During pregnancy an additional 10 grams of high quality protein should be added per day to the value calculated using the adult factor (0.35), and during lactation the recommended daily increment is 30 grams. In many pathological states and during convalescence the protein requirement is increased, but it is impossible to give data of general applicability. Extremely heavy work (lumbering, mining, harvesting, and the like, without mechanical aids) causes an increase in muscle mass and a substantial increase in protein requirement.

The emphasis today is being placed on the dietary supply of essential amino acids and total utilizable nitrogen rather than on the protein content of a foodstuff or ration. Knowledge of the average requirement of human infants, children, and adults, for each of the essential amino acids is still fragmentary but is becoming increasingly available largely from the laboratories of W. C. Rose, Ruth M. Leverton, L. E. Holt, Jr., H. H. Mitchell, Marvan E. Swendrick, and M. S. Dunn, and their associates. Many others have made important contributions. Only eight amino acids appear to be essential in the diet to maintain nitrogen equilibrium in adults. Histidine is essential for the growing child. Tentative values are shown in table 55.2. Whereas the adequacy of the essential amino acids determines the nutritional quality of a protein, the pattern of the nonessential amino acids is important for several reasons: (a) tyrosine can spare phenylalanine, (b) cystine can spare methionine, and (c) unless an ample supply of nonessential amino acids (or other forms of utilizable nitrogen) is provided, the need for essential amino acids will be increased because they will be used to make nonessential amino acids that are inadequately supplied by the ration.

It must be remembered that if one diet is higher

(Taken from FAO Bulletin No 16 1957)

in protein content than another, it is not necessarily superior, since the biological value depends upon the completeness of the essential amino acids provided. In very few countries is it possible for the bulk of the population to live principally on foodstuffs containing high quality proteins. In many regions wheat, rye or millet, rice, potatoes, maize, pulses, or cassava provide the major proportion of the food eaten. None of these supplies all of the essential amino acids in proper ratio or in adequate amount. As was pointed out by Osborne and Mendel many years ago, certain combinations of these vegetable proteins may supplement each other with marked improvement of nutritive properties. For example, the maize protein (which is very poor in tryptophane and lysine), the navy bean protein (deficient in methionine and tryptophane) and sesame seed protein (deficient in lysine and valine) when combined in the ratio 40:30:30 offer a product that is much improved nutritionally.

The Indispensability of Fat

Since body fat can be derived from carbohydrate food it might be thought that dietary fat could be dispensed with. However, this does not seem to be so. Fats provide fat soluble vitamins and certain fatty acids (linoleic, linolenic, and arachidonic) that are essential for health which cannot be synthesized (at least not at an adequate rate) by the body. If purified fat soluble vitamins and essential fatty acids are made available, there is no evidence that fats (glycerides) are essential components of the diet.

Although glycerides may not be dietary essentials, they increase palatability of the food and

decrease the bulk necessary to provide adequate calories.

The essential fatty acids are provided principally by plant oils: lard, egg yolk fat, and butter fat. Highly unsaturated fatty acids are abundant in fish liver oils but they are of different structure from the animal oils and their value as essential fatty acids is doubtful.

In 1929 Mendel and his colleagues noted that the growth of rats on a fat-deficient ration is poor, and in the same year, Burr and Burr described a new deficiency disease (in rats) caused by the elimination of all fat from the diet. After about 3 months a scaly condition of the skin developed, later the tail became inflamed and swollen, and eventually the tip became necrotic. The feet also became swollen and sore. The hair fell out about the face, throat, and back, and sores often appeared on the body. Kidney lesions led to death. Later, Burr and his associates showed that very small amounts of either linoleic acid ($C_{18}H_{32}O_2$ with two double bonds) or linolenic ($C_{18}H_{30}O_2$ with three) produced beneficial effects in rats. More recently certain other polyunsaturated fatty acids (e.g., arachidonic, $C_{20}H_{38}O_2$, with four double bonds) have been found to possess similar activity, although the several members are not entirely equivalent in protective effect. Some restore growth and cure skin lesions, others only restore growth. Linoleic acid is the only vegetable acid that meets all the requirements of the animal for essential fatty acids. Arachidonic acid (found only in animal lipids) also restores growth and cures the skin defects. It appears to be from 2 to 6 times as effective as linoleic acid, depending on the methods of making the comparison. Probably

arachidonic acid is the functional compound and linoleic and linolenic acids are dietary precursors. It has been suggested that conversion (in the animal) of some of the dietary linoleic acid of plant origin to arachidonic acid explains the disappearance of all the signs of deficiency. Linolenic acid, in contrast, is converted principally to a six double bonded acid which is unable to cure the skin lesions but which does stimulate growth and fat synthesis. The wide spread occurrence in vegetable oils of glycerides containing linoleic acid (soybean oil 50 to 60 per cent, cottonseed oil 40 to 48 per cent, and corn oil 34 to 42 per cent) and the presence in animal fats of arachidonic acid (lard 0.4 per cent, and butterfat, a trace) makes it unlikely that deficiency of essential fatty acids will occur in man or animals eating a good variety of natural foods.

No data are available to indicate the magnitude of the human requirement for linoleic or arachidonic acids. Some workers even doubt whether the essential fatty acids are of importance in human nutrition.

There is some evidence, however, that certain eczematous conditions in the human subject are due to fatty acid deficiency. These subjects show a low content of unsaturated fatty acids in the blood lipids. Babies kept for several months upon a diet very low in fat often developed a generalized eczema which was corrected when the fat of the diet was restored. During the period of low fat feeding, the iodine number of the serum lipids of these infants was depressed (See Burr and associates). Fat pork, beans, and peas (vegetables relatively rich in fat) are prominent items in the diet of Canadian lumbermen and construction workers. The daily energy expenditure of some of the former workers may run to 8000 Calories. Another advantage of fat is its superior "staying power." Its digestion and absorption are extended over a much longer period than those of carbohydrates. Hunger, "emptiness," and fatigue are experienced much sooner upon a diet high in carbohydrate than upon one containing a liberal allowance of fat. The actual efficiency of fat as a fuel for muscular work as shown by Krogh and Lindhard (p. 881) and by Murlin and Marsh is from 10 to 12 per cent less than that of carbohydrate. It is often recommended that children be given a larger proportion of fat in the diet (30 to 35 per cent of the calorie intake) than is suggested for adults, 20 to 25 per cent. Actually, very little, if any, information is available on the fat requirement of man. It appears that fat and

carbohydrate can replace each other, within wide limits, as a source of energy.

Much has been written on the comparative nutritive value of different fats. Better growth of rats was reported when diets containing butterfat were fed than when corn, cottonseed, coconut, or soybean oils were used. Later it appeared that this superiority depended upon the nature of the carbohydrate in the diet. The subject has been controversial, if there are any differences they are small.

Discovery of a statistical correlation between the concentration of cholesterol esters in the blood serum and the incidence of cardiovascular disease, led to the proposal that the incidence of atherosclerosis in adults is connected with the cholesterol content of the diet. More carefully controlled studies on patients, human volunteers, and animals revealed that dietary cholesterol has only a limited effect on the level of cholesterol esters in the serum. Epidemiological and experimental studies showed that the fat content of the diet is the dominant factor. Some workers believe that animal fats (especially butter) are more deleterious than vegetable oils. The effects of diet on the walls of the blood vessels and on blood-clotting are currently being studied with great vigor. A number of dietary factors appear to be involved in the etiology of atherosclerosis—the kind and amount of fat, cholesterol, protein, sulfur containing amino acids, carbohydrate, choline, pyridoxine and possibly other vitamins, and magnesium, exercise (or lack of it) and energy balance are possibly contributing factors. Much experimental work is still necessary before proper dietary advice can be given on this subject. The preferential use of vegetable oils in cooking has been recommended. The data currently available do not warrant any drastic alteration in menus, such as complete elimination of eggs, bacon, and butter, as advised by some clinicians. Reduction of the intake of animal fat to minimal amounts providing palatability and variety may be desirable.

Mineral Constituents (See pp. 72, 1005, and 1055)

The minimal daily requirements of calcium, phosphorus and iron for the average adult (70 kg. in weight) are

Calcium	0.8 gram
Phosphorus	1.2 gram
Iron	15-20 mg

In childhood and in pregnancy (especially in the later months) and in lactation the calcium requirement is higher than that given above. For

* Tentative goal toward which to aim in planning practical diets, can be met by a good diet of natural food. Such a diet will also provide other minerals and vitamins, the requirements for which are less well known.

† Requirements may be less if provided as vitamin A, greater if provided chiefly as the provitamin carotene.

‡ 1 mg of thiamin equals 333 IU, 1 mg of ascorbic acid equals 20 IU.

§ Vitamin D is undoubtedly necessary for older children and adults. When not available from sun shine, it should be provided, probably up to the minimum amounts recommended for infants.

¶ Needs of infants increase from month to month. The amounts given are for approximately 6 to 8 months. The amounts of protein and calcium needed are less if derived from human milk.

|| Allowances are based on needs for the middle year in each group (as 2, 5, 8, etc.) and for moderate activity.

Further Recommendations

The requirement for iodine is small, probably about 0.002 to 0.004 mg a day for each kilogram of body weight (about 0.15 to 0.30 mg daily for the adult). This need is easily met by the regular use of iodized salt, its use is especially important in adolescence and pregnancy.

The requirement for copper for adults is in the neighborhood of 1.0 to 2.0 mg a day. Infants and children require approximately 0.05 mg per kilogram of body weight. The requirement for copper is approximately one tenth of that for iron.

Fatty foods because of their high energy content, are preferred by men performing heavy work, especially in cold climates. Not only do fats provide 9 Calories per gram, as compared with 4 for carbohydrates and protein, but fat-rich foodstuffs are much lower in water content than are carbohydrate-rich foods (e.g., butter contains only 15 per cent water, bread contains 35 to 40 per cent). Thus, on a bulk or weight basis, fatty foods are up to four times as rich in energy as those low in fat.

infants and children up to 12 years the minimum is placed at 10 to 12 grams per day, and from 13 to 20 years at 14 for boys or from 13 to 10 for girls. In the later months of pregnancy, when from 20 to 30 grams of the mineral are being deposited in the fetus, daily allowance should be at least 15 grams, 2 grams should be the daily allowance during lactation. The best source of calcium for the growing child is milk, which contains about 13 grams per quart. Other dairy products, e.g., cheese and ice cream, are excellent sources of calcium. Cereals also are rich in calcium though much of it is not absorbed and retained, meat contains insignificant amounts of this element (see table 553) (p. 947).

It is unnecessary, as a rule, to pay attention to the phosphorus content of the diet provided that the protein and calcium of the diet are adequate, for protein is relatively rich in phosphorus, and the latter is associated with calcium in milk, eggs, cereals, legumes, and several other foods.

The daily requirement of children for iron is, on a weight basis, higher than for adults, milk fed infants, therefore, tend to develop anemia (ch. 9) after the fourth month or so unless given iron in inorganic form because milk is very poor in this element. Egg yolk, meat, liver and kidney, fruits, and nuts are the main sources of iron.

TABLE 554

*Per capita consumption of some major foods
(United States 1949)*

	Lb. per year
Dairy products (excluding butter)	429
Fats (including butter)	65
Eggs	46
Meats, poultry, fish	159
Potatoes (and sweet potatoes)	116
Grain products	173
Dry peas, beans and nuts	16
Citrus fruits and tomatoes	98
Leafy green and yellow vegetables	111
Other vegetables and fruits	235
Sugars and syrups	106

These foods provided average amounts of certain nutrients per day, estimated to be as follows:

Energy	3250 Calories
Protein	94 grams
Fat	141 grams
Carbohydrate	403 grams
Calcium	1.05 grams
Vitamin A	8500 IU

The basic elements, sodium, potassium, and magnesium, are derived chiefly from cereals, fruits, and vegetables. Sodium chloride is also added during cooking and at the table. The average daily intake is from 10 to 12 grams. Many preparations of table salt are also sources of iodine, since it has become the custom of the manufacturer to add minute quantities of potassium iodide to his product. The daily iodine requirement of adults is from 100 to 150 μ g. Other elements (trace elements), e.g., copper, cobalt (for erythropoiesis), fluorine (for tooth and bone structure), zinc (for the action of carbonic anhydrase and insulin), and manganese (for erythropoiesis and the action of phosphatase) are essential, but are present naturally in the diet in adequate amounts.

The dietary allowances recommended by the food and nutrition board of the National Research Council, Washington, are given in table 553.

THE PROPER PROPORTION OF THE THREE FOODSTUFFS IN AN ADULT DIET

From data given in table 554 one may calculate the proportions of the different nutrients consumed by the average American citizen to be as follows:

	Grams	Calories	Per cent of total calories
Protein	94	376	12
Fat	141	1269	39
Carbohydrate	403	1612	49
Total		3257	

There is no evidence that these calorie ratios (approximately 10:40:50) are *proper*. According to many authorities both the protein and fat intakes are greater than necessary. Stare and his associates, at the Harvard School of Public Health, found the protein requirement (for a 70 kg. man) to be met by 30 to 40 grams of mixed proteins (50 per cent from white bread), a range of values consistent with that found by Bricker, Mitchell, and Kinsman. Increasing the fat content of the diet can influence protein utilization, when both are fed at low levels, and there is other evidence that the nature of the nonprotein calories may affect the utilization of protein, i.e., different carbohydrates are *not strictly interchangeable*.

The daily dietary allowances recommended by the Food and Nutrition Board of the National Research Council (U.S.A., 1958) call for 1 gram of average mixed protein per kilogram of body

weight (i.e., 70 grams for the average man or 58 grams for the average woman). These values appear to be generous. This figure will be used in the following calculation.

Data given in *Recommended Daily Dietary Allowances* (1948) support the recommendations of the British Medical Association Committee on Nutrition that 20 to 25 per cent of the calories should be provided as fat, with slightly larger proportions for very active persons (laborers, children, and adolescents). These proposals would result in caloric ratios of approximately 10:20:70, as indicated below.

	Grams	Calories	Per cent of total Calories
Protein	70	280	9
Fat	67	600	20
Carbohydrate	530	2120	71
Total		3000	

Present knowledge does not permit us to state with exactness the optimal amount of fat compatible with health, nor the proper proportions in which the three major foodstuffs should be consumed. Balanced nutrition should supply sufficient calories (mainly as carbohydrate and fat) but should avoid excess; it should provide minerals, vitamins, essential amino acids, and utilizable nitrogen in adequate amounts and in proper ratios to caloric intake and to each other.

SECTION SEVEN

The Ductless Glands or Endocrines

(THE ENDOCRINE FUNCTION OF THE PANCREAS IS DEALT
WITH IN CHAPTER 48)

Introduction

EVOLUTION Two methods are used by the organism for transmitting messages from one organ to another. First, the nervous system forms an interconnecting mechanism by means of which rapid communication between different regions is established. And second, chemical substances called *hormones* are liberated into the blood from particular glands, and carried humorally to exert specific effects on distant structures. These latter act more slowly, and may have a more prolonged effect, than those messages sent by the nervous system. They are also of more ancient lineage, for it has been found that plants, in which no nervous system exists, use various hormones (auxins and others) to influence budding, growth, flowering, and possibly other functions. In the last 20 years much work has been devoted to the study of hormones in the invertebrates. Endocrine systems have been described in worms, crustaceans, insects, mollusks, and tunicates. Particular attention has been paid to the mechanisms controlling color changes in crustaceans and growth, differentiation, and moulting in insects. It is of special interest that in many of these forms the brain seems to play a dominant role as an organ of internal secretion. The process of elaboration of a hormone by the nervous system has received the term *neurosecretion*. Such a process in higher forms is discussed more fully below. The homology between higher invertebrate and lower invertebrate glands is, in many cases, uncertain.

