1800 to 36 000 μ g (usually about 10 000 μ g) per 100 grams. Among foods of animal origin lean pork is the richest source of thiamine (500 to 1500 μ g per 100 grams), other meats contain much less (e.g., beef 80 to 300 μ g). Ox liver contains 350 to 450 μ g per 100 grams. Milk contains relatively little thiamine, eggs somewhat more. Oatmeal is a good and cheap source, one serving supplying more thiamine than 2 cups of milk or 5 average boiled eggs. To illustrate that

it is relatively easy for Americans and Canadians to obtain a liberal supply of thiamine the following tabulation (after McHenry) shows the thiamine contribution made by average servings of a few foods commonly used in North America

1 orange	0.12 mg
1 serving oatmeal	0.22 mg
3 cups milk	0.27 mg
4 slices enriched bread	0.21 mg
1 serving roast beef	0.05 mg
1 boiled potato	0.14 mg
1 serving carrots	0.01 mg
1 serving cabbage	0.06 mg
Total	1.14 mg

RIBOFLAVIN

As early as 1917 Emmett and McKim noted that two growth factors exist in the water soluble extract of rice polishings one (later called vitamin B₁) that cures rat polyneuritis and another, more heat stable, that produces weight gains under specific dietary conditions (see Fractionation scheme on p. 917). Emmett and Luros (1920) found the same two factors in yeast. The dual nature of water soluble B was also shown by Smith and Hendrick (1926).

Goldberger and Lillio (1926) in the course of their study of pellagra produced a deficiency disease in rats characterized by ocular changes (conjunctivitis, corneal vascularization and eventually corneal opacity), and bilaterally symmetrical loss of hair. The factor that prevented these lesions was heat stable and was called the "P P" (pellagra preventive) factor by Goldberger although his admirers called it vitamin G and in Britain it was called vitamin B₂. Meanwhile, other workers using different dietary conditions were reporting different lesions (including a dermatitis so called "rat pellagra") cured by a heat stable factor. Finally it became clear that several different factors, all more stable to heat than vitamin B₁, were involved. The discovery that canine black tongue could be induced by diets similar to those producing rat pellagra seemed an indication of progress, but in due course, it appeared that neither lesion was caused by lack of vitamin B₂. Birch, Gyorgy and Harris (1935) differentiated the anti black tongue and P P factor from vitamin B₂ (riboflavin) and the dermatitis factor (vitamin B₆). In 1936 Dann reported that riboflavin did not cure human pellagra, and in 1937 Sebrell and his colleagues confirmed that it did not cure canine black tongue. It was thus obvious by 1937, that vitamin B₂ (riboflavin) had no direct connection with pellagra although its absence from the ration may complicate the pellagrous condition. Thus the term vitamin B₂, initially intended to designate the factor that cures pellagra, came in the end to be

applied to riboflavin, the rat growth factor that is responsible also for preventing characteristic ocular lesions.

CHEMISTRY Elucidation of the chemical nature of vitamin B₂ was rather rapid because at the time (1925-1933) a number of workers were studying fluorescent pigments isolated from sources as varied as egg yolk, dandelion flowers, grass, milk, liver, kidney, muscle and retinae. Names indicating the source were applied (*ovoflavin* to the substance from eggs, *terdoflavin* from grass, *lactoflavin* from milk, etc.), but subsequently many of these substances proved to be identical. Kuhn, Gyorgy and Wagner-Jauregg (1933) isolated from egg white an orange yellow compound with an intense yellowish green fluorescence which at doses of 100 µg per day, stimulated the growth of rats on a purified diet. A similar growth promoting fluorescent substance was isolated from whey (Booher, 1933). Kuhn suggested that these pigments might be related to the "yellow enzyme" isolated from yeast by Warburg and Christian in the preceding year. This yellow respiratory ferment was separated by Theorell (1934-1935) into a protein fraction and a small molecule (the pigment flavin), neither of which alone possessed enzymic activity. The identity of this flavin with the yellow pigments from various sources was soon shown and its structure was established by synthesis (accomplished almost simultaneously by two groups in 1935—Kuhn and his colleagues at Heidelberg and Karrer and co workers in Switzerland). When the yellow compound C₁₇H₁₂N₄O₄ was shown to contain the penta sugar ribose attached to a dimethyl derivative of isoalloxazine the name *riboflavin* was suggested.

Riboflavin crystallizes from dilute acetic acid alcohol or pyridine in fine orange yellow needles. It is only slightly soluble in water (about 12 mg per 100 ml at 25°) and is insoluble in ether, chloroform and benzene. Compounds such as urea, propylene glycol and sodium desoxycholate increase the solubility of riboflavin in water. It is relatively stable under ordinary cooking condi-

tions but it is less stable to bright sunlight than many other vitamins

The enzymes containing riboflavin are called flavoproteins. These enzymes accept hydrogen atoms from specific substrates, thus oxidizing them, the hydrogen is then passed on to other molecules. Alternate reduction and oxidation of the enzyme accomplishes oxidation of one and then reduction of a different component of the metabolic cycle.

The first of these prosthetic groups to be identified was the "riboflavin mononucleotide" of Warburg and Christian's "yellow enzyme" (which Theorell had split by dialysis into the protein carrier (apoenzyme) and the yellow coenzyme). The nature of the latter was established by Kuhn and Rudy (1936) as riboflavin 5' phosphoric acid. It is the coenzyme for three different systems: Warburg's yellow enzyme, for cytochrome *c* reductase and for L amino acid oxidase. A second active form of riboflavin (coenzyme) is riboflavin adenine dinucleotide, in which a complex of adenine ribose phosphoric acid is attached to the riboflavin phosphate to give a large complex molecule with a central pyrophosphate linkage. This compound acts as coenzyme for many systems, including xanthine oxidase, fumaric hydrogenase, the Schardinger enzyme aldehyde oxidase, glycine oxidase, D amino acid oxidase, diaphorase, histaminase and other diamine oxidases, etc.

Riboflavin Deficiency

The role of riboflavin in human nutrition is still somewhat controversial. As in animal studies, the lesions affect the eyes and skin. In rats, failure of growth is followed by dermatitis, loss of hair, cataract, some nerve degeneration and reproductive defects (cessation of estrous cycles, atrophy of testes). The early studies in man were complicated by the presence (unsuspected, of course) of other dietary deficiencies. One of the earliest reports of artificial riboflavin deficiency in man (Sebrell and Butler, 1938) revealed (1) fissures developing in the lips and at the corners of the mouth (cheilosis), (2) a sore tongue (inflamed and smooth) simulating the glossitis of pernicious anemia, (3) a seborrheic dermatitis affecting especially the face (ears, nose, forehead). (4) Sydenstricker has described a vascularization of the cornea due to lack of riboflavin (fig. 51-2). The cornea does not normally contain blood vessels, but when the diet lacks sufficient riboflavin for prolonged periods, capillary loops extend into the cornea, the eye becomes itchy, light sensitive (photophobia), vision is poor in dim light, and in time the corneal vascularization may lead to severe interstitial keratitis. These

observations have been confirmed in a number of clinical centers and in several species of animals. Other workers have failed to induce corneal vascularization in subjects kept for some months on a diet very low in riboflavin. Several factors (some not yet understood) may be concerned. Corneal changes of this nature, when present, are not specific signs of riboflavin deficiency. Some patients with such lesions have responded to supplements of riboflavin, many have not. Whereas the cheilosis and glossitis often respond to riboflavin alone, sometimes nicotinic acid and other members of the vitamin B complex are required to effect improvement.

The absence of more profound and specific effects of riboflavin deficiency in man is curious because riboflavin is in the prosthetic group of so many enzyme systems catalyzing important transformations.

RIBOFLAVIN REQUIREMENT There is no International Unit for riboflavin. The quantities of this (and of most other vitamins available in crystalline form) are now stated on a weight basis.

The riboflavin requirement of man, like that of most of the vitamins, is not known, although there is general agreement that the minimal intake for maintenance of health lies between 0.5 and 3 mg. per day. A common method of expression is to relate it to the energy intake. This is done because riboflavin is concerned in the oxidative processes going on in practically all cells and its loss and replacement quota might reasonably be expected to be proportional to the energy production. Several lengthy clinical studies indicate that about 0.3 mg. per 1000 Cal. of food are adequate. The Canadian Council

FIG. 51-2 Showing engorgement of the limbic plexus and vascularization of the cornea in riboflavin deficiency. Note the loops of vessels of the limbic plexus penetrating more than half way to the pupil. White areas are corneal opacities.

on Nutrition (1950) recommend 0.5 mg riboflavin per 1000 Cal. For an average man consuming food to give 3000 Cal per day this would be 1.5 mg riboflavin.

The United States Food and Nutrition Board (1953) decided that the riboflavin requirement is not related to energy intake or muscular activity. They recommend that the riboflavin allowance be calculated in terms of the recommended protein intake, (although the evidence relating riboflavin need to protein metabolism is sketchy). They recommend 0.025 mg of riboflavin for each gram of protein eaten, thus an average adult man getting 65 grams of protein per day would need 1.6 mg per day, essentially the same value as recommended by the Canadian Council.

SOURCES OF RIBOFLAVIN All cells seem to require riboflavin. It is one of the most widely distributed vitamins. The richest known edible sources are some highly pigmented crustaceans (dorsal muscles of some crabs contain from 2.4 to above 20 mg per 100 grams). Other good sources are liver (0.1 to 4.4 mg per 100 grams), kidney, heart, muscle (meat, fish, fowl), egg white, milk and growing leafy vegetables.

Cow's milk usually contains between 0.1 and 0.15 mg per 100 ml and pasteurization (143 to 145° for 30 minutes) has a negligible effect. Irradiation of milk to increase its content of vitamin D does not reduce the riboflavin content but prolonged exposure to sunlight does. Milk is the chief source of dietary riboflavin (3 cups per day provide about 1.2 mg). Cheese, eggs, meats and vegetables in the diet usually fail to satisfy the riboflavin requirement unless some milk is consumed; a deficiency may occur.

Riboflavin can now be produced more cheaply by fermentation than by chemical synthesis. Exceptional yields are obtained from the molds *Eremothecium ashbyi* or *Asbya goessypii*, in submerged culture with continuous aeration and agitation, yields up to 600 mg per liter in 4 days have been reported from commercial producers.