HISTORY The science of endocrinology began with the observations of Berthold in 1849, that removal of the testes in cocks resulted in changes in the birds so that they approached the build and behavior of the hen, and that these changes could be avoided by grafting the testes to the gut. The evidence was very strong then that the testes liberated some substance into the blood stream that was responsible for the masculine features and behavior of the normal cock. Claude

Bernard is usually regarded as the originator of present views regarding internal secretion, though his discovery that the liver liberates glucose into the blood cannot now be included as an endocrine phenomenon. It was from clinical studies that modern views of endocrinology first became clarified. Semon (1883) suggested, and Horsley (1885) showed, that myxedema and cretinism were due to failure of thyroid secretion, and Murray (1891) reported the benefit accruing to a case of myxedema from administration of thyroid extract. Later clinical studies suggested that various disease states might result from over secretion of endocrine glands (Greenfield, 1893, Graves' disease, Tamburini, 1894, and Benda, 1900, acromegaly). The physiological evidence on endocrine organs may be said to date from the classical studies of Oliver and Schafer (1894) on the pressor principle of the adrenal medulla. Oliver and Schafer (1895) and Dale (1900) on the pressor and oxytocic actions of posterior pituitary extracts, and Marshall and Jolly (1907, 1908) on the activity of ovarian transplants. Bayliss and Starling (1904) first established that a chemical substance could be secreted by one organ (in their case, secretin from the intestinal mucosa) and carried by the blood stream to exert a specific effect on distant structures. They also proposed the term '*hormone*' (from *ὁρμῶν*—I arouse to activity). Great impetus was given to the subject by the studies of H. M. Evans and his group on the effects of hypophysectomy and replacement therapy in the rat (P. E. Smith, 1927), on the estrous cycle and vaginal smear technique in the rat (Long and Evans, 1922), on vitamin E and its relation to reproductive phenomena (Evans and Scott, 1922), and on the purification of various anterior pituitary hormones.

STRUCTURE In the vertebrates the following organs are now well established as endocrine glands: anterior pituitary (adenohypophysis), posterior pituitary (neurohypophysis), ovary,

testis, thyroid, adrenal cortex, adrenal medulla, parathyroids, islets of Langerhans in the pancreas, and various parts of the intestinal mucosa.¹ All these organs have certain anatomical features in common. First, they are typical glands (except the neurohypophysis which belongs to a special class of neurosecretory organs) in that they are composed of masses of secretory cells arranged usually in columns or clumps. These cells may occasionally, as in the case of the thyroid, be arranged in alveoli or acini with their secretory product stored in the lumen. More commonly, however, the hormones or their parent substances are stored as granules in the cells. Second, although glandular in nature, no ducts are present. Third, since the blood stream functions as a "duct" and carries off the secretory products, they are all richly vascularized. And fourth, the passage of the hormones into the vascular stream is facilitated by the replacement of thick collagenous connective tissue fibers by fine reticular fibers and by the nature of the blood vessels which are thin walled sinuoids.

CHEMISTRY The hormones fall into several chemical groups. The pituitary hormones are proteins or polypeptides, the gonadal and adrenocortical hormones are steroids, whereas the thyroid and adrenomedullary hormones are composed of simpler and smaller molecules. These compounds seem to be surprisingly uniform in their nature and biological activity throughout the vertebrates. Extracts of sheep thyroid, for example, are active in amphibians and pituitaries from amphibians, reptiles, and mammals accelerate sexual development in fish. However, it may be mentioned that anterior pituitary interstitial cell stimulating hormone from sheep has a lower molecular weight than the same hormone obtained from swine, that the vasopressor hormone extracted from beef and swine material has a slightly different amino acid constitution, and that growth hormone obtained from subprimate forms does not appear to be active in man.

THE HORMONES AND THEIR FUNCTIONS In order to study the endocrine glands in detail, it is advantageous to have a general picture of the system as a whole first.

The pituitary gland or hypophysis is connected to the base of the brain by the pituitary stalk. The anterior pituitary gland is usually thought to secrete six hormones. The names of these, their

synonyms, and abbreviations (their site of action being given in parentheses) are as follows

Anterior pituitary hormones

✓ Gonadotrophic hormones

- 1 Follicle stimulating hormone, FSH (ovary and testis)
- 2 Luteinizing hormone, LH, or interstitial cell stimulating hormone ICSH (ovary and testis)
- 3 Luteotrophic hormone, LTH, or prolactin, or lactogenic hormone (ovary (in some species) and mammary glands)

✓ Thyrotrophic hormone, TSH (thyroid)

✓ Adrenocorticotrophic hormone, ACTH (adrenal cortex)

✓ Growth hormone, or somatotrophic hormone STH (body tissues (stimulates growth))

From this outline it may be seen that the anterior pituitary has a wide field of action. In addition to exerting a major influence over body growth (growth hormone) and over milk secretion in mammary tissue (lactogenic hormone), its hormones are largely, if not solely, responsible for maintaining and regulating the functions of the thyroid, adrenal cortex, ovary, and testes. In the absence of the anterior pituitary these latter four glands undergo atrophy and a great diminution in activity.

The thyroid gland secretes thyroxine and small amounts of triiodothyronine, hormones which are responsible for maintaining oxidative processes in bodily tissues in general. The adrenal cortex, like the thyroid, has no specific target organ upon which its hormones act, but by means of steroidal compounds it exerts a major influence over carbohydrate, protein, and electrolyte metabolism. The gonads also secrete steroidal hormones, estrogens and progesterone in the case of the ovary, and androgens in the case of the testes. They act both upon tissues in general (as may be seen from the changes produced under their influence at puberty), and upon specific target organs such as the breast, uterus, vagina, seminal vesicles, prostate, and penis.

The posterior pituitary gland secretes one or two hormones. Two physiologically active polypeptides have been extracted from the gland and obtained in a highly purified state. They have also been synthesized. The antidiuretic or vasopressor hormone exerts a regulating action on the volume of urine, and amount of chloride excreted by the kidney. In large doses this hormone has a

¹ It is possible that the pineal and thymus are endocrine glands, but little is known as to their function at the present time.

pressor action, increases intestinal motility, and raises the blood sugar. The *oxytocic hormone* causes contraction of uterine muscle and of mammary tissue. It thus aids in the expulsion of the fetus from the uterus and of milk from the breast. The *adrenal medulla*, a gland in several ways comparable with the posterior pituitary, secretes adrenaline and noradrenaline in amounts which vary in proportion in different species and probably in different individuals within a species. These two hormones are secreted during times of emergency or stress. Under conditions of fright, rage, pain, and similar states, the adrenal medulla is activated. In general it may be said that its hormones tend to reinforce the action of the sympathetic nervous system and exert widespread effects, such as increasing the general blood pressure, dilating the vessels of skeletal and cardiac muscle, and raising the blood sugar, which equip the animal as a more efficient machine for "fight or flight."

The *parathyroid glands* secrete a hormone, often referred to as *parathormone*, which has an important influence over calcium and phosphorus metabolism.

REGULATION OF ENDOCRINE ACTIVITY—THE NEUROENDOCRINE HIERARCHY AND THE FEED

FIG 56.1 The relationship between the nervous system and endocrine system. —, nerve pathway; - - -, vascular pathway. Note that two glands, the adrenal medulla and neurohypophysis are regulated by a direct nerve supply whereas the activity of the other glands is controlled by humoral or hormonal agents carried in the blood stream.

BACK MECHANISM The adjustment of endocrine function to meet the varying needs of an organism in an unstable environment is clearly a matter of some importance, but it is only in the last few years that data has become available on this subject.

A few of the glands may be dealt with briefly at this point. The regulation of insulin secretion by the islet tissue of the pancreas is dealt with elsewhere (ch. 48). Little is known regarding the control of parathyroid function. It appears unlikely that the parathyroids are under the control of either a secretomotor innervation or of a trophic hormone from the pituitary. Available evidence indicates that their activity is directly affected by the blood concentration of calcium.

Figure 56.1 depicts various relationships involved in the control of the major part of the endocrine system. The function of two of the glands is dependent upon, and regulated by, a direct secretomotor nerve supply. The neurohypophysis is controlled by the supraopticohypophyseal tract from the hypothalamus. This same part of the diencephalon also regulates adrenomedullary activity by means of nervous pathways descending in the brain stem and spinal cord, with outflows to the gland through the sympathetic chain and splanchnic nerves. It is of interest that the posterior pituitary and adrenal medulla are among the most rapidly reacting endocrine glands and that they are under the direct control of the nervous system with its well known high speed of response.

There can be little doubt that various parts of the central nervous system (such as the reticular formation of the brain stem, the temporal lobes and amygdaloid nuclei, the frontal lobes, and other regions), acting through the hypothalamus, influence the secretory activity of the anterior pituitary which in turn controls the ovary, testis, thyroid, and adrenal cortex. The hypothalamohypophyseal unit may, in general terms, be looked upon as a bottle neck between the two great systems, the nervous and the endocrine. The neuroendocrine hierarchy, central nervous system, and hypothalamus → anterior pituitary → target glands, may be analyzed in terms of three "levels of activity."

1 **Intrinsic or autonomic activity of the target glands.** This is revealed in the hypophysectomized animal. In the absence of the pituitary the gonads show no sign of endocrine function, but the thyroid and adrenal cortex still secrete, though at a very low rate.

2 **Intrinsic activity of the anterior pituitary**

If the pituitary gland is disconnected from the hypothalamus, by section of the pituitary stalk and insertion of a plate between the cut ends, or by transplantation of the gland to a distant site in the body, it also shows some low level intrinsic activity. As far as can be seen with present tests, secretion of FSH and LH ceases, though TSH, TSH, and ACTH are still released into the blood at low rates. Thus, in the pituitary stalk sectioned animal the ovaries appear totally inactive (except that any corpora lutea present at the time of operation may be maintained) whereas the thyroid and adrenal cortex show some function. The level of function in these latter two glands is greater than that seen in the hypophysectomized animal, since to the autonomous function of the target glands is added the autonomous release of TSH and ACTH by the anterior pituitary.

3 Normal activity. The full activity of the anterior pituitary target gland system is only seen when the central nervous system maintains and regulates anterior pituitary function through intact connections between the hypothalamus and adenohypophysis. The connections concerned are the hypophyseal portal vessels of the pituitary stalk.

The hypothalamus, then, occupies a key position in regard to the endocrine system. Not only does it regulate the activity of the adrenal medulla and neurohypophysis through direct nerve supplies to these glands, but through its influence over the anterior pituitary it also regulates the activities of the ovary, testis, thyroid, and adrenal cortex. The effects exerted by the central nervous system over these endocrine organs may be summarized as follows:

1 It maintains their function at a normal level. In the absence of neural control, the activity of some glands ceases entirely (posterior pituitary gland) and in the others falls to low levels.

2 It is responsible for maintaining rhythmic activity, such as that of the ovary during normal sexual cycles.

3 It acts as an intermediary between the varying external environment and the endocrine system. Environmental stimuli, acting through the central nervous system, evoke changes in endocrine activity appropriate to the situation.

4 It possibly acts as part of the central mechanism involved in the "feed back" action of the target gland hormones. The anterior pituitary and its target glands act in reciprocity. For example, if the blood concentration of thyroid hormone is increased, then by some central action the rate of secretion of TSH is reduced so that thyroid activity and the blood level of thyroid hormone is also reduced. If the blood concentration of thyroid hormone falls, the reverse situation is brought about.

Similar reactions occur with changes in the blood concentration of gonadal or adrenal cortical hormones. It is uncertain whether alterations in the blood level of the target gland hormones elicit these changes in pituitary activity by exerting a direct action on anterior pituitary cells, or whether the hypothalamus is sensitive to changes in blood concentration of these hormones and in turn regulates anterior pituitary activity appropriately. This feed back mechanism whereby the anterior pituitary and its target glands form a self balancing system, probably acts to stabilize endocrine activity under basal resting conditions, rather than to regulate activity under conditions calling for increased or decreased function. This phenomenon becomes a matter of practical importance in considering transplantation of endocrine glands. Halsted many years ago, pointed out that most endocrine transplants take more readily if a state of deficiency in the host exists for the particular gland concerned. This statement has been verified many times and has become known as *Halsted's Principle of Deficiency*. As an example of this principle, it may be said that ovarian transplants survive better in an ovariectomized animal than in a normal animal. This is probably because the ovariectomized animal has a higher level of circulating gonadotrophic hormone than has the normal.

In summary, then it may be said that the main factor maintaining endocrine activity at a normal level and concerned with regulating this activity under varying environmental conditions, is the influence exerted by the central nervous system. The feed back mechanism probably operates as a stabilizing system whereby endocrine function is maintained at a preset level under constant conditions.

THE NATURE OF HORMONES AND THEIR TRANSPORT. The term *hormone* refers essentially to a chemical messenger in the blood stream. In the case of some glands the hormone has been identified in the venous blood from the gland or in the general systemic circulation, but in other cases data as to the nature of the hormone has been surmised from studies on material extractable from the gland itself. This latter approach may be fallacious. For example, it is known that the thyroid stores thyroglobulin, and that this substance is degraded before the hormone itself is liberated into the blood. Therefore, material extractable from a gland may represent a precursor of the hormone rather than the hormone itself. However, in the case of some glands, such as the anterior pituitary, the only information available is derived from studies of glandular extracts. Six purified and pharmacologically active extracts

have been obtained from adeno-hypophyseal tissue, and although it is convenient and customary to speak of these pituitary principles as separate hormones, there is no means of knowing whether the active materials obtained by rather drastic methods of extraction are actually secreted as separate entities by the living gland. It may be that the extraction products of the anterior lobe represent, as Riddle suggests, "hormone fragments" or as Collip expresses it, "chemically dissected" parts which represent prosthetic groups split off from a smaller number of larger hormone molecules. The only unequivocal test is the identification of the hormones, individually and separately, in pituitary venous blood. The position is further complicated by the fact that some hormones, such as thyroxine, become bound to plasma proteins during transport in the blood, and by the possibility, not yet established, that a hormone may need to be chemically changed in the tissues before it is able to exert its characteristic action.

CELLULAR ACTION AND EXCRETION OF HORMONES It is not possible at the present time to state the precise nature of hormone action at a cellular level. Two general views are that hormones act at cell surfaces or boundaries to affect cellular excitability or metabolism, or that they form part of an enzyme system within the cell. It is too early to make a definite statement but studies such as those of Cesapo, on the relationship between estrogens and the actomyosin content of uterine muscle and his finding that progesterone alters the balance of extracellular and intracellular sodium and potassium as well as the excitability of uterine muscle, may point the way to further elucidation of this difficult problem. For detailed discussions of this topic the reviews of Hechter (1955) and Levine (1957) may be consulted.