Toxicity The low solubility in water may be responsible for the low toxicity of riboflavin. Oral doses of 2 grams per kg to dogs and 10 grams per kilo to rats produced no signs of toxicity. Mice given 5000 times the therapeutic dose, intraperitoneally, suffered no ill effects. In rats the LD_{50} for riboflavin (intraperitoneally) is 560 mg per kg. Death occurred in 2 to 5 days due to kidney concretions, cytological changes

were also noted in the pituitary, adrenals, pancreas and heart.

NICOTINAMIDE AND NICOTINIC ACID (P-P FACTOR)

Nicotinic acid and its amide have similar physiological activities, but it is in the form of nicotinamide that the vitamin is found in its natural, active combinations. Both compounds prevent pellagra. Nicotinamide functions as an essential unit of several different coenzymes that act as prosthetic groups for a variety of enzymes. Coenzyme I (also known as cozymase, cohydrogenase, and diphosphopyridine nucleotide (DPN)) contains, besides nicotinamide, one molecule of adenine, two molecules of ribose and two molecules of phosphoric acid. Coenzyme II, previously known as the coferment of Warburg's yellow enzyme is a triphosphate ester; the third phosphate group being attached to carbon atom 2 of the ribose joined to adenine, it is now more commonly referred to as triphosphopyridine nucleotide or TPN.

CHEMISTRY AND FUNCTION OF NICOTINAMIDE Nicotinic acid was first obtained by Huber in 1867, by the oxidation of the alkaloid nicotine. Its presence in biological material was first shown almost simultaneously by Suzuki and associates (1912) who obtained it from rice bran during attempts to isolate the antiberberi substance and by Funk (1911, 1913) who identified it as a component of his "vitamin" fraction from yeast. Both observed its inability to cure berberi and set it aside as of no interest. Neither suspected that they had in hand the cure for another equally devastating deficiency disease but that 25 years would elapse before this was realized. In 1926 Vickery again isolated it from yeast and commented that "it has so far not been found in any other materials than rice polishings and yeast." Its nutritional importance remained unknown.

Nicotinic acid, $C_6H_5O_2N$, is a white crystalline substance that is only moderately soluble in water (about 1 per cent) but which is readily soluble upon the addition of alkali or acid, due to salt formation with the carboxyl group or

* This means 50 per cent of the lethal dose (LD_{50})

basic nitrogen atom, respectively. The amide is more soluble in water. It is stable to heat in neutral solution but is converted to nicotinic acid by acid or alkali.

In the United States nicotinic acid is known as *niacin*. This name was coined to make the distinction between the vitamin and the alkaloid (nicotine) clear to the public lest they get the mistaken idea that "enriched" foods are being poisoned by the addition of the tobacco alkaloid. The terms *niacin* and *niacinamide* are official in the United States. In the present discussion the universally accepted names will be used.

Nicotinic acid, its ethyl ester, nicotinic acid γ -methyl amide, β -picoline, and several related compounds display vitamin activity, presumably being readily converted to nicotinamide in the animal body.

In 1934 Warburg and Christian found nicotinamide in coenzyme II, which they showed accomplishes hydrogen transport in cells and a year later von Euler and his colleagues found it in coenzyme I, which is necessary for the fermentation of carboxylate. Thus by an unusual inversion of the ordinary sequence of events in the vitamin field, the biological significance of nicotinamide was understood before its specific nutritional importance was realized. It was not until 1937 that Smith and others demonstrated its therapeutic value in pellagra.

The prosthetic groups containing nicotinamide (coenzyme I or DPN and coenzyme II or TPN) are unique in that they appear to be loosely bound to the protein part of the enzyme system, i.e., they are mobile coenzymes. About 40 reactions are known to be catalyzed by either one or both of these coenzymes. For example, DPN is specific for 3-phosphoglyceraldehyde dehydrogenase, TPN is specific for isocitric dehydrogenase, yet either can function with glutamic dehydrogenase. DPN occurs in all animal and plant cells in which carbohydrates are metabolized. It effects the conversion of glucose to gluconic acid, of a glycerophosphoric acid into phosphoglyceric acid, and of ethanol into acetaldehyde. It also effects the dismutation of aldehyde into alcohol and acid, of β -hydroxybutyric acid into acetoacetic, of lactic acid into pyruvic acid, and of malic into oxaloacetic acid. The list of reactions catalyzed by DPN in the presence of specific apoenzymes, i.e., different protein carriers, could be greatly extended. A different list, with some common items, could be made for metabolic reactions catalyzed by TPN.

Nicotinamide Deficiency

Deficiency of nicotinamide in man leads to serious consequences. Lack of it has led to the most serious of the deficiency diseases encoun-

tered in North America—*pellagra*. Between 1907 and 1937 the disease was endemic in the southern United States. The name is of Italian origin (*pelle agra* means rough skin). The disease is known to have occurred in Spain before it was first described by an Italian physician in 1771. In the past century pellagra was endemic in parts of Egypt, Rumania and France. The skin, especially the areas exposed to sunlight (face, neck, hands, sometimes the feet) becomes bronzed, resembling sunburn, and later thickened. The tongue is swollen, glossy and 'beefy'. The disease follows a terrible and inevitable course from mild psychic disturbances through dementia to death.

That pellagra is undoubtedly of dietary origin was made clear by Goldberger and his associates in 1915. The consumption of maize was recognized to be a prominent feature, but some workers suspected the presence of a toxic principle or bacterium in the corn. In view of the relationship between dietary tryptophan and nicotinic acid, established in the early 1950's, it is interesting to recall that Goldberger suspected that an amino acid deficiency as well as a vitamin deficiency was involved in the etiology of pellagra.

Liver and a commercial extract of liver proved to be strongly curative, and fractionation studies were initiated in a number of laboratories. The use of experimental animals in the search for the curative agent for pellagra led to bewildering and often contradictory results that were difficult to interpret. As mentioned earlier, canine black tongue is readily produced when young dogs are maintained on the Goldberger diet, a dermatitis produced in rats by a similar maize diet was called 'rat pellagra', and later a dermatitis of dietary origin in chickens was called 'chick pellagra'. In the end it turned out that the work with rats and chicks was irrelevant to the disease in man. The lesions in both species were cured by extracts of autoclaved yeast and of liver that cured black tongue in dogs and pellagra in man, but the appellation "pellagra" was unfortunate and unwarranted in both cases. In 1934 Gyorgy showed that these dermal lesions of rats are prevented by vitamin B₃ (pyridoxine) and five years later Jukes showed that the chick lesions are cured by pantothenic acid.

Eventually it became clear that the food stuffs and liver fractions that cured black tongue in dogs also cured pellagra in man. About this time Knight, in London, and others found that nicotinamide is a growth factor for bacteria. In

1937 Elvehjem, Madden, Strong and Woolley isolated nicotinamide from a fraction of liver extract with marked antilack tongue activity and showed that it, and nicotinic acid, were highly curative. The beneficial effect of nicotinic acid in pellagrous patients was soon established, and a new era dawned in the treatment of pellagra.

NICOTINIC ACID TRYPTOPHAN RELATIONSHIP A new aspect of the puzzling pellagra problem was exposed when Krehl and his colleagues in Elvehjem's group found, in 1945, that extra tryptophan could substitute for nicotinic acid in purified diets of rats: addition of either 1 mg nicotinic acid or 50 mg L-tryptophan per 100 grams of diet restored growth to the normal rate. This discovery was an outstanding event in nutritional research for, as a rule, vitamins of the B complex cannot be formed by the tissues of higher animals. Later work showed that nicotinic acid can be synthesized from tryptophan with variable efficiency in many species (rat, pig, dog, horse, chick, turkey, and others) provided that other B vitamins (pyridoxine, riboflavin and thiamine) are adequate. This discovery explained several curious paradoxes: (1) although wheat and rice are essentially as low in nicotinamide content as is maize, pellagra is far more prevalent among maize eaters (maize is much lower in tryptophan content), (2) milk and milk products are among the most valuable pellagra preventing food stuffs and yet they are known to be low in nicotinamide (the milk proteins are, however, very good sources of tryptophan). The reason for the special susceptibility of maize eaters to develop pellagra was at last understood, and also why rats (with good synthetic powers) failed to develop lesions and even thrived on diets that were deficient for monkeys and pigs.

REQUIREMENTS AND SOURCES Since dietary tryptophan can to some extent supply the tissues with nicotinamide, and since many other factors are now known to affect the requirement, exact information on the human requirements is not available. In 1941 the Food and Nutrition Board of the National Research Council (United States) estimated the nicotinic acid requirement of adults to vary from 23 mg per day for a very active man to 12 mg for a sedentary woman. Current recommendations are somewhat lower, 12 to 18 mg for man, 10 to 15 mg for women. The Canadian recommendations for adults range from 5 to 16 mg nicotinic acid per day.

Both nicotinamide itself and nicotinic acid may be present in foods. Animal tissues usually contain

a larger proportion in the form of the amide. Plant tissues often have more present as nicotinic acid. For practical purposes the ratios in which they occur are unimportant as they possess equal biological activity. Fish and meat are good sources; kidneys are richer than corresponding muscle, and liver is richer still. The richest edible and readily available source is yeast. Baker's yeast contains 7 to 12 mg and dried brewers' yeast from 30 to 90 mg per 100 grams. Nuts are richer than legumes and these, in turn, contain more nicotinic acid than do most vegetables and cereals. Fruits are poor sources.

Nicotinic acid tablets (50 mg) are sold by pharmaceutical suppliers. The acid has a marked pharmacological effect, a pronounced but transient vasodilator action. An oral dose of about 20 mg causes flushing and tingling of the skin, fall of blood pressure and dizziness that may be alarming to patients not warned to expect these effects. Nicotinamide does not have this action. Both compounds are relatively nontoxic, the ratio of therapeutic dose to toxic dose being at least 1:1000. The toxicity of nicotinic acid is lower than that of nicotinamide, the LD_{50} for rats being 4 to 7 grams per kg and 1.5 to 1.7 per kg, respectively. As much as 5.4 grams of nicotinic acid per day has been given orally to man without harmful effect.

PYRIDOXINE (VITAMIN B₆) AND ITS AMINE AND ALDEHYDE

In the previous section it was mentioned that when rats were fed a purified diet deficient in vitamin B₆ they developed a dermatitis which Goldberger believed to be analogous to that seen in pellagrins. It was thought that cure of this condition in rats could be used as a test for the P-P factor. In Britain where the lesion was called rat acrodynia, Birch, György and Harris (1935) found that it was cured not by nicotinic acid (the P-P factor) or vitamin B₆ (riboflavin) but by a factor to which György assigned the name vitamin B₇. György's substance was adsorbed from yeast extract onto charcoal, from which it could be eluted. It was found to be adsorbed also onto fuller's earth from which it could be eluted with baryta solution. Hence, it came to be called the *eluate factor*, or Factor 1. Meanwhile, in the United States a "chick dermatitis" factor was being investigated. Because it was not adsorbed on fuller's earth, the chick factor came to be called the *filtrate factor* or Factor 2. The use of different sources (yeast, liver, rice bran), of different adsorbents and of different test animals led to considerable confusion during this period. The fractionation scheme (p. 917) indicates the prominent characteristics that assisted in the fractionation and influenced interim naming of the components of the vitamin B complex.

In 1938 the isolation of vitamin B₆ in crystal line form was announced from five laboratories (1) Gyorgy and (2) Kuhn and Wendt obtained it from yeast, (3) Lepkovsky, (4) Keresztesy and Stevens and (5) Ichiba and Michi isolated pyridoxine from rice bran extract, later a sixth laboratory reported a different method of isolation from rice bran (Matukawa, 1940) It is interesting to note that some years earlier, in 1932, Ohdake had isolated from rice polishings a nitrogenous compound with the same empirical formula, C₈H₁₁O₃N HCl. No biological activity was attributed to it, and only later was it shown by Ward (1938) to be identical with vitamin B₆.

CHEMISTRY The constitution of vitamin B₆ was established in 1938 by Kuhn and Wendt in Germany, who proposed the name "adermin." An independent synthesis by Harris and Folkers in the United States in 1939 confirmed the structure. Gyorgy and Eckardt (1939) proposed the name "pyridoxine" which is now the one generally accepted.

In 1942 Snell and his associates studied the growth promoting effects of pyridoxine on different microorganisms. Marked discrepancies were found when three different assay procedures (chemical, animal and microbiological) were used to measure the vitamin B₆ potencies of extracts of tissues. Out of these studies came the finding of two new substances closely related to pyridoxine, one in which the —CH₂OH on carbon 4 is oxidized to an aldehyde, the other in which the same —CH₂OH group is altered to —CH₂NH₂. These compounds are now called pyridoxal and pyridoxamine, respectively. All three have essentially equal growth effects in rats. However, in the case of some lactic acid bacteria, the aldehyde and amine have a growth promoting activity several thousand times that of pyridoxine.

Pyridoxine (2-methyl-3-hydroxy-4,5-di(hydroxymethyl) pyridine (C₈H₁₁O₃N))

Pyridoxal is the biologically active compound. Its phosphoric ester is the coenzyme concerned in the decarboxylation of certain amino acids.

Transaminases, racemases and several other types of enzymes concerned with amino acid metabolism appear to contain pyridoxal phosphate as coenzyme.

In mammals, pyridoxine and pyridoxamine are converted to pyridoxal. Foods contain varying proportions of the three compounds. Since all three have equal growth promoting effects in rats, the activity is usually expressed as "milligrams of vitamin B₆."

Pyridoxine Deficiency

Effects of pyridoxine deficiency have been seen in all species of animals studied, but these signs vary considerably. Rats lose their appetite, fail to maintain their weight, sometimes develop a typical dermatitis with swelling and edema (acrodynia), after prolonged deficiency loss of muscle tone develops and convulsions occur. In dogs a microcytic hypochromic anemia is regarded as a characteristic feature of vitamin B₆ deficiency. Turkeys develop hyperexcitability and convulsions without anemia. Ducklings develop anemia without convulsions or paralysis. Chickens exhibit various convulsive movements. Pigs, like rats, may have epileptiform fits, and they develop a microcytic anemia.

Observations *in vitro* have tended to implicate vitamin B₆ in protein metabolism, but systematic attempts to explore this in animals have given ambiguous results. One observation that should be mentioned is the similarity in the dermatitis produced in rats by essential fatty acid deficiency and vitamin B₆ deficiency. Witten and Holman suggest that vitamin B₆ is concerned in the conversion of linoleic and linolenic acids to arachidonic acid, which they regard as the essential fatty acid.

In man the effects of pyridoxine deficiency are less definite. Attempts to produce vitamin B₆ deficiency in human subjects have not been very successful. After a subject had been fed for a 55-day test-period on a diet devoid of vitamin B₆, Hawkins and Barsky found no marked alterations in the blood picture or biochemical findings. Nitrogen equilibrium was maintained, indicating

no serious abnormality in protein metabolism. The test period may have been too short to bring on the deficiency state. Holt and associates fed

a diet deficient in vitamin B₆ to two infants one developed convulsions the other hypochromic anemia. These limited observations made little impression and were practically overlooked. Then in 1951 an epidemic of convulsions among babies fed a commercial liquid formula occurred in the United States. A dry powder preparation made from the same formula in the same plant did not induce convulsions. The cause was traced to excessive destruction of vitamin B₆ in the sterilization of the liquid preparation. Addition of extra pyridoxine to the liquid formula eliminated the trouble.

Vilter and his associates produced vitamin B₆ deficiency in patients by giving a pyridoxine analogue, desoxypyridoxine, which appears to have antivitamin effects. Some of the patients developed skin lesions and various other effects were noted that could be cured by giving pyridoxine. It is now generally accepted that vitamin B₆ is essential for man.

For the most part, the therapeutic use of vitamin B₆ has been empirical. It has been of no value in the treatment of the anemias. Muscular weakness has not responded and various types of nervous disorders and convulsive seizures have not been cured. The nausea and vomiting of pregnancy as well as that following X-ray treatments were claimed to respond to 10 to 20 mg. doses three or four times daily, but there have been more failures than successes, where benefit was noted it may have been largely psychogenic. Pyridoxine has been reported to be of value in cheilosis and post-adolescent *acne vulgaris*.

Requirements, Sources and Toxicity

The pyridoxine requirements of man are not known. A figure of 1.5 to 2 mg. per day has been suggested, based on animal studies, but it is only a guess. The vitamin occurs in the tissues of plants and animals, often combined in protein complexes.

The richest natural sources of pyridoxine are those foods known to be good sources of the other members of the B complex, yeast, rice polishings, meats, liver, egg yolk, whole grains and grains of various cereal grains. Cucumber, lettuce and green peppers are excellent vegetable sources. No natural antagonist is known. The synthetic antagonist, desoxypyridoxine, is phosphorylated in the body, and as phosphoric ester competes with pyridoxine phosphate for the apoenzyme.

Pyridoxine has very low toxicity, doses up to

1 gram per kg. being tolerated without obvious effect by rats, rabbits and dogs. In rats the LD₅₀ orally is 5.5 grams per kg., by subcutaneous injection 3.7 grams per kg. and intravenously 657 mg. per kg. Tonic convulsions precede death in mice and rats. Daily doses larger than 1 gram per kg. in rats, rabbits and dogs caused impaired coordination within two or three days, progressing to severe tonic convulsions and death in the stage of paralysis (Unna, 1940).

PANTOTHENIC ACID

In 1901 the Belgian scientist, Wildiers recognized that yeast requires for optimal growth a special factor in addition to the known nutrients. He called it *bios* and attempted to isolate it. Professor Lash Miller in Toronto with G. H. W. Lucas and others separated *bios* into several components—*bios* I (later identified by Eastcott as mesoinositol) and *bios* II. The latter was soon shown to be a mixture. The component called *bios* III (later found to be pantothenic acid) was shown by Miller to contain β-alanine which in itself is sufficient for some yeasts.

In 1938 R. J. Williams and associates isolated from liver an acidic substance that had a marked effect on the growth of yeast. Because it is found widely distributed in plant and animal tissues Williams suggested the name pantothenic acid (meaning from everywhere). In the same year Woolley and others in Elvehjem's laboratory isolated the chick pellagra factor (filtrate factor) and believed it to be identical with pantothenic acid. Within a few months this was confirmed by Jukes and about a year later Williams and Major at the Merck laboratories established the structure by synthesis.

CHEMISTRY

Pantothenic Acid

This condensation product between pantoic acid (α-γ-dihydroxy β-β-dimethylbutyric acid) and β-alanine is a yellow, viscous oil soluble in water and labile to acid, alkali and heat. The sodium and calcium salts, which are soluble in water and crystalline, are considerably more stable.

ACETYL COENZYME A (ACETYL-CoA). A specific functional role for pantothenic acid was soon discovered. In 1942 a stimulatory effect of pantothenic acid upon pyruvic oxidation had been observed in *Proteus morgani*. Then in 1946 Lipmann while studying the acetylation of sulfanilamide by liver, found that a new coenzyme was involved.

which could not be replaced by any of the coenzymes known at the time. Also in 1946, Feldberg and Mann in England and Nachmansohn and Behrman in the United States found that a new stable cofactor is necessary for the acetylation of choline. These and other observations on acetylating systems led to the isolation of a new cofactor, called coenzyme A (A for acetylation), and to the finding of pantothenic acid in it. The presence of 1 mole of adenosine, 3 moles of phosphoric acid and 1 atom of sulfur per mole of pantotheic acid was soon shown, and the following structure was finally established by Hoagland and Novelli (1954)

Coenzyme A acts as an acetyl carrier. It is shown elsewhere that carbohydrate (via pyruvate) and fat (via acetoacetate) give rise in the body to a metabolically active fragment containing two carbon atoms. The work of Lysen and Reichert in Germany, and of many others, culminated in proof that the "active two carbon fragment" or "active acetate" is attached to the $-\text{SH}$ group

Pantothenic Acid Deficiency

All species of animals tested (e.g., rat, mouse, dog, fox, monkey, pig, chick and others) require pantothenic acid. The effects of deficiency vary considerably from species to species. Deficiency of this vitamin in the rat results in failure of growth, achromotrichia (graying of the hair) in black or brown strains, adrenal necrosis, hemorrhagic lesions, "bloody whiskers" (porphyrin caked), "spectacled eyes" (circumocular loss of hair) and a sticky exudate on the lids, dermatitis, a spastic gait, and, sporadically in some animals, anemia and leucopenia. In chicks, dermatitis (mouth and eyelids chiefly, feet slightly), poor feathering, poor growth with weight loss are seen, followed by incoordination, paralysis and death. Turkeys, ducks and pigeons react similarly to lack of pantothenic acid. In dogs, irritability develops and sudden prostration occurs, respiration and heart beat become rapid and convulsions lead to death.