The rate of inactivation or excretion of some hormones is very rapid. For example, ACTH is quickly lost from the blood (in seconds/minutes), as are the posterior pituitary and adrenomedullary hormones. Some information is available as to the tissues which inactivate and/or excrete certain of these substances. Thyrotrophic hormone appears to be inactivated by thyroid and lymphatic tissue. Estrogens are conjugated in the liver and excreted to some extent in the bile. Thyroxine is also partly excreted in the bile and feces. Many hormones appear to be partially degraded and excreted in the urine (some anterior pituitary and placental hormones, ovarian and cortical steroids).

HORMONES AND BEHAVIOR Attention has been drawn above to the regulating effects the central nervous system exerts on endocrine function. The reciprocal picture also exists. It is clear that various hormones act on the central nervous system to determine the behavioral response of the organism to environmental stimuli. A simple example may be taken from the field of reproductive physiology. A female cat with a low blood concentration of estrogen reacts to the attentions of a male cat with signs of displeasure (spitting, striking with the forepaws) and avoidance, whereas a female cat with a high blood concentration of estrogen reacts with a complicated but stereotyped pattern of courtship and mating activities. In the clinical field, a striking difference in mental state is seen in the extreme nervousness and irritability of patients suffering from hyperthyroidism (Graves' disease) as compared with the mental apathy and sluggishness of cases of hypothyroidism (myxedema). Although it seems almost certain that these behavioral changes are brought about by a direct action of the hormones on the central nervous system, very little information is available as to what regions of the nervous system are affected by the different hormones or indeed to what extent the hormones are able to cross the 'blood-brain barrier'.

METHODS OF STUDY Studies on an endocrine organ fall into two groups, those necessary to demonstrate that a particular organ is a gland of internal secretion and those dealing in detail with its regulation, hormones, and mode of action.

To establish that an organ is an endocrine gland several or all of the following criteria should be fulfilled:

- 1 A typical syndrome is induced by its destruction by disease or experimental removal. The initial observations have, in many cases, been made on the human. Attention was first drawn to endocrine deficiencies resulting from castration, tubercular destruction of the adrenal glands and removal of the thyroid from observations on man.
- 2 Substitution therapy. The deficiency state induced by removal or destruction of the gland should be reparable by administration of suitable extracts of the gland or by grafting the removed gland into a distant site in the body. The preparation of a suitable extract may present many difficulties. In the case of the thyroid gland it was early shown that a simple glycerine extract of the sheep's gland was curative in cases of myxedema.

However, the thyroid offered favorable circumstances for this demonstration in that it stores large quantities of active material which is effective when administered by mouth. Such is not the case for the other glands, for which delicate methods of chemical extraction may have to be developed before a suitable extract is obtained. The repair of a deficiency state by transplantation of an endocrine gland to a distant site in the body is a classical procedure in endocrine studies, and demonstrates that the organ concerned produces its effects by secretion into the blood stream, and also that its activity is dependent on some humoral agent carried in the general circulation. There is no evidence that the neurohypophysis or adrenal medulla has ever been transplanted and shown normal function. This is due to the fact that these glands are dependent on a nerve supply for normal function, and cannot be taken as evidence related to their mode of action. In transplantation studies attention must be paid to the source of the material. Tissue removed from and transplanted back into the same animal (*autotransplant*) has the best chance of 'taking' and remaining viable. Tissue removed from a donor animal and transplanted into a closely related member of the same species (*homotransplant*) often 'takes,' remains viable for a few weeks and then undergoes lymphocytic infiltration and absorption. Tissue removed from a donor animal and grafted into a recipient of an other species (*heterotransplant*) is usually absorbed within a few days. For this reason, it is unlikely that endocrine transplantation will ever form a useful therapeutic procedure. The beneficial results occasionally claimed following the transplantation of animal material into human cases may in part be due to absorption of hormone stored in the transplanted material or to the psychological effects of the procedure.

- 3 Administration of large doses of a glandular extract should produce signs of overdosage and a state that is often comparable to disease states, in which a secreting tumor of an endocrine gland results in the discharge of excessive amounts of hormone into the circulation. For example, excessive dosage with thyroid or adrenocortical hormones in the human produces states similar in many

ways to Graves' disease and Cushing's syndrome, respectively.

After an organ has become established as a gland of internal secretion the following major points require investigation.

- 1 The factors regulating the activity of the gland. A change in the external environmental conditions exerts a powerful influence on the activity of many endocrine glands. Thus, the gonads of many seasonal breeding forms are activated by increased periods of illumination, a fall in environmental temperature leads to increased function of the thyroid gland, stresses and conditions of emergency excite adrenal cortical and medullary activity, and so on. The physiological mechanisms by which such factors influence endocrine function still require further investigation. In order to study these factors it is advantageous to have a simple and quick measure of glandular activity. From the point of view of the organism as a whole, the most exact definition of such activity is, the amount of hormone secreted into the blood in unit time. In order to obtain this estimate it is necessary to know the rate of blood flow through the gland and the hormone content of the arterial blood entering, and the venous blood leaving, the organ. Ideally, it is desirable to be able to make such observations in the unanesthetized animal. At the present time this is barely possible, so that indirect measures of glandular activity are generally used, such as observing the effect the hormone exerts on some process or target organ (e.g., vaginal epithelium in the case of the ovarian hormones, basal metabolic rate for the thyroid hormones), or observing the concentration of the hormone in the general systemic circulation or the rate of excretion of the hormone or its degradation products in the urine.
- 2 The analysis of the biochemical processes occurring in the gland. Simple substances (glucose, amino acids, inorganic salts) are extracted by the gland from the blood, converted into more complex compounds (steroids, polypeptides) and secreted back into the blood. A rudimentary knowledge of the chemical changes involved has been obtained in some cases. Radioactive iodine has been a valuable tool in analyzing such processes in the thyroid, and the use of the arti-

ficially perfused gland with blood containing C^{14} labeled substrates has aided materially in work on the adrenal cortex. In the case of other glands, such as the anterior and posterior pituitary, very little data exist. Such information may be of much practical use. In cases of hyperthyroidism it is possible to administer antithyroid compounds which block the organic binding of iodine by the gland and so prevent the secretion of excessive amounts of hormone.

3 The carriage and fate of hormones in the

blood. Knowledge as to the carriage of hormones in the blood (i.e., whether as a complex with plasma proteins), the metabolic changes undergone in the tissues, and the processes of inactivation and excretion of the hormones are largely dependent on the development of reliable assay methods for the hormones in body fluids.

4 The mechanism of action of the hormones at an organ, cellular and organelle level. As mentioned above, very little knowledge has so far been obtained on this topic.

THE PITUITARY GLAND OR HYPOPHYSIS CEREBRI

Origin and Structure

The average weight of the human hypophysis is about 0.5 gram. It is slightly heavier in females, especially in those who have borne children, than in males. Its average dimensions are 10 mm (sagittal) by 13 mm (transverse) by 6 mm (vertical). It lies within the small cavity formed by the *sella turcica* of the sphenoid bone which is closed above by a thin membrane, *diaphragma sellae*, except where it is pierced by the pituitary stalk. The stalk connects the pituitary gland below to the hypothalamus of the brain above.

The pituitary body consists of an anterior and posterior part readily separable along a natural line of cleavage, which represents the original, embryonic cavity of Rathke's pouch (see below). Until recently the two parts of the pituitary were generally referred to as the anterior and posterior lobes, and the stalk as the *infundibulum*. Though these terms are still used somewhat loosely, it is preferred, for more precise description of the hypophysis, to employ a nomenclature based upon the origins of its different parts. The pituitary has a dual origin in the embryo—from the ectoderm in the roof of the primitive mouth (stomodaeum) just in front of the buccopharyngeal membrane as well as from the base of the brain. In the early embryo a pouch extends from the stomodaeum to meet a corresponding hollow diverticulum prolonged downward from the floor of the third ventricle. The evagination from the primitive mouth is called *Rathke's pouch*. Through pressure upon its posterior wall by the downgrowth of nervous tissue, this wall of Rathke's pouch is approximated to the anterior wall and the cavity reduced to a cleft or (in the human) to a row of vesicles. The original stalklike connection of Rathke's pouch with the stomodaeum, known as the *cranio-pharyngeal canal*, also becomes largely obliterated, though a remnant may remain as a "pharyngeal pituitary" (embedded in the mucosa on the dorsal wall of the pharynx) and other fragments may in later life give rise to tumors situated in the anterior wall of the *sella turcica*. The original cavity of the neural element of the pituitary disappears completely in man, so that the pituitary stalk becomes solid, though in some adult animals, such as the cat, this cavity persists and communicates with the third ventricle. It should be mentioned

that bilateral diverticula of Rathke's pouch, the *lateral lobes*, climb upward to surround the upper end of the stalk and give rise to the *pars tuberalis*.

The part of the pituitary which originates from Rathke's pouch has a glandular structure and is, therefore, called the *adenohypophysis*. The portion developed from the brain is known as the *neurohypophysis*. Each division of the hypophysis is subdivided into three parts. Thus, the *neurohypophysis* consists of the expanded distal portion, the *infundibular process* or *neural lobe*, the nervous part of the stalk known as the *infundibular stem* or *neural stalk*, and the expanded upper end of the stalk, which is the *median eminence* of the tuber cinereum. It is important to realize that all three parts of the *neurohypophysis* are glandular and may liberate hormone into the blood stream. The tissue of the neural stalk and median eminence constitutes about 13 per cent of the total *neurohypophysis*. The *adenohypophysis* consists of the *pars tuberalis* (a thin strip of tissue surrounding the median eminence and the upper part of the neural stalk), the *pars intermedia* (that portion posterior to the cleft and in contact with the neural lobe), and the *pars distalis* or *anterior lobe* (the major secretory part of the gland lying anterior to the cleft). The development and different parts of the gland are summarized in figure 56.2 and table 56.1.

The neural stalk, together with its sheath, the *pars tuberalis*, is known as the *hypophysial* or *pituitary stalk*.²

The *pars distalis* is richly vascular, showing numerous blood sinuses between cords of cells. The cells fall into two main groups, (a) *chromophobe* or *reserve* cells which possess no granules, stain lightly, and apparently do not secrete, and (b) *chromophil* cells which contain large numbers of granules which stain readily (they are believed to elaborate the secretions of the anterior lobe). On a basis of the character of the granules, the chromophil cells are grouped again into two varieties (a) *acidophil* (or α) cells which stain more readily with acid dyes, and (b) *basophil* (or β) cells, which have a greater affinity for basic

²The spelling "hypophysial" is correct. The alternative "hypophyseal" became current as the result of a misprint in one of Dr. Harvey Cushing's monographs.

stains. The three types of cells (chromophobe and the two types of chromophil cell) are scattered indiscriminately throughout the pars distalis. The proportions found in man by Rasmussen, were around 50 per cent chromophobes, 35 per cent acidophils, and 15 per cent basophils. It now appears that the chromophobes represent mother cells and, by development, give rise to either acid

FIG 56.2 The embryological development of the different parts of the pituitary. The neurohypophysis consists of three parts, the median eminence, infundibular stem, and infundibular process, and the adenohypophysis also of three parts, the pars tuberalis, pars intermedia, and pars distalis. In some forms (such as the whale and elephant) a thick connective tissue septum extends upward between the infundibular process and pars intermedia, to merge with the connective tissue wedge illustrated in the diagram. However, in all forms the pars tuberalis encircles the median eminence and forms the bed of a vascular path linking the median eminence and the pars distalis.

ophils or basophils. Catchpole (1947) first stained glycoproteins in anterior pituitary basophil cells, using the periodic acid Schiff method (PAS). Since then two subdivisions of the basophils have been distinguished in the rat gland by the use of special stains. Halmi refers to these as β and δ cells, whereas Purves and Griesbach, who used the PAS method, termed them gonadotrophs and thyrotrophs on the ground that they believe them to secrete gonadotrophic and thyrotrophic hormones, respectively. Dawson and Friedgood have described two classes of acidophils on the basis of a special azocarmine stain. The ordinary acidophil cell stains orange, whereas the "carmine cell," which they believe to secrete luteinizing hormone, stains a bright red. It is of interest that the gonadotrophs, thyrotrophs, and carmine cells have their own distinctive distribution in the pars distalis. Under special physiological conditions variations of the above cell types become discernible. After castration certain basophils undergo enlargement and vacuolization, with displacement of the nucleus to one side of the cell. They thus have the appearance of a signet ring, and are termed "signet ring" or "castration cells." Other cell types described are "thyroidectomy cells" and "pregnancy cells." The pars intermedia is the least vascular part of the pituitary. In some forms (cat, rabbit) it forms a well marked, thick layer but in the human it consists of only a few cells. It is common to find cysts of various sizes, containing a hyaline or colloid material, in the region of the pars intermedia. The pars tuberalis resembles the pars distalis in being constituted of cords of cells separated by blood sinuses. The cells, however, are nongranular.

The three parts of the neurohypophysis—the median eminence, infundibular stem, and process—are composed of similar tissue which is different from that of the hypothalamus proper in vital staining properties, vascular supply, and cytology. Naked eye inspection of the region would lead one to draw the line of demarcation between the neurohypophysis and hypothalamus at the level of the infundibular stem, whereas it is in reality at a considerably higher level. This fact has important implications when considering various ex-

TABLE 56.1

Origin	Primary Division	Subdivisions

(Posterior lobe)

Neural stalk

permental findings concerning the neurohypophysis. The tissues of the neurohypophysis consist of (a) a profusion of unmyelinated nerve fibers, (b) fusiform cells with several processes and containing granules of a brown pigment in their cytoplasm (the pituicytes of Bucy), and (c) numerous blood vessels, neurological cells, mast cells, and hyaline bodies. The hyaline bodies are of historic interest, in that Herring (1908) put forward the view that the active material in the posterior lobe is derived from basophil cells of the pars intermedia migrating posteriorly into the neurohypophysis, and becoming transformed into hyaline masses. These hyaline masses, he supposed, were traveling up the pituitary stalk to be liberated into the cerebrospinal fluid in the third ventricle and there to exert their action on the nerve centers in the hypothalamus. This view was current for many years and had the support of such authorities as Harvey Cushing. However, it now seems clear that the neurohypophysis passes its secretion directly into the blood stream.

The extent to which the adenohypophysis makes contact with the neural lobe varies considerably. It may almost entirely surround the latter (cat), or in some forms (elephant, cetacea, armadillo) is separated from the neural lobe by a connective tissue septum. However, in all forms examined the pars tuberalis establishes contact with the neural stalk.

THE BLOOD SUPPLY OF THE HYPOPHYSIS (fig. 56-3). The vascular territory of the neural lobe is separated from that of the median eminence and adenohypophysis. It is supplied by posterior or inferior hypophysial arteries and drains by short veins into the surrounding venous sinuses.

The blood supply of the pars distalis may be compared with that of the liver in that it possesses a systemic arterial supply, a portal supply, and a venous drainage. The venous drainage is similar to that of the neural lobe in that it passes by short wide veins into adjacent venous sinuses. The arterial supply varies in different forms. The rabbit pituitary is supplied by a branch of one internal carotid, usually the left, arising and penetrating the gland at a level below the diaphragma sellae. However, Daniel and coworkers claim that the pars distalis of the human, and some other forms, lacks a direct arterial supply. The portal supply of the pars distalis was first described by Pops and Fielding (1930) in the human, and their anatomical findings confirmed by Wierlocki and others in many lower forms. The general arrangement of the system is as follows. Small arterial twigs from the circle of Willis supply a vascular plexus situated in the pars tuberalis, which in turn supplies a multitude of capillary loops or tufts situated in the nervous tissue of the median eminence and in fundibular stem. These capillaries are known as the primary plexus of the hypophysial portal vessels.