In man, until recently, no definite pathological lesions due to deficiency of pantothenic acid had

been described. Perhaps the abundance of pantothenic acid in most foodstuffs accounts for this. There is no evidence to support extravagant claims that graying or loss of hair in man is due to lack of pantothenic acid. One condition has come to light, "burning feet syndrome," that may be due to lack of pantothenic acid. This syndrome was observed in prisoner of war camps in Japan and Burma and is common in parts of India. It does not respond to thiamine, riboflavin or nicotinic acid, singly or together. Gopalrao has reported striking improvement following daily injections of 20 to 40 mg. calcium pantothenate.

REQUIREMENTS, SOURCES AND TOXICITY No data on human requirements for pantothenic acid are available. The average intake on different dietary regimens has been estimated. Average (American) diets probably provide between 3 and 12 mg. daily, with a mean value about 9 mg. The highest excretion on normal diets was 5.3 mg. per 24 hours. Liver, kidney, egg yolk and fresh vegetables are the best dietary sources of pantothenic acid. Yeast and royal jelly are also good sources. Milk, meat, grains, fruits and nuts are fair to good, corn and rice are relatively poor sources.

The pantothenic acid in foods is reasonably stable for periods of storage, up to one year, under proper conditions, e.g., eggs and meat in cold storage, cereal grains, intact or ground, at room temperature. Usual cooking procedures and dehydration do not cause appreciable loss, but holding products at high temperatures for long periods (100 to 150° for 2 to 6 days) destroys much of their pantothenic acid.

Little is known concerning the pharmacology of pantothenic acid. Its toxicity is very low. The LD_{50} , orally, for mice is 10 grams per kg. of body weight, but rats given the same dosage survive without showing any signs of toxicity. Monkeys weighing 4 to 5 kg., fed 10 gram daily over a period of 6 months, showed no abnormality. Doses of 100 mg. have been given to man, intravenously, without toxic reactions, doses of from 10 to 20 grams given orally occasionally produced diarrhea, and in a few patients, edema.

BIOTIN

The essentiality of biotin for man seems proven, but whether it ever poses a problem in practical human nutrition is questionable. Biotin deficiency has been produced experimentally in human volunteers. Several spontaneous occurrences have been reported, but because biotin

occurs so widely distributed in Nature (in wheat and most other seeds, in animal organs, in yeast, etc.) endemic deficiency is unknown

The complex nature of Wildier's bios was suggested in 1922 by Fulmer and Nelson. By 1924 Lash Miller in Toronto had separated bios into three fractions, all of which were essential for *Saccharomyces cerevisiae*. The identities of bios I and of bios IIa (thought to be β alanine but later found to be pantothenic acid) have already been mentioned. The third factor, bios IIb, later given the name biotin, proved to be identical with vitamin H, a factor that cures the strange condition known as 'egg white injury'.

Skin lesions, loss of hair, progressive emaciation, nervous manifestations and death followed the feeding of diets containing a large proportion of raw or commercially dried egg white (Bateman, 1916, confirmed by others). Two women workers have contributed much to this field. M. A. Boas-Fixsen in 1927 observed that liver and yeast contain a 'protective factor', and that cooked egg white is not toxic. In 1933 Helen T. Parsons and E. Kelly reported that small supplements of liver, yeast or egg yolk to the diet neutralized the toxic effect of the uncooked egg white. The toxicity of raw egg white can be eliminated by digestion with pepsin or with hydrochloric acid as well as by adequate treatment with heat. Attempts to isolate vitamin H (a name chosen by Gyorgy for this vitamin because of its ability to alleviate the peculiar skin lesions, *Haut = skin*, in German) from liver and yeast progressed slowly because the animal assays were laborious and not very sensitive. Identification of biotin (the potent growth factor for yeast, isolated from egg yolk by Kogl and Tonnies) with the curative factor (vitamin H) was made by Gyorgy, Melville, Burk and duVigneaud in 1940. Its structure was published by duVigneaud in 1942 and its synthesis was accomplished in 1943 by Harris and his colleagues.

CHEMISTRY, SOURCES AND REQUIREMENTS Biotin, $C_{10}H_{16}O_2N_2S$, is an acid, sparingly soluble in cold water and dilute acids, but freely soluble in hot water and in dilute alkali. It is practically insoluble in organic solvents.

Biotin ($C_{10}H_{16}O_2N_2S$)

A number of homologues (compounds with side-chains of different length) and analogues (with oxygen replacing sulfur) have been prepared, some of which can substitute for biotin and some of which are inhibitory. Ox-biotin can cure biotin deficiency in rats and chicks, but larger doses than of biotin are required. Desthio-biotin stimulates the growth of yeast (*Saccharomyces cerevisiae*) in a biotin free medium, in contrast, it acts as an antimetabolite with *Lactobacillus casei*, blocking the utilization of biotin. The most potent inhibitors are biotin sulfone and di-homo-biotin (with five methylene groups (CH_2) in the side chain).

Biotin occurs in natural products mainly in bound forms. One of these, biocytin, is a peptide with L-lysine. Biocytin, like biotin, is water soluble and dialyzable, yet tissue biotin is not dialyzable until after treatment with acid (pH 3) or dilute sodium hydroxide. The binding is perhaps a peptide linkage since pepsin frees biotin. For the physiologist and nutritionist one of the most interesting bound forms of biotin is its combination with avidin, a special protein component of egg white. Avidin, so named because of its avidity for biotin, by forming an insoluble compound with biotin is responsible for the toxic effect known as "egg white injury." Avidin is denatured by heat and thereby inactivated. Biotin bound to avidin is not released by treatment with acid or the combined action of trypsin, pancreatin and papain. Biotin bound to avidin passes through the alimentary tract unchanged. Avidin has been found only in egg white (eggs of hens, turkeys, geese and ducks) and in the egg jelly of frogs. It appears to be a secretion from the mucosa of the oviduct.

The attempts to isolate biotin containing co-enzymes have not been successful although a number of enzymatic processes have been discovered in which biotin appears to play a part directly or indirectly. There is some evidence that biotin-co-enzymes are concerned in decarboxylation and in carbon dioxide fixation as well as in the deamination of aspartic acid, serine and threonine.

The biotin requirement of many microorganisms is known, but that of man and higher animals is less certain. An intake of 150 to 300 μ g per day has been suggested for man. Such figures can at best be called a guess. Balance studies in man have shown a urinary excretion greater than the intake in some cases, and the fecal output is often greatly in excess of the intake. This suggests that in man

synthesis by intestinal bacteria may provide more biotin than does the food

P-AMINOBENZOIC ACID (PABA)

In 1935 a new red dye with spectacular properties was described by Domagk. It could kill hemolytic streptococci in mice although it lacked this property *in vitro*. Tréfouël and his associates in France studied a series of related azo dyes and noted that all the ones displaying this property possess a sulfonamide group in the para position to the nitrogen linkage. Following this lead para-aminobenzene-sulfonamide was tested and found to be highly active both *in vivo* and *in vitro*. Discovery of the potent antibacterial activity of sulfanilamide was not only a milestone in medicine causing a tremendous new interest in chemotherapy but led to a new concept in metabolism viz of antimetabolites. Woods (1940) fractionated an antisulfanilamide fraction of yeast extract and obtained a material (with many of the properties of PABA) that neutralized the antibacterial action of sulfanilamide. When he tested PABA and found that it did indeed nullify the antistreptococcal activity of sulfanilamide he suggested that the action of the latter was the result of its competing with PABA for an enzyme controlling metabolic reactions essential for bacterial growth. Later Rubbo and Gillespie (1940) isolated pure PABA from yeast and showed that 1 mole of PABA could antagonize 23 000 moles of sulfanilamide. Fildes (1940) expressed Wood's theory in more general terms by suggesting that PABA is an essential metabolite although not necessarily a growth factor for organisms inhibited by sulfanilamide. Ansbacher (1941) believed that PABA is a vitamin necessary for the growth of chicks and that it acts as an anti-gray hair factor in the rat. There is no evidence to support the claim that PABA prevents or cures the graying of human hair. The modern view is that PABA should not be considered a vitamin since its essentiality is confined to microorganisms; it is not required in the diet of animals.

CHEMISTRY

PABA is a white crystalline solid that is readily soluble in alcohol and ether and slightly soluble in water. It occurs widely distributed

throughout the plant and animal kingdom. It is found both free and in combined forms. One of the better known conjugates is folic acid. Thus the view expressed by Fildes that PABA is an essential metabolite even though it may not be a dietary essential has been substantiated.

PABA is relatively nontoxic in either single doses or on prolonged administration. The acute LD₅₀ for mice, rats and dogs (oral administration) is about 3 G and 1 to 2 grms per kg, respectively. Large doses (20 to 30 grms per day) have been administered to patients with louse-borne rickettsial diseases (typhus and Rocky Mountain spotted fever) without serious pathological changes being caused by the drug.

FOLIC ACID (PTEROYLGLUTAMIC ACID, PGA)

(See also ch. 9)

Five different fields of work merged in the discovery of folic acid. Some groups were fractionating liver extracts in the search for a cure for pernicious anemia; others were looking for vitamin M (needed by monkeys) and still others were trying to isolate vitamin Be, a factor needed to prevent hyperchromic macrocytic anemia in chicks. Meanwhile microbiologists had found that certain bacteria, e.g., *Lactobacillus casei* and *Streptococcus faecalis* R (formerly called *S. lactis* R) would not grow on a mixture of salts, sugars, amino acids and known vitamins, but that addition of extracts of leaves, liver or yeast would initiate growth. Thus one of these latter groups of workers was searching for the *L. casei* factor and another for the *S. lactis* R factor. A feature common to the isolation of all these agents (i.e., the several factors comprising the folic acid complex) is that all are adsorbed on charcoal and eluted more or less quantitatively by dilute ammonia. Hence the term *nitrite eluate* factor was also applied to the material before it was isolated and identified.