FIG. 56-3. Diagram of a sagittal section through the pituitary gland (below) and hypothalamus (above) of a rabbit, showing the blood supply of the gland. The anterior and posterior hypophysial arteries (a and b) are derived from the internal carotid arteries. The arterial twigs (c) to the pars tuberalis and the primary plexus of the portal vessels in the median eminence are derived from the internal carotid and posterior communicating arteries. The venous drainage (d) passes to surrounding venous sinuses in the dura mater or in the basisphenoid bone. In many forms the arterial supply to the pars distalis (a) is reduced or appears to be absent. In these cases the portal vessels may form the sole blood supply to the anterior pituitary gland. (From Harris.)

They drain by means of large vascular trunks which pass down the pituitary stalk to distribute their blood into the sinusoids of the pars distalis. These vessels, therefore, start as capillaries in the median eminence and end as sinusoids in the pars distalis (fig. 56-4). Since the median eminence is part of the neurohypophysis, the entire extent of the portal vessels is contained within the hypophysis and they should be referred to as the hypophysial portal vessels and not as the hypothalamo hypophysial portal vessels. When it became apparent that these vessels might form an important part of the functional link between the central nervous system and the pars distalis of the pituitary, and be involved in some neurohumoral mechanism whereby the nervous system controls anterior pituitary activity, they were re-investigated in detail and the following significant points established: (a) They are present in all the major classes of vertebrates (Green, 1951), (b) the direction of blood flow in these portal vessels is from the median eminence down to the pituitary (this was observed by microscopic examination of the vessels in living amphibians, rats, mice, and dogs), and (c) after cutting the pituitary stalk they have marked powers of regeneration so that investigations on the effects of pituitary stalk section must be carried out on animals in which a plate or some impervious barrier is placed between the stalk ends.

THE NERVE SUPPLY OF THE HYPOPHYSIS (fig. 56-5). The adenohypophysis receives a very scanty innervation, if any at all. From time to time it has been suggested that the pars distalis might be

FIG 554 Photograph of anterior aspect of pituitary stalk of man. The blood vessels have been injected with neoprene latex. Note the prominent trunks of the portal vessels. These vessels start as capillaries in the median eminence (HS) of the tuber cinereum and neural stalk and carry blood downward into the sinusoids of the anterior lobe (PD). (From Nureh, Prichard and Daniel.)

FIG 555 Diagram of a sagittal section through the pituitary gland showing the large nerve tract derived from the supraoptic and paraventricular nuclei and other nuclei of the hypothalamus, which innervates the neurohypophysis. A few nerve fibers penetrate into the pars intermedia. (From Harris.)

innervated from one or more of three sources: (a) by nerve fibers from the hypothalamo hypophyseal tract in the pituitary stalk, (b) by the carotid sympathetic plexus, and (c) by a parasympathetic

innervation derived from the greater superficial petrosal nerves. However, the most careful histological studies (Rasmussen 1938, Green 1951) have failed to reveal any innervation of the secretory cells. The scanty nerve fibers seen in the anterior lobe are (as seems to be the case with some other endocrine glands, such as the thyroid and adrenal cortex) in all probability vasomotor in nature. Such a view is supported by recent studies with the electron microscope.

The *neurohypophysis* is richly innervated by the *hypothalamo hypophyseal tract* from the hypothalamus. These fibers originate in the supraoptic and paraventricular nuclei in the hypothalamus and probably from other as yet undetermined nuclei. The number of fibers in this tract has been estimated at 10 000 (rat), 50 000 (dog monkey) and 100 000 (man). They are fine unmyelinated fibers; they may be stained with one of the silver impregnation methods or with the Gomori chrome alum haematoxylin method. Their origin has been determined by microanatomical studies and by the fact that the supraoptic and paraventricular nuclei undergo retrograde degeneration and lose some 90 per cent of their cells if the nerve tract is cut above the median eminence. Their termination is in close proximity to blood vessels in all three parts of the neurohypophysis. This has been clearly established by such studies as those of Bodian (1951) on the neurohypophysis of the opossum. In this animal a more orderly architecture prevails in the neural lobe than in most other animals. In recent years great interest has centered around the neurosecretory potentialities of this nerve tract (see below).

The Physiology of the Adenohypophysis

The adenohypophysis is the master gland of the endocrine system. Many different types of effects have been identified with this part of the pituitary. Most of these actions can be produced by one of the six purified extracts that have been obtained from anterior lobe tissue. These extracts are, by common usage, referred to as hormones and are known as (a) the *growth* or *somatotropic hormone* (STH), (b) the *thyrotrophic* or *thyroid stimulating hormone* (TSH), (c) the *adreno corticotrophic hormone* (ACTH), (d) and (e) the *gonadotrophic hormones* (*follicle stimulating hormone* (FSH), and *luteinizing hormone* (LH)), and (f) *prolactin* or *lactogenic hormone* (in some species also gonadotrophic, and known as *luteotrophic hormone* (LTH)).²

²The Third International Conference on the Standardization of Hormones has recommended that the suffix *trophic* in the adjective qualifying the hormones of the anterior pituitary be replaced by *trophic* (see Collip), and that the termination *trophin* be used in forming the name of the hor-

The effects of hypophysectomy The results of early work on hypophysectomy were complicated by the fact that the operation involved a trans temporal intracranial approach to the gland, with the risk of concurrent damage to the hypothalamus. It was at first thought that removal of the pituitary was fatal within a few days. The development of the parapharyngeal operation by P. E. Smith, in which hypothalamic injury is avoided, showed that hypophysectomized animals may survive for long periods, though their life span is ultimately shortened. In this operation the gland is removed through a trephine hole in the base of the skull. The diaphragma sellae remains intact, and the infundibular stem and median eminence (of the neurohypophysis) and the pars tuberalis (of the adenohypophysis) are left *in situ*. These remnants may be sufficient to prevent signs of neurohypophyseal deficiency (see below) but important abnormalities result from the loss of anterior lobe hormones. These are (a) arrested growth, (b) atrophy of the gonads and, indirectly, of the accessory organs of sex, (c) suppression of milk secretion and involution of the mammary glands, (d) atrophy of the thyroid and adrenal cortex, (e) lowered metabolic rate, (f) a tendency to hypoglycemia, and an increased sensitivity to insulin and reduction in liver and muscle glycogen, and (g) depression of spontaneous activity, and diminished resistance to infections and shock. With the advent of hypophysectomy as a therapeutic procedure for mammary carcinoma and other conditions, many of these effects have been observed in the human, though the position here is usually complicated by the necessary replacement therapy with thyroxine and cortisone.

It may be mentioned that in some fish and in amphibia the loss of the pars intermedia hormone (intermedin) results in a silvery, albino appearance. This is due to contraction of the melanophores of the skin. No defect due to loss of this hormone is known in mammals.

The Growth or Somatotrophic Hormone (STH)

The first indication that the pituitary gland exerted an effect on body growth came from the observations that human cases of acromegaly and

gigantism (e.g. thyrotrophin). The suffix *tropic* is from the Greek *trepein* to turn, and in this sense has been used in such terms as heliotropic, geotropic, etc. The suffix *trophic* is derived from the Greek word *trophein* to nourish or nurture and is therefore more appropriate as an ending for those pituitary hormones which affect the development and growth of other endocrines. The *tropic* ending is also accepted usage

gigantism commonly have pituitary tumors, and that hypophysectomized dogs (Crowe, Cushing, and Homans, 1910), tadpoles (Smith, 1916, Allen, 1916), and rats (Smith, 1930) show reduced body growth. In 1921, Evans and Long showed that injection of an extract of ox pituitary resulted in gigantism in rats.

Purified preparations of growth hormone have been prepared from both ox and pig pituitary tissue. Such preparations have been reported free from other active contaminants and to behave as a homogeneous substance to various physico-chemical tests. The data indicates that the material is a protein, with a molecular weight of 45,000 to 50,000. It is comparatively insoluble in water and has an isoelectric point at pH 6.85. It is destroyed by pepsin and trypsin. It is not active when given by mouth. After injection it remains in the circulation some 9 hours.

The source of growth hormone appears to be the acidophil cells of the anterior pituitary. The evidence is that acromegaly and gigantism in man are associated with over-secreting tumors (adenomata) of this cell type and that pituitaries of dwarf mice are lacking in acidophils.

The loss of growth hormone resulting from hypophysectomy results in two main deficits in the organism—a reduction in the rate of body growth (fig. 56.6) and disturbances in metabolism, especially of proteins and carbohydrates. Growth does not always cease in the hypophysectomized animal but may continue at a greatly reduced rate, perhaps 50 per cent of the normal. The fact that in the absence of the pituitary, mitotic figures appear in the mammary glands of parturient rats and that hypertrophy of the remaining kidney follows unilateral nephrectomy, also demonstrates that STH is not the sole factor controlling growth. Growth of the hypophysectomized animal is favored, at least transiently, by the provision of a nutritious diet by insulin adminis-

FIG. 56.6 Hypophysectomized puppy (right) and litter mate control (left) 3 months after removal of the hypophysis when 3 weeks old. (From Dandy and Ruckert.)

tration, or by androgen therapy. Further, hypophysectomy affects the growth of some tissues more than others. Thus rats hypophysectomized at 6 days of age die at about 75 days, since growth of the skull fails to keep pace with that of the brain. Removal of the pituitary results in a striking increase in sensitivity to insulin. In some animals, such as rabbits, this results in a certain mortality from hypoglycemia during the first few days after operation. If placed on a restricted diet, hypophysectomized rats show a greater loss of body weight and a greater loss of body protein, but less of fat, than the controls. The deposition of protein is clearly an essential part of growth processes. The fasted hypophysectomized animal rapidly develops hypoglycemia and shows abnormally low liver and muscle glycogen stores.

The effect of anterior pituitary extracts on growth was first demonstrated by Evans and Long. These workers found that an alkaline or saline extract of the gland when given daily by intraperitoneal injection (but not by mouth) extended the growth period beyond the normal limit. Some of these animals finally attained a size larger, by 100 per cent or more, than that of their untreated litter mates (fig. 567). The effect was usually greater in the female. Similar results have been obtained in dogs. Gigantism, acromegaly (p. 959), and splanchnomegaly have been produced in bulldogs by Putnam, Benedict, and Teel. Airedales, Boston terriers, and dachshunds have been shown by others to respond to such an extract (fig. 566). Administration of growth hormone to adult rats produces more uniform body growth than in adult dogs. This is because the epiphyseal cartilages of rats do not fuse so that the limbs retain the potentiality of growth in length (cf. the effect of acidophil adenomata in the immature and adult human). The width of the epiphyseal cartilage is reduced after hypophysectomy. Growth hormone exerts a specific stimulating effect upon such a cartilage. The cartilage cells become enlarged, active osteoblasts appear, the whole plate becomes thicker, and a zone of newly formed bony trabeculae develops. Studies

with radioactive calcium show that the rate of deposition of calcium in the cartilage is accelerated by STH. As might be expected, the stimulus to growth is accompanied by an increase in the body stores of protein and a positive nitrogen balance. The extra nitrogen stored under the influence of growth hormone is deposited as protein, mainly in the muscles. Some muscles of the rat have shown an increase of nitrogen content of as much as 60 per cent under these conditions. These changes are initiated quickly. Within a few hours after administration of STH to a fasted animal, the concentration of free amino acids in the blood and tissues decreases. That this is due to protein anabolism is shown by the simultaneous decrease in urea formation and excretion.

The anterior pituitary gland is related to carbohydrate metabolism in many ways. Housay first showed that dogs made diabetic by pancreatectomy showed a marked amelioration of the diabetes if subjected to hypophysectomy. Such a preparation, known as the *Housay dog*, may live for long periods without insulin. They are, however, in a state of unstable equilibrium and easily become diabetic or hypoglycemic if subjected to adverse conditions. These observations show the antagonistic influences the pituitary and pancreatic secretions exert over carbohydrate metabolism. This fact was again emphasized by the classical work of Young, who showed that administration of anterior pituitary extracts to adult dogs and cats for periods of several weeks might result in a permanent state of diabetes mellitus. Such animals show severe damage of the pancreatic islet tissue. This early study, performed with crude pituitary extracts, raised several questions, is the diabetogenic activity a property of a known pituitary hormone or not? and, why are immature dogs and cats, as well as adult animals of some other species such as the rat, resistant to the diabetogenic activity of pituitary extracts? With the advent of purified extracts it became clear that diabetogenic effects are associated with the growth hormone. Diabetogenic action can be demonstrated even with the most highly purified

FIG. 567. Litter mate female dachshunds 11½ months old. HY 26 injected with growth hormone for 35 weeks, HY 27 control. (From Evans and associates.)

preparation and is apparently a property of the growth hormone molecule itself. In reply to the second question, it has been suggested that the variability of the diabetogenic activity of STH in the young as opposed to the adult dog, and in different species, is due to variation in the capacity of the pancreas to secrete insulin. Administration of growth hormone results in certain metabolic effects which elicit increased secretion of insulin. If the pancreatic response is adequate then protein deposition and growth ensues. In the adult dog and cat, however, the pancreatic response fails, "exhaustion atrophy" of the islet tissue occurs, and a state of diabetes supervenes. In this context it may be noted that rats, which are resistant to the diabetogenic action of pituitary extracts, may respond to such extracts in the fasting states with a hypoglycemia, hypertrophy of pancreatic tissue may also occur. Administration of ACTH or adrenal cortical steroids results, in some respects, in effects similar to those induced by growth hormone. Thus adrenal cortical hormones increase gluconeogenesis and reduce the rate of glucose oxidation. If given to the fasting hypophysectomized animal the danger of hypoglycemia is reduced. Further, the effect of adrenalectomy on the carbohydrate metabolism of pancreatectomized animals may be very similar to that of hypophysectomy. Thus, in considering the overall relationship of the endocrine glands to carbohydrate metabolism, the pituitary gland, through its secretion of STH and ACTH, exerts opposing actions to those of insulin. ACTH acts through the intermediation of the adrenal cortex, although STH acts directly and not through the intermediation of other glands.

In the early days when only crude anterior pituitary extracts were available, a number of actions of these extracts were ascribed to specific "factors." These, and their actions, may be enumerated as follows: (a) *Hyperglycemic factor*, causes an immediate increase in blood sugar, (b) *hypoglycemic or pancreatrophic factor*, decreases blood sugar from stimulation of the islet tissue of the pancreas, (c) *glycotrophic factor*, inhibits the action of small doses of insulin, (d) *glycolytic factor*, maintains the muscle glycogen of fasting, hypophysectomized animals, (e) *ketogenic factor*, increases the ketosis of a fasting state, and (f) *fat mobilizing factor*, increases liver fat and the metabolism of fat, at the expense of depot fats. It is probable, though, that these actions are not due to "factors" separate from the usually accredited pituitary hormones, but may be attri-

buted to the actions of either STH or ACTH, or both.

Until recently, growth hormone preparations derived from ox or pig tissue were disappointing in their effects on the primate. It now seems very likely that this hormone is species specific, since extracts of primate origin have been found capable of causing marked nitrogen retention and the typical changes in carbohydrate metabolism in primates, whereas bovine and porcine preparations are inert in this regard. The effect of primate growth hormone on growth has recently been demonstrated by Knobil and his colleagues using the histological changes in the costochondral junction of hypophysectomized monkeys as a test object. Treatment of a pituitary dwarf with somatotrophin prepared from human glands has been found to result in increased body growth (Raben).