The isolation of an active agent from spinach and its wide spread occurrence in green leaves led to the name folic acid (Nitebell, Snell and Williams, 1941, 1944) from *folium*, a leaf.

Concentrates from different sources displayed variable potency when tested in different species. For a short period the nature and relationships of these several closely related growth factors were uncertain.

Fermentation *L. casei* factor was found to contain three glutamic acid residues and yeast vitamin Be conjugate contains seven such residues.

Pteroylglutamic acid produces partial and sometimes even complete remission of pernicious anemia and certain other macrocytic anemias in man. Although folic acid promotes regeneration of red blood cells it is unable to control the disorder.

ation of the spinal cord that occurs in pernicious anemia. In some cases treatment with folic acid hastens the degeneration. Thus early hopes that folic acid would prove to be the antipernicious anemia factor of liver were dashed.

Meanwhile the nutritional requirements of *Leuconostoc citrovorum* were being studied by Sauberlich and Baumann (1943) and isolation of another unknown factor, the so called *citrovorum factor* (CF), also referred to as *leucovorin*, was attempted. A relationship to pteroyl glutamic acid was soon discovered. The structure of this new growth factor, now referred to as *folic acid*,

18

to be essential in man when the proper test has been made.

Function of Folic Acid

The primary biochemical role of folic acid appears to be concerned with the incorporation of a one-carbon unit into a variety of essential metabolites: purines, pyrimidines and certain amino acids. The labile one-carbon unit has been referred to as "active formate" or "active formaldehyde." Formate precursors include the methyl groups of choline, methionine, sarcosine and dimethylglycine, the beta carbon of serine,

Folic acid
(5-formyl-5,6,7,8 tetrahydropteroyl glutamic acid)

It is probable that in many biochemical systems folic acid is not active as such, but that it must be converted to folinic acid which is (or is closely related to) the *citrovorum factor* (CF) which seems to be the functional form of the compound or is closely related to a more labile intermediate (transformylating coenzyme).

Effects of Deficiency

The pteroylglutamates are necessary for monkeys, chicks, turkeys, dogs, foxes, mink, guinea pigs and for rats treated with sulfa drugs (see ch. 9). An experimental deficiency of folic acid has not been produced in man so it is not possible to state with assurance that man requires it. On the other hand, the proven value of folic acid in sprue and the pernicious anemia of pregnancy, and in megaloblastic anemia in infants, nutritional macrocytic anemia and related megaloblastic

anemias makes it likely that it will prove the methylene carbon of glycine, and histidine and acetone. Active formate or active formaldehyde appear to be compounds with tetrahydrofolic acid that aid in the transfer of one-carbon units, i.e., that act as transformylating coenzymes.

Although folic acid and vitamin B₁₂ have been shown to play a role in lipotropic phenomena, the details of the picture are obscure. The lipotropic effect is clear cut in rats fed certain diets, on other diets these vitamins may produce no alteration in liver fat or they may even exert an antilipotropic effect. Neither folic acid nor vitamin B₁₂ is necessary for *transmethylation*. Folic acid is needed for transformylation reactions and vitamin B₁₂ seems to be concerned in the reduction of formate via formaldehyde to biologically labile methyl.

The folic acid antagonists *aminopterin* (4-amino-*pteroylglutamic acid*) and *A methopterin* (4-amino-10-methyl-*pteroylglutamic acid*) inhibit the incorporation of radioactive carbon from formate into the nucleic acid purines. These and other folic acid antagonists have been used therapeutically in attempts to control leukemia in man. Remissions have been induced that are more frequent and of longer duration than those common to the natural course of the disease, but no cures have been reported.

SOURCES AND TOXICITY Substances with folic acid activity, as measured by microbiological assay, are widely distributed in nature. Most of the activity is present in bound forms (conjugates). Liver has the highest activity; vegetables and many fruits are rich sources; nuts, dried beans, and peas are good sources. Folic acid is synthesized by intestinal bacteria. The extent to which this occurs affects the dietary requirement.

Pteroylglutamic acid has very low acute and chronic toxicity.

VITAMIN B₁₂ CYANOCOBALAMIN

Animal Protein Factor (APF)

Several papers appeared during the period 1934 to 1936 indicating that an active substance, different from other known dietary factors, improved the hatchability of hen's eggs and increased the growth rate and survival time of chicks fed cereal rations free from animal protein. Because the factor (or a related substance) was found in products as diverse as liver, animal flesh, fish meals, condensed fish solubles, chicken droppings, and cow dung, but not in plant materials, it was called the animal protein factor or APF. In 1946 Cary and associates described a new factor, λ , necessary for the growth of rats. It occurred in crude casein but could be leached out by suitable treatment. Factor λ appeared to be the same as, or closely related to, the animal protein factor.

In 1948 Mary Shorb reported that a certain bacterium, *Lactobacillus lactis* Dorner, could be used to test for and assay the rat growth vitamin APF. Later work of Shorb, Folkers, and others suggested that this new factor, which they named vitamin B₁₂, was identical with the long sought-for antipernicious anemia principle. The final stages of the isolation of vitamin B₁₂ were greatly accelerated by using this bacterial assay method, which in a few hours gave answers that by animal tests had taken weeks and months by the tedious and costly clinical tests.

CHEMISTRY Vitamin B₁₂ is a red crystalline substance (mol. wt. about 1350) which contains

a metal porphyrin nucleus similar to that of heme or chlorophyll but with cobalt (4.5 per cent) as the metal. It has the most complex structure of any vitamin known. The base, dimethylbenzimidazole (which also occurs in riboflavin) was identified fairly early; later it was shown to be linked to ribose phosphate, a 2-aminopropanol unit, later shown to be Dg 1-aminopropanol, and a cyanide ion were also identified. The short name cobalamin was proposed for the active material.

A search for other and possibly richer sources of vitamin B₁₂ led to the discovery that it occurs in many animal products but that plant materials show no measurable activity. It now seems that neither animals nor higher plants can make vitamin B₁₂. Certain nonphotosynthetic organisms serve as the primary source. It was from the fermentation broth of a strain of *Streptomyces griseus* that the workers in the United States isolated crystalline vitamin B₁₂.

Fermentation broths from other organisms provided several closely related compounds with equal activity in the treatment of pernicious anemia. They are related coordination compounds of cobalt in which the CN⁻ ion is replaced by a hydroxyl group or water molecule. The three compounds are therefore called cyanocobalamin (B_{12a}), hydroxycobalamin (B_{12b}), and aquacobalamin, respectively. Analogous compounds are known in which unnatural nucleotide bases have been introduced by biosynthetic means or in which halogens, thiocyanate or nitrite ions have replaced the cyanide ion.

Seven years were required to elucidate the arrangement of the recognized fragments in the antipernicious anemia vitamin. It is of great scientific interest that a new tool was used with outstanding success in solving this problem.

The structure of the formidably large and complex vitamin B₁₂ molecule was deduced largely from crystallographic evidence supplied by X-ray reflections (Hodgkin *et al.*). Using automatic computers, a series of calculations of successive degrees of approximation to the correct electron density distribution provided a solution to the chemical structure of the nucleotide-free hexacarboxylic acid (C₆₄H₈₈O₁₄N₁₄CoCl·2H₂O) that was obtained from vitamin B₁₂ by alkaline hydrolysis. Elucidation of the structure of such a molecule from X-ray data represents a great triumph for crystallography. This information, in conjunction with the chemical evidence accumulated during the seven years, enabled Todd and Smith and their associates to propose the formula C₆₃H₈₆O₁₄N₁₄Co and the probable structure

VITAMIN B₁₂

(Taken from Nature 176, 329, 1955)

OCCURRENCE Accurate figures for the occurrence of vitamin B₁₂ were not easily obtained, microbiological assays, animal tests and clinical trials frequently gave inconsistent data. Many values in the earlier literature are therefore suspect. Plant materials show no measurable activity, animal tissues and secretions usually show some, but extremely variable, potency. Extracts of human livers and of livers of 26 species of mammals and 3 species of fish were active in pernicious anemia. Estimates of the amount of vitamin B₁₂ in various foodstuffs (μg per 100 grams) are: mammalian muscle (horsemeat, beef, pork, mutton) 1 to 5, different organs showed considerable variability (beef kidney and liver 15 to 20), egg yolk, 1 to 3, milk, traces, cheese, milk powder and crude casein, 1 to 3. Concentrates of cobalt-containing pigments from cow-dung and from certain mould cultures are inactive in pernicious anemia but become active after digestion with gastric mucosa or pancreatic enzymes.

Effects of Deficiency

The greatest interest in vitamin B₁₂ concerns its effectiveness in the treatment of pernicious anemia. Doses as small as 1 to 3 μg per day cure both the hematological and neurological defects. Vitamin B₁₂ is more effective in patients by in-

jection than by mouth. Oral doses 30 to 60 times the effective parenteral dose may cause a slow response in some patients. Vitamin B₁₂ has other physiological effects besides the stimulation of hematopoiesis. It promotes the growth of animals fed diets low in the animal protein factor, i.e., consisting mainly of protein from plant sources. There appears to be a relationship between B₁₂ and thyroid activity but this needs further study.

In vitamin B₁₂ deficiency, rats develop enlarged kidneys and elevated blood urea levels. Deficient chicks also show an elevated blood NPN. A nutritional edema preventable by vitamin B₁₂ (and also by choline) has been described in dogs and rats. Vitamin B₁₂, in conjunction with folic acid, is concerned in the metabolism of the one carbon fragment including the biosynthesis of methyl groups. This vitamin is not involved in transmethylation reactions but it does seem to be concerned in the reduction of active formate (5-formyltetrahydrofolic acid) to active formaldehyde (5-hydroxymethyl tetrahydrofolic acid) with ultimate formation of a biologically labile methyl group.