The bioassay of pituitary growth hormone is best performed on the hypophysectomized rat. The ability of the hormone to increase the body weight or to increase the width of the tibial epiphyseal cartilage, may be utilized. The tibial cartilage assay is a specific and sensitive test, and may detect as little as 5 μ g. of an active extract.

The factors controlling secretion of STH are unknown. It is indeed, debatable as to how actively this hormone is secreted in adult life. Young (1945) has suggested that growth hormone is secreted during conditions of starvation. This view is based on the fact that the metabolic pattern of an adult animal consuming a normal ration of food, but given anterior pituitary extract, is similar to that of a starving animal. The fragmentary data available suggests that secretion of STH is under hypothalamic control, since transplantation of the pituitary to a site remote from the sella turcica leads to marked retardation of body growth, and since hypothalamic lesions may be followed by signs of interference with carbohydrate metabolism which may be rectified by administration of growth hormone.

The Thyrotrophic Hormone, Thyrotrophin, Thyroid Stimulating Hormone (TSH)

A functional relationship between the pituitary gland and thyroid was suspected during the last century after it had been found that thyroidectomy results in histological changes in the pars distalis. The effect of hypophysectomy in preventing metamorphosis of the tadpole was ascribed by Adler (1914) to the associated atrophy of the thyroid. Smith showed clearly that replacement

therapy (pituitary implants) would repair the atrophic thyroid gland of the hypophysectomized rat. An acid extract of the anterior pituitary was then prepared (Loeb and Bassett Aron) which was found to have thyroid stimulating properties on injection.

The cells of origin of TSH in the anterior pituitary are basophilic and stain with the periodic acid-Schiff technique. They are centrally situated in the pars distalis of the rat and are angular and polyhedral in shape.

Several procedures are available for obtaining TSH in a highly purified state, though it has not yet been established that the preparations are entirely free from other pituitary hormones or that they are chemically homogenous. The data indicates that TSH is a protein or polypeptide with a molecular weight of about 10 000 and that the molecule probably contains a carbohydrate moiety. It is inactivated by proteolytic enzymes and must be administered by injection.

The thyrotrophic hormone exerts a powerful controlling influence over the activity of the thyroid gland and has also been implicated as having a direct action in the development of exophthalmos in certain pathological states. The thyroid gland extracts iodide ions from the blood stream, combines these organically and stores its hormonal activity as a protein known as thyro-

globulin. From this protein thyroxine and triiodothyronine are liberated into the blood stream to stimulate the metabolism of nearly every tissue in the body. Hypophysectomy does not abolish thyroid function completely but greatly reduces it. In man hypophysectomy results within some weeks in a condition of thyroid deficiency known as myxedema. The thyroidal changes resulting from removal of the pituitary may be summarized as follows: (a) Reduction in size, weight and vascularization; (b) histological changes notably a reduction in the height of the epithelial cells of the acini and an increased amount of acinar colloid (fig. 56.8) and (c) a reduction in all the chemical processes of iodine metabolism in the gland. The uptake of iodide ions from the blood conveniently measured as a thyroid serum (T/S) ratio (ch. 57) may be reduced in the rat from values of about a 100 to about 2. The organic binding of iodine in the gland and the liberation of iodine containing hormones from the gland are also markedly depressed by hypophysectomy. These changes are all reversible by the administration of an exogenous TSH extract. Not only may the state and function of the gland of the hypophysectomized animal be returned to normal but injection of excessive doses of TSH result in a hyperplastic thyroid and signs of hyperthyroidism. The gland enlarges and becomes hypervascular. The acinar cells show hypertrophy and hyperplasia with a reversal in the polarity of the mitochondria and Golgi apparatus. The colloid undergoes a peripheral vacuolization, a change in its staining properties so that it appears basophilic instead of eosinophilic and becomes reduced in amount as the stored hormone is liberated into the blood in increased amounts. As the blood concentration of thyroid hormones rises signs of thyrotoxicosis ensue. An increased metabolic rate, sweating, nervousness, tremor and cardiac irregularities have been reported in the human. The above changes do not occur simultaneously after administration of TSH. Within half an hour of TSH injection there is in the experimental animal an increase of proteolytic enzyme in the follicles and an increased release of thyroidal hormone as detected by examination of thyroid vein blood. Some 8 hours or so later an increase in the rate of uptake of iodine from the blood occurs. The different time relationships of these processes are shown in figure 56.9. The enlargement of the gland and the signs of hyperthyroidism take longer to develop.

Thyrotrophic hormone acts directly on the thyroid gland and probably on intraorbital tis-

FIG. 56.8. Photomicrographs of sections through the thyroid gland of a normal dog (above) and a dog which has received seven daily injections of anterior pituitary extract containing thyrotrophin (below). (From Ham.)

sues. Patients with a diffuse enlargement of the thyroid gland and signs of thyrotoxicosis often show exophthalmos. This protrusion of the eyes is characterized by edema and a lymphocytic and fatty infiltration with fibrosis of the retrobulbar tissues. A similar state of the eyes has been produced in normal and thyroidectomized guinea pigs by injection of extracts rich in TSH, and on these grounds it has been suggested that in Graves' disease both the thyroidal disturbance and the exophthalmos are due to direct actions of TSH. Since in these cases blockage of thyroid activity by thyroid inhibiting drugs, or thyroidectomy (procedures which increase TSH secretion in the normal animal) are often followed by an increase in the severity of the exophthalmos, and since administration of large doses of adrenal corticoids or pituitary stalk section (procedures which decrease the secretion of TSH in the normal animal) have been reported to decrease or abolish the exophthalmos, indirect support for this view is forthcoming. However, McCullagh, who has critically examined the evidence, points out that thyroidectomy or myxedema in previously normal subjects does not lead to the development of exophthalmos. A possible explanation of the pituitary relationship to exophthalmos comes from the work of Dobyns and his collaborators. It has previously been found that a marked exophthalmic state developed in Fundulus, the common Atlantic "minnow," following administration of small amounts of anterior pituitary extract. Using this animal as a test for exophthalmic producing substance (EPS), Dobyns found it possible to separate TSH and EPS in pituitary extracts by means of their different solubilities in trichloroacetic acid. TSH was obtained free from EPS, although the EPS fraction still contained some TSH activity. The evidence is suggestive then that an exophthalmos producing principle is often, though not always liberated in association with TSH. Another observation which may help to explain the increase in the exophthalmos seen after thyroidectomy is that thyroid tissue slices *in vitro* have been found to inactivate both the thyroid stimulating and exophthalmic producing actions of TSH extracts.

Species differences exist in the quantity of TSH stored in the pituitary gland and in the sensitivity of the thyroid gland to a given dose of TSH. The anterior pituitary content of thyrotrophic hormone of several forms has been given, in ascending order, as follows: guinea pig, chick, cat, rabbit, man, ox, sheep, pig, dog, mouse, and rat. The guinea pig and chick thus have a low TSH con-

FIG. 56.9 Showing the percentage loss of radioiodine from and the delayed increase in radioiodine in the thyroid under influence of TSH (From Rawson)

tent in their anterior pituitaries and also less active thyroids than the other forms. They are, therefore, animals of choice for assay of TSH preparations. On the other hand, the rat, which normally has a more active thyroid, is less sensitive to administration of TSH.

A refractory state to the action of TSH develops after repeated administration of thyrotrophic extracts. This state has been shown by Collip and Anderson to be due to the formation of some inhibiting substance (antihormone, see p. 979) which they have found in the serum of the treated animals. Friedgood also found that though guinea pigs responded at first to an extract of the anterior lobe of the pituitary by thyroid hyperplasia and a rise in the basal metabolic rate, the animals later became refractory. The responsive period was followed by one during which the BMR fell to normal or to a subnormal level (though the injections were continued), the thyroid hyperplasia, however, persisted. Eventually the thyroid returned to its normal size and histological appearance, in spite of the uninterrupted administration of the extract. Slight prominence of the eyeballs appeared toward the end of the responsive phase, but the most pronounced exophthalmos occurred during the refractory phase. The production of the effect on the eyes appeared from this study also, to be independent of the

effect on the thyroid gland and the BMR. As mentioned above (see ch. 44), exophthalmos has been induced by the administration of anterior pituitary extract to thyroidectomized animals.

Many assay methods are available for measuring the TSH content of materials rich in thyrotrophic activity. Few of these methods however will detect or measure the amounts of TSH normally present in body fluids. The increase in weight of the thyroid gland in immature male guinea pigs, the increase in mean cell height of the thyroidal epithelium of few day old chicks, the increase in uptake of ^{131}I by the thyroid glands of young rats (in which thyroidal activity has been depressed below normal by previous feeding with iodinated casein) and other criteria of thyrotrophic activity have been utilized as a basis for assay methods. The "stasis tadpole" method of D. Angelo is among the most sensitive. The starved tadpole develops thyroid atrophy and a consequent arrest of metamorphosis. Injection of TSH in about 1/100th the amount detectable in the young guinea pig produces histological changes in the thyroid gland. Other, recently published methods for which high degrees of sensitivity are claimed involve the release of radioactive hormone from the thyroid gland of the guinea pig or mouse and the ^{131}I turnover in the guinea pig thyroid cultured *in vitro*. An assay method that would accurately determine TSH levels in body fluids would be of great value in the study of the factors determining the rate of TSH release in the normal animal and would throw light on the etiology and changes occurring in hypo- and hyperthyroid states in man. It should be emphasized that the thyrotrophic activity of any given sample is best expressed in terms of the recently established (1955) International Unit (IU). The International Unit is approximately equal to the pre-existing national (USP) Unit and is defined as the activity of 13.5 mg. of an international standard powdered preparation.

TSH is rapidly inactivated and excreted from the body. Using the stasis tadpole technique D. Angelo calculated that only 3 per cent of an injected dose was present in the blood of a rat at the end of 1 hour, and 1 per cent at 5 hours. The fate of the hormone is uncertain. Since it disappears from the blood of thyroidectomized animals more slowly than intact animals, and since *in vitro* tests show that thyroid (and lymphatic and thymic) tissue inactivates thyrotrophin, it is possible that it is inactivated by its own target gland.

The regulation of the release of TSH from the anterior pituitary gland is influenced by two chief factors, (a) the blood concentration of thyroid

hormone, and (b) nervous influences from the hypothalamus. As described earlier, the blood concentration of hormones from the pituitary target glands determines, within limits, the rate of secretion of the appropriate pituitary trophic hormone. Thus a rise in concentration of thyroid hormone in the blood depresses the secretion of TSH, and a fall in concentration increases TSH release. This homeostatic or feed back mechanism may be illustrated in several ways. A fall in level of thyroid hormone in the blood may be brought about by administration of a goitrogenic drug (which blocks the synthesis of thyroid hormone in the gland). Under these conditions the thyroid becomes depleted of colloid, shows hypertrophy and goiter formation and all the signs of thyrotrophic activation. Such does not occur if the drug is administered to the hypophysectomized animal or to an animal receiving large doses of thyroxine. Dempsey and Astwood (1943) used these observations to study the rate of release of thyroid hormone at various environmental temperatures. Thyrotoxic treated rats were exposed to temperatures of 1°, 25°, and 30°C, and the least amount of thyroxine to maintain a normal thyroid histology was estimated. It was found that the daily dose required was 9.5 µg at 1°, 5.2 µg at 25°, and 1.7 µg at 35°C. These experiments demonstrate the amount of exogenous thyroxine required to maintain the pituitary thyroid equilibrium under varying environmental conditions. The decreased secretion of TSH which follows a rise in blood level of thyroid hormone is shown by the thyroidal inhibition which follows administration of thyroxine to the normal animal. This has been clearly observed in the rabbit, in which the rate of release of radioactive hormone from the thyroid was studied. It was found that the release of thyroid hormone was inhibited within 2 hours by injection of thyroxine, and that a dose of about 15 µg per day was required to suppress thyroid function. This amount of thyroxine then appears to be the equivalent of the daily secretion of the thyroid in this species.

The hypothalamus regulates the pituitary secretion of thyrotrophic hormone through a mechanism involving the hypophyseal portal vessels of the pituitary stalk. If the pituitary stalk is cut, or if the pituitary gland is transplanted to a distant site in the body, the activity of the thyroid is decreased, and various environmental influences which previously modified thyroid function are now without effect. The hypothalamus appears to exert a tonic influence in maintaining the basal level of thyrotrophic secre-

tion and by means of nervous reflexes, to modify TSH release in accord with the requirements of the environment. Thus stress stimuli of an emotional or nervous type which normally inhibit TSH release and the stimulus of a cold environment which normally excites TSH release no longer do so after the pituitary is disconnected from the central nervous system. The influence of the hypothalamus on TSH secretion or thyroid activity has recently been investigated with regard to the effects produced by localized hypothalamic lesions and electrical stimulation. It has been found that lesions in the anterior hypothalamus in the region of the supraopticohypophyseal tract result in reduced thyroid function whereas stimulation of approximately the same site results in an increase in thyroid activity. Since the supraopticohypophyseal tract is known to regulate the release of posterior pituitary hormones it has been suggested that the regulation of TSH secretion by the hypothalamus is mediated through the release of these hormones into the pituitary portal vessels which supply the pars distalis.

Two questions arise from the above discussion. First whether the feed back effects of thyroid hormone act through the intermediation of the hypothalamus and second whether feed back or neural influences take priority in the normal animal. The evidence relating to the former problem is indeterminate. The effect of the blood level of thyroxine in regulating TSH output is still apparent in the pituitary stalk cut or pituitary transplanted animal. However hypothalamic lesions decrease the sensitivity of the animal to the goitrogenic action of propylthiouracil (Greer) or to the effects of hemithyroidectomy (Reichlin). It may be that the feed back system operates at both a hypothalamic and pituitary level and that in the normal animal the hypothalamus forms the more sensitive receptor mechanism. The answer to the second question is more certain. Presently available evidence indicates that the feed back system acts to stabilize thyroid function at a particular level and that the nervous system superimposes its action on this baseline. Thus as Brown Grant has shown emotional stress in the rabbit is associated with a decrease in thyroid activity at the same time as there occurs a fall in thyroid hormone in the blood. Conversely Harris and Woods have found that electrical stimulation of the hypothalamus results in a marked and maintained increase in thyroid activity in spite of a rise of blood concentration of thyroid hormone.

The Adrenocorticotrophic Hormone (ACTH) Corticotrophin

Since the early work of Smith it has become firmly established that the adrenal cortex is under the control of a hormone secreted by the anterior pituitary gland. Smith found that atrophy of the adrenal cortex occurred in the hypophysectomized rat and that repair took place under the influence of pituitary implants.

It is uncertain which cells of the anterior pituitary secrete ACTH. The observations of Cushing that a certain clinical entity characterized by adrenal cortical hypertrophy and overactivity was associated with a basophil adenoma of the pituitary led many workers to cite a basophil origin of this hormone. Recent studies of the human gland have indicated that under acute conditions of stress in which it is known that ACTH is secreted in increased amounts a basophil degranulation occurs with recovery under chronic conditions. However other studies on the cytology of the rat pituitary under a wide variety of experimental conditions have not succeeded in establishing a correlation between ACTH secretion and any particular cell type.

Collip and his colleagues (1933) were the first to prepare an extract from the anterior pituitary which acted specifically upon the adrenal cortex. This extract was highly effective in restoring to normal the atrophied adrenal cortex of hypophysectomized animals. A protein with high corticotrophic activity was isolated by Li and his associates in 1942 and by Sayers and his colleagues in

FIG 56-10 Showing adrenal atrophy following hypophysectomy. Normal gland (above) and gland of hypophysectomized animal (below). (From P. Smith.)

1943 These extracts were found to have a molecular weight of around 20 000 The technique of Astwood and his colleagues, who employed oxycellulose to adsorb and purify adrenocorticotrophin, enables a polypeptide of a molecular weight of about 4000 to be extracted from these original preparations This polypeptide retains all the physiological activity and is about 100 times as active as the starting protein extract The amino acid components of ACTH are being elucidated and a proposed structure for one of the highly purified extracts (β corticotrophin) has been proposed ACTH is fairly resistant to pepsin but destroyed by trypsin It is almost inactive when given by mouth The most effective route of administration is by slow intravenous infusion If injected subcutaneously or intramuscularly the effect of a given dose is increased if the extract is mixed with a diluent that slows absorption, such as beeswax and oil or gelatin

The physiological activities of ACTH may be divided into those indirect functions which are dependent on stimulation of the target gland and those direct activities which possibly occur in the absence of the adrenal cortex

Adrenal activities Hypophysectomy results in adrenal cortical atrophy although the different zones of the cortex atrophy to different degrees Greep and Deane emphasize that the zona glomerulosa of the rat remains well developed after hypophysectomy, and other workers have reported somewhat similar findings in the dog Greep correlates this fact with the relatively intact electrolyte metabolism found in the hypophysectomized, but not adrenalectomized, animal and suggests that the zona glomerulosa is responsible for secreting aldosterone (see p 1036) and that this function is largely free from pituitary control It has recently been shown by *in vitro* methods that the outer zone of the adrenal cortex synthesizes aldosterone at a higher rate than other parts The zona fasciculata shows marked thinning after hypophysectomy, loses much of its lipid material and develops a characteristic sudanophobic zone These changes are all reversible by administration of ACTH The injection of ACTH into the hypophysectomized or normal animal or the exposure of the normal animal to stressful or noxious stimuli (known to evoke ACTH discharge from the pituitary) results in the reverse changes Thus administration of ACTH induces (a) increased size of the adrenal which may be detectable within a few hours (b) a depletion of the ascorbic acid content of the

adrenal within 15 to 30 minutes (the exact physiological significance of this response is unknown but it forms the basis of the most widely used assay method for ACTH), (c) a fall in concentration of adrenal cholesterol and stainable lipid (it is now known that cholesterol is a precursor of the adrenal steroids, so that the fall in adrenal cholesterol presumably reflects increased hormonal synthesis), and (d) an increased release of adrenal steroids as detected by assay of adrenal vein blood (this is a rapid response, occurring within a few minutes, and is associated with an increased blood flow through the gland) In general it may be said that the adrenal cortex secretes three groups of steroids glucocorticoids mineralocorticoids, and androgenic steroids It is of interest that administration of ACTH may affect the type of glucocorticoid secreted in a particular species Thus the rabbit which normally secretes corticosterone releases predominantly hydrocortisone after chronic treatment with corticotrophin There has been much discussion as to the control the pituitary exerts over aldosterone secretion It seems established that aldosterone release is less dependent on pituitary adrenocorticotrophin than is the release of the glucocorticoids Aldosterone output is reduced but not to such a marked degree as that of the glucocorticoids by hypophysectomy in the dog or cat and the effect of administration of ACTH on aldosterone secretion is reported as inconstant or small in comparison with the effect on glucocorticoid secretion Little is known about the regulation of secretion of adrenal androgens 17 ketosteroids have been found in the adrenal vein blood of the dog and man but their physiological role is uncertain In certain pathological states of virilism in young girls the androgenic secretion of the adrenal cortex seems to be maintained by pituitary ACTH, since Wilkins has found that administration of cortisone (which inhibits ACTH release through the feed back mechanism) may control the disease

The quantitative aspects of ACTH control of glucocorticoid secretion has been studied most carefully in the dog Hypophysectomy lowers the amount of 17 hydroxycorticosterone (F) in adrenal vein blood whereas injection of a large intravenous dose of ACTH (20 to 40 units), or surgical trauma raises the 17 hydroxycorticosterone secretion from a resting figure of about 7 μ g per kilogram per hour to about 50 μ g per kilogram per hour It should be pointed out that under certain conditions the adrenal cortex is relatively

resistant to the action of ACTH. The atrophic adrenal consequent to hypophysectomy, a hypopituitary state or to chronic blockade of ACTH release by cortisone, is insensitive to ACTH and may require several days of corticotrophin administration before normal sensitivity is regained. States of adrenal cortical deficiency may be encountered clinically if cortisone therapy is stopped too suddenly.

Certain extra-adrenal activities of ACTH have been described from time to time. It is now known that many of these were due to impurities in the extracts used. However, it appears likely that ACTH does have melanophore stimulating actions as an intrinsic property of its molecule. This may be due to the fact that a certain amino acid sequence in the polypeptide chains is common to both β -corticotrophin and melanophore stimulating hormone (MSH). The present known preparations of ACTH also seem to possess fat-mobilizing (adipokinetic) activity and ketogenic activity.

The physiological actions observed after administration of ACTH are very largely those mediated by the adrenal cortex, and chapter 58 may be consulted for an account of these. Minor differences in the effects observed after ACTH or hydrocortisone administration in the human have been reported. ACTH therapy is said to be followed by a greater degree of salt and water retention, and by a greater incidence of uricizing manifestations. These effects may be due to the stimulation of secretion of aldosterone and androgenic steroids, as well as of 17-hydroxycorticosterone by ACTH.

The assay of ACTH is dependent on biological methods. These may be divided into those employing intact or hypophysectomized animals although *in vitro* procedures have been newly proposed. It is probably inadvisable to rely upon methods using intact animals in view of the ease in which endogenous ACTH can be discharged by such trivial stress stimuli as those associated with handling or with injection. However, the use of animals in which the release of ACTH has been blocked with DOCA has been proposed as an alternative to hypophysectomy (Buttle and Hodges). The more important methods include: (a) *Ascorbic acid depletion test* (Sayers' test) in which the left adrenals of male rats (120 to 180 grams) are removed 24 hours after hypophysectomy. The hormone preparation is then given intravenously and the right adrenal removed 1 hour later. Both adrenals are analyzed for ascorbic acid and the response is calculated as the difference in ascorbic acid between the right and left glands. As little as 0.2 munits of the international standard can

be detected by this method. (b) *The repair test* in this case the quantity of ACTH required in a 4 day period to restore the normal histological appearance of the adrenal cortex of 28 day-old female rats hypophysectomized 14 days previously is determined. (c) *The maintenance test* a unit of ACTH as defined by this test is the amount required over a period of 15 days to maintain the preoperative weight of hypophysectomized 40 day old male rats. (d) *Corticosteroid release* hypophysectomized dogs are maintained on ACTH until about 16 hours before the assay. For the assay the adrenal vein is cannulated, samples of adrenal vein blood are collected at intervals and the corticosteroid content determined by the Porter-Silber reaction. The effect of ACTH preparations may then be directly compared with a standard by means of the increase in corticosteroid output induced (Nelson and Hume). (e) *Release of corticosteroids in vitro* rat adrenal glands are cut into pieces and the fragments incubated with ACTH preparations in a Warburg apparatus. The steroids released are extracted from the medium and assayed by chemical means. It has been suggested that since the results obtained by the adrenal weight method and the Sayers' method do not give parallel findings for some pituitary extracts that there are two corticotrophins: an adrenal weight factor and an adrenal ascorbic acid depletion factor. The different results obtained by the two methods are perhaps more easily explained by the different routes of administration of the extracts used in the two assays. Amounts of ACTH should be expressed quantitatively in terms of the international standard. The International Unit is the activity of 1 mg of the international standard powder (La 1 A).

The inactivation of ACTH occurs very rapidly in the body. It is not excreted in the urine though appreciable amounts of an administered dose may be recovered from kidney tissue. The half life of the hormone in the blood of the rat is about 1 minute.

The regulation of the secretion of ACTH by the anterior pituitary has been intensively investigated since it became realized that release of the hormone at increased rates was one of the organism's defense reactions to stress or trauma, and that ACTH given in large pharmacological doses was of use in rheumatoid arthritis in other so-called collagen diseases, and in various allergic disorders. As with most other pituitary trophic hormones the secretion of ACTH appears to be controlled by two main factors: the feed back of its target gland hormones (the adrenal steroids) and by an influence from the central nervous system *via* the hypothalamus. In the following

discussion two points should be borne in mind. First the adrenal cortex of the *hypophysectomized* animal still secretes sufficient steroids to maintain life under optimal conditions, and second the pituitary gland removed from the influence of the central nervous system still secretes basal amounts of ACTH. Thus both the adrenal cortex and anterior pituitary possess some autonomous secretory activity and it is against this background that the factors regulating ACTH secretion have to be studied. It was at one time claimed that the feed back mechanism of the adrenal cortical hormones was sufficient to regulate the output of ACTH under resting conditions and also under conditions of stress (starvation, cold exposure, infection, tissue damage, emotional excitement etc) in which corticotrophin secretion is greatly increased. It was argued that stressful stimuli increased the tissue utilization of adrenal cortical hormones, that the blood concentration of these hormones was thereby decreased, and that via the feed back action the liberation of ACTH was augmented leading to increased adrenal cortical activity. There can be no doubt that an increased blood level of adrenal steroids tends to suppress ACTH release and *vice versa*. Arguments against this view are the lack of evidence that noxious influences do in fact increase the tissue utilization of adrenal corticoids, and that if this mechanism holds true then it would seem impossible for the organism to maintain an increased blood concentration of adrenal steroids for any length of time. That this hypothesis does not represent the whole story was shown most convincingly by Snyder and Sayers (1954). These workers developed a method for assaying the blood level of ACTH in rats. It was found that adrenalectomized rats had a higher level than that of normal rats (which was undetectable by the method) and that stress stimuli (ether anaesthesia, scalding, bleeding) had a rapid and dramatic effect in increasing the blood ACTH concentration in both normal and adrenalectomized animals. It is clear that the stress stimuli could not have affected ACTH secretion by a feed back action in the adrenalectomized rats. It is likely that the servo mechanism acts rather as a stabilizing system to maintain a constancy of adrenal cortical function at any set level. The most potent influence in maintaining the normal rate of ACTH secretion, and in increasing this rate under conditions of stress, appears to be derived from the hypothalamus. Reasons for this statement are as follows: (a) Separation of the pituitary from the

hypothalamus by section of the pituitary stalk and the placement of a plate between the stalk ends, or by pituitary transplantation, results in adrenal cortical atrophy (though the ultimate size of the gland is somewhat greater than that of the hypophysectomized animal), (b) hypothalamic lesions have been found to result in a diminution of ACTH concentration in systemic blood, a diminution of 17 hydroxycorticosteroids in adrenal vein blood, a loss of the compensatory hypertrophy which follows unilateral adrenalectomy, and abolition of the adrenal cortical response to stress stimuli, (c) administration of morphine has been found to blockade the ACTH release evoked by such stress stimuli as injection of histamine or unilateral adrenalectomy (it seems likely that morphine exerts this effect by an action on the nervous system), and (d) electrical stimulation of the hypothalamus results in increased corticoids in adrenal vein blood and in signs of increased adrenal cortical activity (lymphopenia, eosinopenia, decreased adrenal ascorbic acid and histological changes in the sudanophilic material of the adrenal cortex). The pathway by which the hypothalamus affects the activity of the pars distalis is a vascular one—the portal vessels of the pituitary stalk. The exact mechanism is unknown although evidence is accumulating that it involves the transmission of a humoral agent from the tuber cinereum to the anterior pituitary.

One corollary to the above discussion should be added. Stressful stimuli which involve tissue damage or metabolic disturbance still evoke ACTH discharge even when the pituitary gland is separated from the nervous system. On these grounds, Fortier originally divided stresses into two types: *neural* (emotional excitement, uncomfortable noise, pain, fright), acting on the anterior pituitary solely through the nervous system, and *systemic* (involving surgical trauma and changes in the composition of the circulating systemic blood), which can act directly on anterior pituitary cells without the mediation of the nervous system. In the intact animal the neural component probably plays a part in the response to both types of stimuli. As pointed out by Fortier, and later by Sayers, this distinction may involve not a difference of modality, but one of intensity, of the stresses used in the original experiments. Thus, a pituitary stalk cut animal may liberate enough "humoral transmitter" from the tuber cinereum, in response to a severe stress, to be carried around the general circulation to affect corticotrophin release by the pituitary gland.

Gonadotrophic Hormones, Gonadotrophins (Follicle-Stimulating Hormone, FSH, Luteinizing Hormone, LH, or Interstitial Cell Stimulating Hormone, ICSH)

Several observations in the past have pointed to extravarian factors as regulators of ovarian activity. After removal of one ovary the same number of follicles develop in the remaining ovary as in the original pair (law of follicular constancy). The fact that ovaries from immature animals grafted into the adult, or ovaries from

adult animals grafted into the immature, be have according to the age of the recipient host, indicated that ovarian function was controlled humorally by some substance external to the ovary itself. This hypothetical substance was termed "generative ferment" by Heape, and "X substance" by other early workers. The gradual atrophy and suppression of sex functions which occurs with diseases of the anterior pituitary in man (acromegaly, Frohlich's syndrome) and the atrophy of the gonads after hypophysectomy in animals, indicated the pituitary as the source of this substance. A firm basis for this belief was established by the following observations: (a) Evans and his associates found that a crude saline extract of the anterior lobe caused luteinization of ovarian follicles (fig. 56 11), (b) Smith and Engle observed that when fresh mammalian anterior lobe tissue was implanted daily into immature female rats or mice, estrus was precipitated and ovulation followed. The ovaries and uterus showed enlargement to about 5 to 10 times normal size (fig. 56 12), the ovaries discharged an excessive number of ova (superovulation) and the solid vaginal canal (typical of the immature rat or mouse) developed a lumen. In immature male animals, the testes, seminal vesicles, and penis were stimulated to increased growth. Further, the gonadal atrophy which followed hypophysectomy was prevented by anterior lobe implants, (c) Ascheim and Zondek first found that injec-

(From Smith and Engle.)

tion of the blood or urine of pregnant women into immature rats caused follicular development, ovulation, and luteinization. They termed this substance Prolan. It has since been found that Prolan originates in the chorion of the placenta (human chorionic gonadotrophin, HCG) and not in the pituitary and that its action is mainly luteinizing, and (d) the discovery that the urine of menopausal women, or of castrated men and women, contains a substance which stimulates the ovary. This substance is probably of pituitary origin and its main action is follicle stimulating. It is now generally held that the pituitary secretes two, if not three, gonadotrophic hormones. The first is concerned with ripening of the ovarian follicles (FSH) or spermatogenesis, the second with ovulation, luteinization, and maintenance of the interstitial tissue of the gonads (LH or ICSH), and possibly a third that maintains luteal activity (prolactin or luteotrophic hormone, LTH).