INOSITOL

Inositol has been known since 1850 when Scherer isolated it from muscle and called it "muscle sugar". It was shown by Maquenne in 1887 to be a hexahydrocyclohexane. In 1928 Edna V. Eastcott first demonstrated its biological importance when she showed mesoinositol to be the growth factor for yeast called bios I. Although inositol is essential for the growth of yeasts and some other microorganisms, its role in mammalian nutrition is less clear.

In 1940 D. W. Woolley found inositol to be an essential dietary factor for a mammal—attempts to rear mice on a purified diet lacking it, results in failure to grow and loss of hair. Production of alopecia in mice and rats fed diets lacking inositol has been confirmed by a number of workers. Inositol improves the growth rate of chicks, guinea pigs and hamsters.

Inositol plays some role in fat metabolism although the mechanism is not known. In fat free diets lacking choline it exerts a small but clear cut lipotropic effect. It exerts a definite supplementary lipotropic action in diets containing choline. The presence of fat in the diet tends to block the lipotropic action of inositol. This fact and its inability to protect weanling rats from developing hemorrhagic kidney lesions when fed hypolipotropic diets shows that it is not a lipotropic agent in the usually accepted sense. Many

text books have misinterpreted the data on the lipotropism of inositol (see Best *et al*, 1950, 1951) The so called "lipotropic effect of inositol under conditions where choline is ineffective" is really a synergistic lipotropic effect of inositol in a ration already containing much more than a maximally effective dose of choline in the basal diet More choline obviously could have no further effect The failure to appreciate that the basal diet contained so much choline led to the erroneous belief that inositol possesses some unique lipotropic properties

CHEMISTRY Inositol, $C_6H_{12}O_6$, is a hexahydrocyclohexane

(A)

(B)

Formula A attempts to show the spatial arrangement of the hydrogen atoms and hydroxyl groups with respect to the plane in which the carbon atoms of the ring lie Formula B is an abbreviated but very useful representation in which the short vertical lines represent the position of the hydroxyl groups As the formula suggests, nine stereoisomers are possible The isomer which is most frequently encountered in nature, and which is important in the nutrition of animals and some bacteria, was originally called "muscle sugar," but because it is optically inactive it has also been called *D*-inositol or *meso* inositol These names are inappropriate because there are six other optically inactive isomers Lardy has suggested that these chemically incorrect and confusing terms be replaced by *myo* inositol

Inositol is present in combined forms in yeast and other microorganisms, in heart muscle, thyroid, kidney, spleen and testes

REQUIREMENT AND SOURCES No lesion due to lack of inositol is known in man and no role can be assigned to it in human nutrition or metabolism No estimate can be made of the human requirement Williams has estimated that the average mixed diet (2500 Cal) provides about 1 gram of inositol

Inositol occurs in leaves and seeds It is found combined with phosphoric acid in esters (mono-, tri- and hexaphosphoric) The latter ester (phytic acid) occurs in cereals as a mixed calcium mag-

nesium salt called *phytin* This compound immobilizes calcium in a nonavailable form and is the compound responsible for the rachitogenic effect of oatmeal Inositol has been found in the phosphatides isolated from soya beans, brain and livers

Choline and the Lipotropic Agents

Choline and the dietary components that serve as precursors are known as lipotropic agents (see ch 49)

The word *lipotropic* was coined to describe dietary factors that prevent the accumulation of fat in the livers of experimental animals fed high fat, low protein diets Later it was shown that no fat whatever in the food is needed to produce fatty livers, provided that the ration is made relatively low in lipotropic agents The nutritional importance of choline was not discovered until 1932 Some workers doubt whether choline should be included with the other B vitamins The amount required is large (5 to 30 mg per day for a rat) compared with that of other recognized members of the B group whose requirement is often measured in micrograms, furthermore, choline is used for structural purposes in nervous tissue

In 1924 Allan *et al* and Fisher noted independently that depancreatized dogs maintained with insulin developed large, fatty livers Feeding raw pancreas prevented this Several years later Hershey showed that commercial egg yolk lecithin also prevented the development of these fatty livers In 1932 Best, Hershey and Huntsman identified choline as the protective agent Betaine was soon found to possess similar activity

The nature of the protein used in the preparation of rations low in lipotropic action, affects the amount of fat deposited in the liver The variable lipotropic effect of protein seemed to be explained when methionine was found to possess lipotropic properties Choline, betaine and methionine are the three lipotropic agents found in common foodstuffs Sulfur analogues of betaine

Choline

Betaine

Methionine

occur in small amounts in some plants. These so-called *thetins* are strongly lipotropic, but their distribution is limited, and probably they play a negligible lipotropic role in normal diets.

Dietary choline is necessary for normal growth and continued health in species as varied as rats, mice, dogs, rabbits, chicks, turkeys, trout, cock roaches, and mosquito larvae. Fatty livers due to lack of choline have been observed in rats, mice, dogs, rabbits, hamsters, guinea pigs, calves, pigs, monkeys and ducklings. (It should be kept in mind that fatty livers may develop from other causes, such as infections, toxic chemicals, hepatic anoxia or other deficiencies that interfere with hepatic function. Choline cannot prevent damage occurring from these conditions.) A prolonged lack of choline leads to the appearance of fibrotic changes in the liver, with the eventual development of cirrhosis. Choline deficiency leads to a number of other abnormalities. Bradycardia has been observed in choline deficient rats. Sore has shown that it is needed for normal lactation in the rat. Weanling rats, calves and pigs develop a hemorrhagic renal lesion that is often fatal and rabbits develop a nonhemorrhagic renal lesion preventable by choline. Muscular weakness has been noted in rats and pigs, and muscular dystrophy in rabbits fed choline deficient rations. Baby chicks, turkey poults and ducklings fail to grow on diets poor in choline and develop perosis (a paralyzing slipped tendon disease). Many other defects due to choline deficiency have been described but cannot be listed here.

Besides the well known accumulation of glycerides and concomitant increase of cholesteryl esters in the liver, several other biochemical changes are caused by lack of choline. The turnover of hepatic phospholipids is decreased in choline deficiency. The prompt increase in the turnover of liver phospholipid P caused by feeding or injecting choline is nonspecific, however for a similar effect may be produced by methionine, cystine or ethanolamine. Plasma phospholipids of rats are decreased in choline deficiency and there is a marked reduction in the low density lipoprotein fraction of the serum. As the liver damage in rats and dogs progresses to cirrhosis, with prolonged choline deficiency the concentration of cholesteryl esters in the blood serum falls to very low levels.

ASCORBIC ACID (VITAMIN C)

As recounted earlier, scurvy in man has been known for centuries and the protective value of fresh vegetables and fruits (especially lemons and limes) was discovered, forgotten and rediscovered several times. When Holst and Frolich in 1907 found that guinea pigs develop an analogous scorbutic state progress in the isolation of the curative

principle became possible. Zilva and associates in Britain, Szent Györgyi (1928) in Hungary and Waugh and King (1932) in the United States made the major contributions to the isolation of the "hexuronic acid" with unusual reducing properties which was soon identified with vitamin C. The configuration was established in 1933 in Haworth's laboratory in England and within a few months the synthesis was achieved almost simultaneously by Reichstein and associates in Switzerland and by Haworth's group.

CHEMISTRY Ascorbic acid, $C_6H_8O_6$, is an enediol of the lactone of L-gulonic acid:

Vitamin C is a moderately strong acid ($pK = 4.21$) which is stable in the crystalline state but in solution is readily oxidized by atmospheric oxygen. The product of this reaction, dehydroascorbic acid, is also produced quantitatively when iodine or the dye 2,6-dichlorophenolindophenol acts upon vitamin C. These reagents are used for its determination. The dehydro compound is readily reduced to reform ascorbic acid. This property of easily reversible oxidation and reduction is bound up with its apparent function in the tissue, namely, transport of hydrogen.

Vitamin C is one of the few vitamins that occurs in nature as a single active compound, viz. L-ascorbic acid and its reversibly oxidized form (cf. vitamins A_1 and A_2 , the several active carotenoid pigments, the several forms of vitamins D, E, K, etc.). Vitamin C has not been found in any coenzyme complex, nor has any "combined form" been isolated. It is one of the few water soluble vitamins for which no acceptable microbiological method of assay has been found. Some fruits and vegetables, notably bananas and cauliflower, contain *ascorbic oxidase*, an enzyme which can cause rapid oxidative loss of vitamin C when the foodstuff is cut or crushed during preparation for the table.

Little was known until recently about the precursors of vitamin C, but now evidence points to the sequence of changes in glucose $\rightarrow$

D-glucurono γ lactone $\rightarrow$ L-gulono- γ lactone $\rightarrow$ L-ascorbic acid D Galactose can also function as precursor by a corresponding series of changes via D galacturonic acid and L-galactono γ -lactone The change from the D- to the L-series at the second step is remarkable, and it is thought that the few species requiring vitamin C do so because they lack the enzyme needed for this change

Ascorbic Acid Deficiency

All species of animals studied have shown a need for ascorbic acid in their metabolism, but most species have the ability to meet this requirement by biosynthesis from carbohydrate precursors The guinea pig and primates (including man) are the only animals known to require vitamin C in the diet Early studies were complicated by the failure to realize that this dietary peculiarity is limited to a few species Once it was recognized that the guinea pig is highly susceptible to lack of vitamin C, and that the resulting lesions are similar to those seen in man, experimental studies enabled the sequence of changes due to vitamin C deficiency to be elucidated

An outstanding feature of vitamin C deficiency is the failure to deposit intercellular cement substances (collagen, osteoid and dentine) This explains the petechial hemorrhages and ecchymoses (related to fragility of the tissues), the pains in bones and joints the weakened bones and badly formed teeth (in children) and loosened teeth in adults with scurvy There is no correlation, however, between the intake of vitamin C and the incidence of human caries Although the final lesions can be attributed to an impairment in the functioning of the formative cells, the underlying biochemical defect is still not known The well known liability to infection, in both guinea pigs and man, during vitamin C-deficiency suggests that the lowered resistance to infection may be due to impairment in the disease resisting mechanisms

Ascorbic acid has been shown, both *in vivo* and *in vitro*, to promote the oxidation of tyrosine and phenylalanine Because other substances, without antiscorbutic activity, can also stimulate tyrosine oxidation, it is doubtful whether this interesting property of ascorbic acid accounts for its prevention of scurvy