A detailed account of the reproductive processes may be found in chapter 60. A summary of the events occurring during a sexual cycle is given in figure 56-13. As a basis for future discussion it may be said that at the beginning of a sexual cycle, when the ovary and the uterus are in a resting phase, the pituitary liberates FSH. Under the influence of this hormone, follicles ripen in the ovary and estrogen secretion occurs. This in turn produces development of the uterus and other parts of the reproductive tract. At about the 14th day of the cycle in the human, release of LH

occurs and under the continued action of LH and FSH, a ripe follicle ruptures, and a corpus luteum develops. This in turn secretes progesterone which results in secretory activity of the endometrium and characteristic changes in uterine muscle reactivity. In some forms luteal secretion is dependent upon prolactin release from the pituitary, but this has not been established for primates. Thus the changes typical of the first, follicular, half of the sex cycle are regulated by FSH release from the pituitary and of the second, luteal, half of the cycle by LH and possibly LTH release.

The origin of the gonadotrophic hormones in the anterior pituitary lies in the basophil cells. Both FSH and LH are glycoproteins and their cells of origin, therefore, stain with the trichrome periodic acid-Schiff procedure. The basophil cells of the rat pituitary may be divided into a group placed centrally in the pars distalis (concerned with TSH secretion), a group located on the lower surface of the gland and another situated peripherally on the upper surface adjacent to the pars intermedia. There is general agreement that these latter groups are composed of cells concerned with gonadotrophin secretion, and there are indications that those on the lower surface release LH and the peripherally placed cells are associated with FSH.

The chemical separation of pituitary extracts into two gonadotrophic fractions was first accomplished by Fevold, Hisaw, and Leonard in 1931. Since then several methods have been developed for obtaining either FSH or LH in a highly purified form. It is perhaps doubtful whether either fraction has been obtained completely pure. It is also debatable whether the pituitary secretes one hormone with multiple gonadotrophic activities or two hormones with actions comparable to those of the present chemical extracts. FSH is a glycoprotein, rich in carbohydrate; its hormonal activity is destroyed by ptyalin and takadiastase, so that its activity may be dependent on the integrity of the carbohydrate fraction of the molecule. It is not destroyed by trypsin, however, a fact which has been utilized in one method to separate it from LH. Purified preparations have been obtained from both sheep and swine pituitary tissue. It is of interest that the preparation derived from these two sources behave alike biologically but may differ chemically. LH is also a glycoprotein but its biological activity is not destroyed by ptyalin. It has likewise been prepared in a purified state from sheep and swine pituitaries, the material obtained from the two sources showing different physicochemi-

Fig 56-13 Diagram summarizing the relationships of the anterior pituitary, ovary, and endometrium through the menstrual cycle

cal and immunological properties. For example, pig LH has a molecular weight of about 100,000 and sheep LH about 40,000.

The physiological properties of FSH and LH extracts are best investigated in hypophysectomized animals using biologically pure preparations. This is even more important in the study of gonadotrophins than for the other pituitary hormones since the presence of small amounts of other endogenous or exogenous gonadotrophins in the circulation may alter the effects observed both quantitatively and qualitatively. The gonads of hypophysectomized animals show pronounced loss of size and weight. Primordial follicles are still present in the ovaries but do not develop to the stage of antra formation. No ovulation occurs and no corpora lutea are formed. In animals such as the rat, in which interstitial tissue is present in the ovary, this tissue shows obvious degenerative changes. The cells become smaller with dense pyknotic nuclei. Hormonal activity on the part of the ovary also ceases, as shown by the atrophy of the accessory reproductive organs (fig. 56-14). On administration of FSH preparations to such an hypophysectomized animal, follicles enlarge and ripen and a marked increase occurs in ovarian weight. Such administration, however, does not result in ovulation or corpora lutea formation, nor repair of the interstitial tissue or hormone secretion by the ovary. The reproductive tract, therefore, remains atrophic. Administration of purified LH to the hypophysectomized rat repairs the interstitial tissue of the ovary. Follicular growth does not occur and no sign of estrogen secretion is apparent in the uterus and vagina. If FSH and LH are administered together then follicular ripening, ovulation and corpus luteum formation occurs. The optimum dosage of these hormones for ovulation is about (FSH:LH) 10:1. FSH and LH given together also result in estrogen secretion and development of the genital tract. However, the corpora lutea do not become functional and secretory in the rat unless prolactin (luteotrophic hormone) is also present. The synergism which exists between the action of FSH and LH when given together is clearly seen when the effect upon ovarian weight is studied. FSH given alone increases the weight of the ovary in the hypophysectomized rat, LH alone has little effect. FSH and LH given together result in a much greater increment in ovarian weight than would be expected from a simple summation of responses. This is known as the *augmentation effect* and must be allowed for when considering assay

procedures for these hormones. In the hypophysectomized male rat, purified FSH results in development of the testicular tubules and spermatogenesis, but has no effect on the interstitial or Leydig cells. On the other hand, purified LH results in development of the interstitial cells and secretion of androgen. The androgenic activity in turn results in development of the seminiferous tubules and spermatogenesis, and also development of the accessory organs such as the seminal vesicles and ventral prostate. The stimulation of gametogenesis by LH in the male, through the androgenic secretion elicited, seems to have no equivalent in the female. It is, however, well established that androgens stimulate the seminiferous tubules directly both in the rat and probably in the human.

Evidence has accumulated that administration of the gonadotrophins results in a reduction of ovarian and testicular cholesterol. It is likely that the cholesterol in these glands is a precursor of estrogens and androgens, and the condition may be compared with that existing in the adrenal cortex.

It is probable that FSH and LH exert the same effects in man as those described above for the rat. However, the therapeutic uses of gonadotrophic hormones have limited value and their actions in the human are ill understood.

Substances with gonadotrophic activity may be extracted from blood and urine in various normal and pathological states. These gonadotrophic substances may be of pituitary or placental origin, but all appear to be glycoproteins.

1. *Menopausal or castration urinary gonadotrophin (CU)*. This substance was first found in the blood or urine of menopausal women and later in the urine of both sexes after castration. It is probably of pituitary origin. Cessation of

FIG. 56-14. Effect of hypophysectomy upon the uterus. On right uterus of normal rat, on left that of an hypophysectomized rat. (From van Dyke, *The Physiology and Pharmacology of the Pituitary Body*, by permission of the University of Chicago Press.)

function, or removal, of the gonads results in release of the pituitary from the feed back of gonadal hormones and an increased secretion of pituitary gonadotrophins. In support of this view is the fact that extracts of the pituitary of the castrate animal have similar physiological effects to CU, in that they are very largely follicle stimulating in nature.

2 *Human chorionic gonadotrophin (HCG)* In 1927, Ascheim and Zondek reported the presence of a gonadotrophic substance in the blood and urine of pregnant women. On injection of an extract of HCG into an immature mouse or rat, follicular development, ovulation, and luteinization occurs in the ovaries. However on injection into an hypophysectomized rat no follicular development occurs. Its actions are explainable on the grounds that HCG stimulates the animal's own pituitary to secrete FSH, while possessing LH like activity itself (for further information see ch 60).

3 *Pregnant mare serum gonadotrophin (PMS)* Cole and Hart (1930) first observed the presence of a powerful gonadotrophic substance in the blood of pregnant mares. On injection into hypophysectomized animals it exerts a predominantly follicle stimulating effect. Unlike the other gonadotrophic substances it persists in the blood stream, after a single injection, for many days (see also ch 60).

The bioassay of gonadotrophins is usually performed with reference to their follicle stimulating or interstitial cell stimulating activity. The augmentation effect must be borne in mind and may be circumvented when assaying FSH either by eliminating the action of LH (by using hypophysectomized animals and purified preparations of FSH), or by deliberately adding to the extract to be assayed amounts of an LH substance which produces maximum augmentation. Thus FSH activity may be assayed (a) by ascertaining the amount of material necessary to re-establish follicular growth in the hypophysectomized animal or (b) by finding the least amount of the preparation that will double the ovarian weight of the normal immature animal when administered in combination with a substance having LH activity. LH activity, on the other hand, may be measured more satisfactorily, since a test is available for LH which is independent of the augmentation effect. The increase in weight of the ventral prostate of the hypophysectomized immature male rat gives an index of the amount of LH activity in an injected extract.

The inactivation of pituitary gonadotrophic hormones in the blood stream proceeds more

slowly than do some other anterior pituitary hormones such as ACTH and TSH. Significant amounts of gonadotrophin may be detectable in the blood some 24 hours after administration of an extract. The measurement of the normal levels of gonadotrophic hormone in the blood is of questionable accuracy throughout the major part of the menstrual cycle. At the midpoint of the cycle, however, at about the time of ovulation, a rise of blood gonadotrophic activity undoubtedly occurs. There is evidence from *in vitro* studies that ovarian tissue inactivates gonadotrophin. Small amounts of these hormones are also excreted in the urine.

The regulation of anterior pituitary secretion of gonadotrophins has been studied in detail. Research in this field preceded investigation of the control of other anterior pituitary hormones since changes in gonadotrophin secretion could be easily inferred from study of the sexual cycles, and since in particular forms specific changes in the environment were found to be associated with alterations in the sexual rhythm. Thus growth of follicles and induction of estrus during periods of sexual quiescence, indicative of increased secretion of FSH, may be induced in birds (Rowan, 1926), ferrets (Bissonnette, 1932), and other forms by exposure to extra hours of daily illumination. Similarly ovulation and the formation of corpora lutea indicative of LH release, does not occur spontaneously in many birds, rabbits, cats, ferrets, and some other mammals, but requires the triggering stimulus of mating for its initiation. It is likely that these are examples of a general pattern of nervous control of the secretion of gonadotrophic hormones. A similar conclusion regarding a nervous influence may be drawn from clinical observations. The fear of pregnancy in unmarried girls, the change of occupation from day to night work, and emotional upsets of many types, such as those induced by aerial bombardment in World War II or by incarceration in a concentration camp, have all been found to be associated with loss of menstrual cycles.

The first clear-cut experimental data that gonadotrophin secretion from the anterior pituitary is dependent upon the nervous system came from experiments in which the pituitary stalk had been cut and a plate placed between the hypothalamus and pituitary, and others in which the hypophysis had been transplanted to a distant site in the body. It is now generally agreed that these procedures result in ovarian atrophy and cessation of hormonal secretion by the ovary. The reproductive tract thus undergoes atrophy. On the

other hand, it has been found by Harris and Jacobsohn that if the pituitary gland is removed from the sella turcica and anterior pituitary tissue placed not in a distant site but directly under the hypothalamus, the hypophyseal portal vessels between the tuber cinereum and pars distalis regrow and normal reproductive functions are regained. Everett and Nikitovitch Winer have even found that if the pituitary gland of a female rat is transplanted under the kidney capsule a period of sexual quiescence and atrophy occurs, but if this same transplanted pituitary tissue is then replaced under the hypothalamus, apparently normal reproductive functions return. In these latter animals the portal vessels were again found to have reconnected the tuber cinereum and anterior pituitary tissue. For these and other reasons given below, it may be said that the hypothalamus maintains and regulates the secretion of gonadotrophins.

In order to analyze the hypothalamic mechanisms involved in more detail, experiments have been conducted in which localized lesions and stimulation have been made in the hypothalamus. Lesions of the hypothalamus have been found to result in (a) cessation of sexual cycles and atrophy of the reproductive organs (median eminence lesions), (b) abolition of sexual cycles with the intervention of prolonged periods of follicular development in the ovary and a state of constant estrus (lesions in the anterior, paraventricular region of the hypothalamus), (c) the induction of a state of sexual activity and development at a time of year when seasonally breeding animals (ferrets) would normally show atrophic organs and sexual quiescence (anterior hypothalamic lesions), and (d) the precocious development of puberty in immature animals (anterior hypothalamic lesions). This last observation is of clinical interest in that young boys and girls afflicted with hypothalamic tumors, especially those of congenital origin known as hamartomata, may show full development of physical and psychic sexual function when only a few years of age. It seems likely that FSH secretion is regulated by a predominantly inhibiting influence of the hypothalamus over the anterior pituitary, and that if this influence is removed by a hypothalamic lesion then signs of a release effect on FSH secretion are observed. It is noteworthy that no records are available of an increase in FSH release following electrical stimulation of the hypothalamus.

Stimulation of the hypothalamus has, however, been shown to evoke release of LH and ovulation

in the rabbit. As mentioned above, this species does not ovulate spontaneously but normally requires the sensory stimuli, associated with the act of mating, to excite various nervous reflex paths and, thus, in turn LH secretion and follicular rupture. Adapting Sherrington's term for spinal reflexes to neuroendocrine reflexes, it may be said that the hypothalamus and pituitary stalk form the "final common path" for the latter. Thus, it seems likely that the electrical stimuli which result in ovulation when applied to the posterior tuber cinereum and median eminence are activating the terminal parts of the reflex paths which normally underlie the ovulation response. The mechanism involved in the cyclical release of LH in spontaneously ovulating forms also seems to involve the hypothalamus, since hypothalamic lesions have been found to block ovulation and to result in a state of continuous estrus in rats, and since such drugs as barbiturates, well known for their action on the central nervous system, may also block ovulation in these animals. Recent data also implicate other areas of the brain, such as the reticular activating system and amygdaloid nuclei as participating in the control of LH release. It is likely that these areas act through their projections to the hypothalamus.

The timing of puberty, and the endocrine changes associated with it, also seem to be under central nervous control. In the early days of this century it was believed that an "ageing process" in ovarian tissue might determine the time of puberty. However, this is clearly not the case since ovaries from immature animals transplanted into ovariectomized adults, behave as adult organs. Also, pituitary tissue from newborn rats, transplanted under the hypothalamus of hypophysectomized adults, has also been found capable of maintaining normal adult function. Therefore, it may be said that puberty is not dependent on a maturation process in ovarian or anterior pituitary tissue. When these data are combined with those indicating that hypothalamic lesions, both in the human and the experimental animal, may be associated with *pubertas praecox* it is clear that the central nervous system is in some way related to pubertal development. One hypothesis that at the moment harmonizes with the experimental data, is that the gonads from birth to puberty secrete gonadal hormones at a low rate, but at a rate sufficient to exert a restraining influence on anterior pituitary activity. This influence may be exerted through the hypothalamus.

mus, and in this case would be abolished by a lesion in this structure

A problem in some ways allied with that of puberty concerns the sexual differentiation of the mechanisms regulating gonadotrophic secretion. The secretion of gonadotrophic hormones occurs in a cyclical fashion in the adult female, but in a more constant manner in the adult male. This may be illustrated by the fact that ovaries transplanted into castrated males show constant follicular development but absence of ovulation and corpus luteum formation. Pfeiffer in 1936, made an extensive study of the effects of gonadal transplants in immature rats on their subsequent sexual function. He concluded that the immature gonads secrete hormone at a sufficient rate between birth and puberty to impose a sexual differentiation upon the maturing pituitary gland, and that the pattern of gonadotrophic release in adult life is dependent upon this sexual maturation of the pituitary. His data indicated that basically the mechanism concerned is cyclic in function and that this is converted in the developing male animal to one that is acyclic. It is now clear, however, that the anterior pituitary gland remains functionally plastic. This can be seen most easily from the fact that pituitary tissue obtained from a male rat can, if transplanted under the hypothalamus of an hypophysectomized female rat, maintain female sexual cycles and pregnancy. Thus pituitary tissue itself retains a male and female bipotentiality. It is likely that the sexual differentiation, observed by Pfeiffer, concerns not the tissue of the adenohypophysis but some neural mechanism in the hypothalamus responsible for regulating gonadotrophin release in the adult animal.