The finding that ascorbic acid is needed by the system concerned with the conversion of folic acid to *citrovorum factor* (folic acid) may

lead to a better understanding of the unclear relationship between scurvy and anemia

REQUIREMENT Improvements in food handling (collection, transportation, storage and processing) have largely eliminated scurvy It is still occasionally seen, however, on this continent, in Britain and elsewhere among both infants and adults

The amount of vitamin C needed to prevent scurvy, known as the "minimum protective dose," appears to be in the region of 10 mg per day, as established by a carefully controlled experiment on adult volunteers at Sheffield, England (1948) However, the amount needed for abundant good health is not known The uncertainty has led to considerable controversy The Accessory Food Factors Subcommittee of the British Medical Research Council concluded that there is no evidence that intakes exceeding 30 mg per day confer any extra benefit Others contend that such evidence does exist The Food and Nutrition Board of the National Research Council, United States (1953) recommends (but without sound experimental data to support the values) daily intakes of 75 mg for adults, with 100 to 150 mg during pregnancy and lactation They suggest that children up to 12 years of age should get 30 to 75 mg daily

Harris and his colleagues in Britain attempted to assess the nutritional status of patients with respect to vitamin C by doing so-called loading or saturation tests which were supposed to reveal the extent of the reserves Persons whose diets have been rich in vitamin C presumably have their tissues saturated with the vitamin, those with lower intakes are presumably in a lower state of saturation In partial support of this concept, a lower urinary excretion of ascorbic acid is usually observed with lower intakes of vitamin C This resting level of excretion did not provide a reliable measure of nutritional status, however A better assessment was obtained by administering a large test dose of the pure vitamin each day, for a period, and measuring the excretion during each 24 hours

If the previous diet had been adequate with respect to vitamin C, the tissues did appear to be relatively saturated with it because most of the extra vitamin C in the loading dose was excreted promptly in the urine The number of days required to reach a high level of excretion was found to be related to the previous intake, with higher intakes (75 mg or more per day) the peak followed the first dose, an intake of 30

Values for pyridoxine, pantothenic acid, biotin and folic acid are not given as many data now in the literature are known to be unreliable.

Taken from United States Department of Agriculture Handbook No. 8, 1950.

mg per day led to peak excretion after 1 or 2 days, patients ill with scurvy required dosing for 7 to 10 days to reach peak excretion values.

Similar loading or saturation tests have subsequently been used in studying the nutritional status of patients with respect to other vitamins. The significance of the findings has not always been clear. There is controversy over the value of some loading tests.

Attempts have been made to measure the vitamin C status of patients by determining the amount of ascorbic acid in their blood. In human blood plasma, ascorbic acid is normally found in the range 0.7 to 1.2 mg per 100 ml, values between 0.4 and 0.7 are believed to indicate a mild deficiency and below 0.4 mg per 100 ml a severe deficiency. There is some evidence that the ascorbic acid content of the white cells may have greater diagnostic value than that of the plasma.

Distribution. Some fruits and vegetables are rich sources of vitamin C (currants, strawberries, citrus fruits, kale, parsley, spinach, tomatoes, cress and green peppers) while others provide a negligible amount (apples, cherries, pears, plums, lettuce, radish, celery, beets). Germinating grains and pulses contain vitamin C. Cow's milk has very little, 0 to 2 mg per 100 ml (calves do not need it). Human milk contains about 6 mg per 100 ml. Foods devoid of ascorbic acid include yeast, eggs, meat, fish, nuts, cereals, bread, dried peas, beans and corn (maize).

SOME OTHER ACCESSORY FACTORS. In 1936 Szent György and his colleagues noted that guinea pigs raised on scorbutic diets did not get as much protection from pure ascorbic acid as they did from an equivalent amount of vitamin C provided in natural food sources, such as citrus fruits and peppers. The difference was attributed to a new agent

which Szent Gyorgyi called vitamin P because it occurs in paprika and lemon peel and was believed to be concerned with capillary permeability and fragility. Other workers have been unable to confirm the role of vitamin P in capillary fragility but it does appear to improve utilization and/or storage of vitamin C. A number of pure compounds possess vitamin P activity. These are flavone glucosides: *rutin* (from tobacco and buckwheat), *hesperidin* and *eriodictin* (from lemon peel) and *esculin* (from horse chestnuts). The pure flavone glucosides are much less active than crude concentrates. Thus neither can properly be called vitamin P.

Joint stiffness has been observed in guinea pigs fed diets rich in milk (Wulzen and Bahrs). The condition has been confirmed in several laboratories. Extensive calcification of the joints, body wall and cavity occurs, and profound changes have been noted in the skull and teeth. Difficulties in assaying the protective principle have interfered with its isolation and identification. A number of steroids possess some antistiffness potency. The subject is still in an unsatisfactory state.

As an outgrowth of studies on rheumatic fever (Coburn, 1945, 1954), it was found that an active fraction from egg yolk will inhibit experimental anaphylactic arthritis in guinea pigs. Certain other lipid rich materials were found to possess anti-inflammatory activity, e.g., peanut (arachis) oil and soybean lecithin. The active principle has been isolated from the latter source and identified as *N* (2 hydroxyethyl) palmitamide.

ANTIMETABOLITES AND ANTIVITAMINS

It has long been known that when a small alteration occurs in the molecular structure of a metabolite, some (and often all) of its activity is lost. In some cases the new compound may actually antagonize the biological action of the metabolite, it is then called an antimetabolite. About fifty years ago chemists found that enzyme action is often inhibited by substances whose molecular structure resembles that of the substrate. Innumerable examples have since come to light.⁴ Kinetic studies have indicated that these effects are due to combination of the unnatural substance with the enzyme to form a

⁴ Malonic acid, for example, is a competitive inhibitor of succinic dehydrogenase.

Malonic acid

Succinic acid

more stable compound, thus blocking normal functioning of the enzyme. In some cases the union is so firm that the combination is classed as irreversible, in such a case the reaction is essentially a complete blocking, or poisoning, of the enzyme. In others, a large excess of the natural substrate can displace the unnatural substance from its union with the enzyme. Thus latter situation is spoken of as *competitive inhibition*. Antivitamins are compounds (antimetabolites) that antagonize the action of vitamins, they often function as competitive inhibitors of vital processes.

Antivitamin action was probably first observed in 1935 by Woolley, Strong, Madden and Elvehjem. Dogs suffering from nicotinic acid deficiency were given two analogous compounds, pyridine 3 sulfonic acid (II) and 3 acetylpyridine (III) to see whether these structures retained any protective properties. Surprisingly, the condition of the dogs was made worse.

About two years later Woods showed that PABA neutralizes the antibacterial action of sulfanilamide, and he suggested that this effect is due to competitive inhibition of some essential metabolic reaction. Fildes (1940) suggested that a series of useful new chemotherapeutic agents might be produced by synthesizing compounds closely resembling vitamins or essential metabolites, but with some small structural change. Within a few months Mellman showed that pyridine 3 sulfonic acid (II) does inhibit several bacteria that require nicotinic acid, and that growth was resumed when a large excess of nicotinic acid was added to the medium. Since that time a large number of "antivitamins" that work in bacterial cultures have been found. Only a few of these have been shown to exert their effects in animals. A few of these have powerful chemotherapeutic effects and are used in medical practice, e.g., *p*-aminosalicylic acid in tuberculosis, pyrimethamine in malaria and *A* methopterin in leukemia.

Several better known examples of antivitamins will be mentioned. Pyrimthamine (thiamine with the thiazole ring replaced by pyridine), produces a characteristic thiamine deficiency in mice. Oxythiamine (in which the amino group of the pyrimidine ring is replaced by hydroxyl) also causes death, but without the signs of polyneuritis produced by the pyridine compound. Oxythiamine prevents the formation of coenzyme B₁₂, its di-phosphate prevents utilization of this coenzyme

Powerful antiriboflavin activity in mice is displayed by an analog in which the pyrimidine ring is replaced by a 2,4-dinitrobenzene ring. Desoxy pyridoxine (in which the $-\text{CH}_2\text{OH}$ group on position 4 is replaced by CH_3) produces signs of pyridoxine deficiency in chicks, rats and man. Recent evidence suggests that the analogue is inactive until it is phosphorylated in the body, the resulting ester combines with the apoenzyme and prevents the normal union of pyridoxal phosphate with the protein(s) to form the amino acid decarboxylase(s). Methoxy pyridoxine (in which the same $-\text{CH}_2\text{OH}$ group is changed to $-\text{CH}_2\text{OCH}_3$) is an antivitamin in chicks, but rats and mice are able to convert it to pyridoxine.

The antituberculosis drug, *isoniazid*, causes signs of pyridoxal deficiency in man, but not by competitive inhibition, the vitamin aldehyde reacts with the drug to form the inert isonicotinyl hydrazone of pyridoxal.

Pantoyltaurine, in which the carboxyl group of pantoic acid is replaced by a sulfonic acid (SO_3H) group displays competitive inhibition of the vitamin in a number of bacteria but is not inhibitory in animals. Although pyridine-3 sulfonic acid inhibits growth of some bacteria it does not produce nicotinamide deficiency in vertebrates. However, 3 acetylpyridine does compete in vertebrates, and either nicotinic acid or its amide can reverse the inhibition, but it is not an antivitamin for bacteria. A large number of antagonists of folic acid have been described, two of the more potent are 4-amino-pteroylglutamic acid, commonly called aminopterin and A methopterin (4-amino- N^6 -methylpteroylglutamic acid). From the observation that substances containing the 2,4-diaminopyrimidine nucleus are antagonists of folic acid in certain microorganisms, but possess low toxicity for mammals, has come a powerful antimalarial drug, pyrimethamine = Daraprim. A whole family of hydrazine coumarins substituted in the 3 position display antivitamin K properties. Even salicylic acid has anticoagulant action that is reversible by vitamin K.

The combination of avidin with biotin to form an inactive compound and the interference of phytin (in cereals) with the absorption of calcium, which indirectly affects the requirement for vitamin D, are examples of vitamin antagonists that do not act as competitive inhibitors.

An enzyme, thiaminase, occurs in several species of fresh and salt water fish and other marine creatures. When these lake or sea foods are fed raw to foxes or other animals a form of paralysis (Chastek) develops that can be cured by giving extra thiamine.

Antagonists of amino acids, purines, pyrimidines, of hormones and of other metabolites are known but cannot be discussed here. An interesting compound which blocks the citric acid cycle is

fluoroacetic acid. It is accepted by cells as if it were acetic acid and appears to cause no damage until it becomes fluorocitric acid. Here it competes with citric acid and quickly causes death of the cell. Some plants, by concentrating fluorides from the soil (when an excess is present) become toxic to cattle, the seeds of ratbane contain a poisonous fluorinated fatty acid which exerts its lethal effect in this way. Many of the insecticides and herbicides now available act by competitive inhibition of some vital function of the insect or plant being controlled. Woolley has published a book on anti-metabolites and Albert has recently reviewed the subject.

DIETARY REQUIREMENTS

In planning a diet the following requirements must be taken into account

- 1 The total caloric value
- 2 The proportions of the different foodstuffs—carbohydrate, fats and protein
- 3 The mineral constituents
- 4 The vitamin content

In order that the body shall not be forced to consume its own tissues for fuel the caloric value of the ingested food for 24 hours must balance the energy (work plus heat) output by the individual during the same period. The basal metabolic rate is obtained by direct determination (ch 44) or by calculation from the subject's height and weight. The average extra caloric allowances for different grades of muscular activity are given in table 55 J (p 947).

Sample Calculation of Caloric Requirement

The approximate basal metabolism of an average size man (20 to 40 years of age) may be calculated as follows: the energy output per square meter is 40 Calories per hour (p 764), the average surface area of 1.8 square meters corresponds to 72 Calories per hour. While the subject is asleep (8 hours) the metabolism is about 90 per cent of this value; during this period about 620 Calories are required. The basal requirement for 16 waking hours (16×72) is about another 1150 Calories. The hourly work increment of those in sedentary occupations varies from 20 Calories for writing to 45 for tailoring while in the more strenuous occupations it varies from 180 (heavy carpentry) to 360

(mining, lumbering) or more. To the total so estimated 10 per cent is added to cover the increased metabolism (specific dynamic action) due to the food itself.

For more precise calculation of the caloric requirements other factors must be taken into account e.g. the body weight and the temperature at which the work is performed. An allowance or a deduction of 3 per cent is made respectively for each 10 degrees F. rise or fall from the average temperature (70°F). Thus if the total metabolism as calculated above is 5620 Calories but the temperature is 60°F the diet is planned for a total energy expenditure of $(5620 \div 170) = 5790$ Calories. In performing certain types of work such as walking, ascending stairs or any work which entails lifting the body or its heavier parts the energy expenditure is more nearly proportional to the body weight raised to the power 0.7 than to the surface area.

The Relation of Age and Sex to the Caloric Requirement

Women have a somewhat lower basal metabolic rate than men and generally speaking they expend less energy in muscular work, their food requirement is proportionately less, approximately 35 per cent of a man's or about 2000 to 3000 Calories per day. The caloric intake should be about 20 per cent greater during the latter part of pregnancy, and about 30 per cent greater during lactation than at ordinary times.

Children require weight-for-weight a greater food allowance than the average adult for three reasons: (a) Their basal metabolic rate is considerably higher especially at the younger ages; (b) A proportion of the food material is utilized for building body tissue; (c) Children as a rule expend more energy in muscular activity than the average adult. For example, a boy of 16 years of age, of average physique and taking an active part in games, requires a daily energy intake equal to that of a man—from 3000 to 4000 Calories or from 50 to 70 Calories per kilogram of body weight per day (average adult requirement, 46 Calories per kilogram).

*Estimated daily
Caloric require-
ment*

Clerk Miner

Metabolism of sleep (8 hours)	520	520
Basal metabolism (16 hours)	1150	1150
Nonwork allowance (8 hours)	400	400
Work allowance (8 hours)	300	3040
Subtotal	2370	5110
10 per cent for specific dynamic ac- tion	240	510
Total	2610	5620

During the first 3 months of life the dietary requirement is about 120 Calories per kilogram. From 4 to 9 months the requirement falls to about 110, and during the ages 10 to 12 months it is about 100 Calories per kilogram. Since a child 1 year of age usually weighs about 9 to 11 kg, its dietary energy requirement is about 900 to 1100 Calories. Data for other age groups are shown in table 55 1.

The Protein Allowance

A great deal of controversy has centered around the question of the protein requirement of the adult. Chittenden, some years ago, made a study of the subject in a series of experiments upon himself and groups of students, soldiers, and athletes. He showed that nitrogen equilibrium could be maintained upon a total daily intake of 25 grams or less of first class protein.¹ Upon an ordinary mixed diet containing proteins of varying biological values, nitrogen equilibrium was established on an allowance of between 40 and 50 grams for a man of average weight (70 kg). This is from 0.6 to 0.7 grams of protein per kilogram. Chittenden claimed that the larger protein intake recommended by previous observers, (e.g., 120 grams by Voit) was unnecessary, if not actually deleterious to health. It was contended that the renal work entailed in the excretion of large quantities of nitrogen was conducive to kidney disease. Many other ills were ascribed to the excessive consumption of protein. He also reduced the total energy intake to around 2000 Calories and stated that the more liberal diets were deflated by appetite rather than by physiological necessity. His subjects, he claimed, could carry out their usual activities just as well upon such a diet and enjoyed better health than they had previously upon their customary fare.

Since nitrogen equilibrium can be established upon a protein intake of around 40 grams per day, it would seem unnecessary to give more. The excess amount must obviously be catabolized to furnish energy, which can be furnished more economically by non nitrogenous food² or be simply stored as carbohydrate or fat. The weak point in this argument is, as many critics of the low pro-

¹ The daily urinary excretion of N on a nitrogen free diet but of adequate calorie value is around 3 grams. This represents the catabolism of 18.75 grams (3×6.25) of tissue protein.

² Calories furnished by protein are by far the most expensive. It has been calculated that 1 000 000 Calories derived from cane sugar require for their production 0.15 acre, as compared with 17 acres necessary to produce the same amount of energy as represented by beef protein.

TABLE 55 1

Effect of age and sex on estimated calorie requirements

(Recommended daily allowances—F A O, 1957)*

Age group years	Calories per Day		
	Male and Females	Males	Females
1	1150		
2	1300		
3	1450		
4 to 6	1700		
7 to 9	2100		
10 to 12	2500		
13 to 15		3100	2600
16 to 19		3600	2400
20 to 30		3200	2300
31 to 40		3100	2250
41 to 50		3000	2150
51 to 60		2800	2000
61 to 70		2550	1800
Over 70		2200	1600

* Allowances are estimated for individuals engaged in moderate physical activity. They are excessive for those in sedentary occupations and low for laborers.

tein dietary have pointed out, that the ability of the body to adapt itself for a few months to a restricted protein intake is not proof that such constitutes the physiological optimum. It has also been pointed out that custom has dictated for persons in temperate climates a higher protein intake than Chittenden's standard. The daily protein intake per person in the United States is between 90 and 120 grams. Even the diets of the Japanese and of the harder races of India, according to McGay, contain a greater quantity of protein than that recommended by Chittenden. Tribes in India who are accustomed to diets with the higher protein content are healthier and of better physique than those subsisting upon a more restricted protein intake. The value of a generous protein allowance is also illustrated by the report of Orr and Gilks concerning two African tribes who, though living side by side eat quite different diets. The members of the meat-eating Masai tribe are some 5 inches taller and 50 pounds heavier than the vegetarian Akikuyu, and their muscular power is about 50 per cent greater. The Masai are comparatively free from disease, whereas bone deformities, dental caries, anemia, pulmonary diseases and tropical ulcer are prevalent among the Akikuyu. Arthritis, however, was

found to be much more common among the Masai

Protein probably plays an important part which is not revealed by short term experiments based upon the study of nitrogen balances. There are indications that physical fitness and resistance to disease are associated with the higher protein intakes. There is little evidence, on the other hand, that a high consumption of protein causes renal or other diseases. Thomas records that the Greenland Eskimos are almost exclusively carnivorous, consuming enormous quantities of meat (and up to 300 grams of fat per day), yet renal and cardiovascular disease is not common among them. The Arctic explorers Stefanson and Anderson showed no ill effects, either upon blood pressure or renal function, after living for 12 months upon a diet composed entirely of meat (reported by Lieb). The effect of a high protein diet upon established renal disease is another matter.

It now appears that the true protein requirement for the average man lies about midway between the two extremes of Chittenden and the older observers. A generous allowance is from 70 to 100 grams (somewhat more than 1 gram per kilogram of body weight) and about 15 per cent less than this for women.

Because of the large differences in the nutritive value of individual proteins any quantitative statement on protein requirement must be related specific proteins or types of protein. Milk, eggs, and meat have long been regarded as of excellent quality, and their superior value for human beings has been confirmed by research on infants and adults. The FAO Committee on Protein Requirement (1957) decided to express requirements in terms of a reference protein which they defined as of "high nutritive value," citing the proteins of milk, eggs, and meat as examples. Later, from a study of human requirements for individual essential amino acids, a provisional *amino acid pattern* was put forward. Whereas neither milk nor egg proteins correspond precisely in composition with this "ideal" pattern, they are similar. It is assumed that a hypothetical protein containing amino acids in these ratios would be of high biological value, falling into the category of a reference protein.

The FAO Committee, emphasizing the provisional nature of their recommendations, tentatively suggested 0.35 gram per kilogram of body weight as the average *minimum* requirement of adults for *high quality protein*. The requirement is greater in children and increases to a maximum in infancy. Unfortunately, the data are least re-

liable in this highly critical period of maximum rate of growth. Possibly it is as high as 2.3 grams per kilogram for suckling infants during the first few weeks, falling to about 1.5 by 6 months, to 1.0 gram per kilogram at about 3 years of age, and levels off between 0.6 and 0.7 grams per kilogram of body weight from 6 to 11 years. Just before puberty, a short-lived but acute spurt in growth occurs (in girls at 10 to 14 years, in boys at 13 to 16 years of age) during which the requirement for high quality protein is temporarily increased, being not lower than 0.8 gram per kilogram. Following this period the requirement falls slowly to the adult value of 0.35 gram per kilogram of body weight.