The feed back of gonadal hormones then seems to be concerned in the changes attendant upon puberty and the sexual differentiation of the mechanism concerned with gonadotrophin secretion. It is an important factor controlling gonadotrophin release in the normal adult. Administration of estrogens to the normal female results in atrophy of the ovaries through inhibition of gonadotrophin secretion. Removal of an ovary results in hypertrophy of the remaining gland. Therefore, it is very probable that a similar feed back effect of target gland hormone occurs in the case of the ovary as for the thyroid and adrenal cortex. Moore and Price (1932) first expressed the view that the cyclical nature of sexual cycles was due to a self regulating reciprocity between the pituitary and the gonads, based on the feed back action. Later evidence tends to the view that the

gonadal hormones exert their effects on anterior pituitary secretion via the intermediation of the hypothalamus. In this case the gonadal hormones would exert an effect on some receptor mechanism in the central nervous system which would adjust pituitary activity accordingly. Such a view would be more in keeping with the finding that an anterior hypothalamic lesion may convert a female rat or guinea pig, showing normal cycles, to one in a state of constant estrus, and it would also explain the findings of Flerkó that small fragments of ovary transplanted into the hypothalamus near the paraventricular nuclei, but not in other regions, result in a diminution of uterine weights.

Prolactin, Lactogenic Hormone, or Luteotrophic Hormone (LTH)

In 1928, Stricker and Grueter reported that injection of pituitary extract into a pseudopregnant rabbit before or after ovariectomy resulted in lactation. Within the next few years several groups of workers reported the isolation of a pituitary extract with lactogenic activity. Hypophysectomy prevents the onset of lactation, or results in abrupt cessation of an existing lactation. However, injection of a suitable anterior pituitary extract into hypophysectomized animals produces lactation. In 1931, Riddle and Braucher found that pituitary extracts caused development of the crop glands in pigeons. These glands consist of circumscribed areas of mucosa in the dorsal part of the crop, and are responsible for secreting "crop milk" which is regurgitated by either parent and utilized to feed the young. Riddle and his colleagues later showed that the crop gland effect in pigeons is probably due to the same hormones which cause lactation in mammals and suggested the term *prolactin*.

The cellular site of origin of prolactin is thought to be some type of acidophile cell in the anterior pituitary. The evidence for this is indirect, and is based on observations that the peripheral zone of the anterior lobe of the ovipituitary contains more prolactin and more acidophils than the central region, and that during the incubation period in pigeons, or lactation in mammals, the main cytological changes in the pituitary concern the α cells of the pars distalis.

Prolactin is a protein with a molecular weight of 25,000 to 30,000. A pure and potent preparation was first obtained by Lyons, and a crystalline preparation by White. Subsequent studies have shown that the extracts behave as pure proteins to physicochemical tests and that they are free

from other pituitary hormones. The purified protein retains lactogenic, crop sac stimulating and luteotrophic activity. To be effective it must be administered by injection.

The physiological activities of prolactin are exerted upon the mammary gland, the pigeon crop sac and, in certain species, the corpus luteum. The effects produced by prolactin on the mammary gland form a difficult subject of study. Species differences and the simultaneous actions of other hormones on the gland must be carefully considered. This subject is dealt with in chapter 60, and it will, therefore, suffice to say here that the initiation of lactation (lactogenesis) and its maintenance are probably due to a complex of pituitary hormones centering around prolactin as an essential element. Lyons and coworkers recently stated "in the Long Evans rat, at least 5 of the 6 well identified anterior pituitary hormones play important parts in mammogenesis and lactogenesis." The effect of prolactin on the crop sac of the male or female pigeon, on the other hand, is a specific and direct action of the lactogenic hormone. It thus forms a more suitable reaction in many ways for assay purposes. The stimulating effect prolactin exerts on the secretory activity of the corpus luteum of the rat was observed in 1941, and led to the synonym luteotrophic hormone (LTH) for prolactin. It would seem established now, that FSH and LH are responsible for ovulation and the formation of the corpus luteum during the normal estrous cycle in the rat. This corpus luteum, however, does not necessarily become functionally active and secrete progesterone. If sterile or fertile coitus occurs during estrus, this in some way triggers the release of LTH from the pituitary and so results in a functionally active luteal phase and an associated period of pseudopregnancy or pregnancy. However, since the original observations, little evidence has accumulated that prolactin exerts a luteotrophic action in other species, such as the rabbit, monkey, or man. Recent work, however, indicates that prolactin has a definite effect in prolonging the active life of the corpus luteum in the sheep.

The assay of prolactin may be performed using the crop gland or mammary response. The increase in weight of the pigeon crop after intramuscular injection of the hormone or histological changes in the crop mucosa after intradermal injection of the hormone immediately over the crop gland are both used. It has been suggested that the increased uptake of radioactive phosphorus by the crop sac under the influence of prolactin may form

the basis of a sensitive and objective assay method. In mammals the formation of milk in the mammary tissue of the estrogen progesterone treated or pseudopregnant rabbit, following either systemic administration or injection into a lactiferous duct may be employed. An international standard of prolactin is available. One IU is the activity contained in 0.1 mg. of the standard preparation.

Little is known regarding the inactivation and excretion of prolactin in the body. Some *in vitro* studies have indicated that prolactin is inactivated by the tissues of the mammary gland, ovary, and pigeon crop gland, that is by tissues of its three target organs.

Factors regulating the secretion of prolactin have been studied by observing the effect of different procedures on the activity of the mammary gland, or the corpora lutea of the rat. These indirect methods of assessing prolactin are necessary since the techniques for measuring prolactin in body fluids are not sensitive or accurate enough to allow direct measurement. In chapter 60 it is pointed out that there is suggestive evidence that the sensory stimuli associated with the act of suckling stimulate by various reflexes the pituitary secretion of prolactin, and, therefore, play an important part in maintaining milk secretion in the breast. Similar evidence relating to prolactin secretion is that the suckling may induce the development of functional luteal tissue in the rat. As mentioned above, corpora lutea are formed, but do not function, during the normal estrous cycle in this animal. If mating occurs, however, prolactin release is stimulated by reflex action, the corpora lutea become functional and the next estrus is delayed for the period of pregnancy or pseudopregnancy. During the period of pseudopregnancy, trauma to the endometrium results in the formation of a tumorlike mass in the uterus known as a deciduoma. Deciduoma formation only occurs in an endometrium under the influence of progesterone. Activation of corpora lutea with the development of a pseudopregnancy may be stimulated in the rat not only by sterile coitus but by experimental procedures such as glass rod stimulation of the vagina, electrical stimulation of the uterine cervix, or massive electrical stimuli passed through the head. The stimulus of suckling produces a similar response. Selye and coworkers showed that the regular estrous cycles of rats and mice could be interrupted by supplying them with relays of litters obtained from other animals. Prolonged suckling in these animals resulted in pseudopregnancy and

lactational development of the mammary gland. It seems clear that in this condition known as suckling pseudopregnancy, the stimulus of suckling has evoked prolactin release. Coitus and suckling then are physiological stimuli which act by nervous reflex paths and the hypophyseal portal vessels, to excite prolactin secretion. The effect of disconnecting the anterior pituitary from the hypothalamus on prolactin release, is difficult to understand. Everett has shown that autotransplantation of the pituitary to the kidney region of rats may even result in signs of augmented LTH release. One possible explanation is that the hypothalamus normally regulates LTH secretion by a tonic inhibitory process. The effect of a feed back action of estrogens on prolactin secretion is discussed in chapter 60, when a possible relationship between estrogen concentration in the blood and lactogenesis is considered.

THE CONTROL OF THE SECRETION OF THE ADENOHYPHYSIS

In discussing the individual hormones above, it has been emphasized that the secretory activity of the anterior pituitary is regulated by the following:

- 1 A feed back of target gland hormones. It is uncertain whether this effect is due to a direct action on anterior pituitary cells or to an action on the nervous system which in turn modifies pituitary function. This mechanism serves as a homeostatic mechanism to maintain a constant level of hormones in the blood.

- 2 The central nervous system, acting through the hypothalamus and hypophyseal portal vessels of the pituitary stalk. The hypothalamus acts to maintain anterior pituitary function at a normal level and to vary this level according to external stimuli and the needs of the organism. The liberation of gonadotrophic hormone by sexual excitement in the rabbit (p. 968) or by extra illumination in birds and many mammals, the release of adrenocorticotrophic hormone under states of emotional stress (p. 974), and the secretion of thyrotrophic hormone upon exposure to cold are outstanding examples of the relationship between the anterior pituitary and the nervous system. It is most probable that peripheral sensory stimuli activate nervous reflex paths which eventually converge into the hypothalamus. However, very few, if any, nerve fibers pass from the hypothalamus to the anterior pituitary. What then is the functional link between the hypothalamus and adenohypophysis? The vascular supply to the pars distalis (p. 957) offers the

basis for an explanation. The hypophyseal portal vessels connect the tuber cinereum of the hypothalamus with the anterior pituitary gland and the evidence is now convincing that these vessels mediate, in some way, the influence the nervous system exerts over the activity of the pars distalis.

The Functional Significance of the Hypophyseal Portal Vessels

- 1 All vertebrates possess a system of vessels passing from the median eminence to the anterior lobe of the pituitary. From amphibians to man, these vessels are truly portal in that they start as capillaries in, or in contact with, the median eminence form vascular trunks which run down the pituitary stalk, and break up into the sinusoids of the anterior pituitary.

- 2 The direction of blood flow in these vessels is from the median eminence to the anterior pituitary.

- 3 The effects of pituitary stalk section are conditioned by the subsequent state of the portal vessels. If these vessels regenerate across the site of the cut, normal anterior pituitary function may be regained. If regeneration of the vessels is prevented by the placement of a plate between the stalk ends, then anterior pituitary function remains greatly reduced.

- 4 The effects of pituitary transplantation vary with the anatomical site of the transplant. If the pituitary gland is removed from the sella turcica and placed in the subarachnoid space below the hypothalamus the tissue may become revascularized by an outgrowth of portal vessels from the tuber cinereum and normal anterior pituitary function regained. If the transplant is placed in a distant site in the body (muscle, anterior chamber of the eye, kidney) then only fragments of normal anterior pituitary function are observed. However, if the tissue is transplanted a second time in the same animal, and placed in contact with the tuber cinereum, then normal anterior pituitary function may be regained.

- 5 Electrical stimulation of various sites in the hypothalamus has been found effective in causing discharge of luteinizing hormone, adrenocorticotrophic hormone, and thyrotrophic hormone from the anterior pituitary. On the other hand if the electrode is placed directly in the adenohypophysis, similar electrical stimuli are ineffective in evoking hormonal release. This finding is compatible with the view that the activity of the gland is normally controlled by a humoral mechanism and not by a direct secretomotor nerve supply.

There can be no reasonable doubt that the functional activity of the adenohypophysis is dependent on its hypophyseal portal blood supply. In some way these vessels transmit the influence the nervous system exerts over the activity of the gland. The mechanism involved is not yet clear. The most probable view is that various hypothalamic nerve tracts liberate some humoral substance(s) into the capillaries of the portal vessels in the median eminence and that the humoral substance(s) is carried by these vessels to the pars distalis where it excites or inhibits the glandular cells. This idea of a neurohumoral mechanism regulating anterior pituitary activity finds indirect support from the present concepts regarding posterior pituitary function. It is now generally held that the posterior pituitary hormones are formed in the cells of the supraoptic and paraventricular hypothalamic nuclei (neurosecretion) are transported down the nerve fibers of the supraopticohypophyseal tract in the pituitary stalk and liberated from the nerve terminals into the blood vessels of the neural lobe of the pituitary (see p 900). Such a mechanism is very closely analogous with that suggested for anterior pituitary control. Both suppose the formation of hormonal substances by hypothalamic neurones and both suppose the liberation of these substances into blood vessels of the neurohypophysis either into the primary plexus of the portal vessels in the median eminence or into the capillaries of the infundibular process. It is of interest that the blood vessels of both these parts of the neurohypophysis have similar permeability properties (as judged by the diffusion of vital dyes and radioactive substance) which are different from those of the hypothalamic blood vessels. It should be mentioned here that the neurosecretory concept is of course not new. The existence of secretory neurones in the nervous system of invertebrates (insects mollusks worms etc.) has been well established.

The isolation purification and identification of a hormonal transmitter agent associated with the portal vessels has not been achieved. Markee and his colleagues suggested that an adrenergic agent was involved in the regulation of gonadotrophic secretion on the grounds that injection of adrenaline into the anterior pituitary resulted in ovulation in rabbits and that the normal postcoital ovulation could be blocked in this animal by adrenolytic drugs. In view of the clinical importance of the adrenocorticotrophic hormone much interest has centered on the nature of a humoral transmitter underlying the release of this hor-

mone. Saffran and his colleagues in Montreal and Guillemin and coworkers have incubated anterior pituitary tissue *in vitro* and obtained evidence that some substance extractable from the neurohypophysis is active in releasing ACTH from such tissue. The work of these and other investigators suggests there is a relationship between neurosecretory material the antidiuretic hormone of the neurohypophysis and the mechanism regulating the release of ACTH from the pars distalis. The antidiuretic hormone has also been implicated by Martini as a humoral agent regulating the release of thyrotrophic and growth hormones. It is impossible at the present time though to draw any definite conclusions regarding the nature of a transmitter agent. The present data could be explained on the view that a polypeptide(s) is liberated from nerve terminals in the median eminence into the portal vessels. Just as vasopressin and oxytocin have a similar molecular configuration and overlapping activities so might the postulated polypeptide have part of its molecular configuration in common with the posterior pituitary hormones and thus have a qualitatively similar effect on anterior pituitary cells.

ANTIHORMONES AND PROHORMONES Collip and his colleagues demonstrated that certain hormones when injected cause the formation of a substance in the serum of the treated animal which exerts a specific antagonism to and may completely abolish the effect of the injected hormone. They thought that the inhibitory principle was not an antibody in the ordinary sense i.e. an immune body developed in some constituent of the hormone acting as antigen but was rather in the nature of an *antihormone*. A substance of this character was first obtained by Collip and Anderson in 1934 in the course of experiments with the thyrotrophic principle of the anterior pituitary. Rats after repeated injections of the thyrotrophic hormone became refractory and subsequently failed to respond to large doses. They were still responsive however to the thyroid hormone. It was found that the serum of these refractory animals was capable of preventing the effect of the thyrotrophic hormone upon nonrefractory animals. To give another example of this antagonism hypophysectomized rats treated with purified growth hormone failed to respond to it after a period of 5 or 6 weeks. The serum of such animals neutralized the effect of the growth hormone upon other untreated hypophysectomized rats. Besides antithyrotrophic and antigrowth principles inhibitory substances have been shown to exist for the ketogenic lactogenic and gonadotrophic principles of the anterior pituitary respectively as well as for

the anterior pituitary-like principle (HCG, ch 60), but not for the adrenotrophic, or for insulin, or the sex hormones

Collip suggested that the inhibitory principles or antihormones were present in the blood of normal animals, each serving to "oppose" or "buffer" the action of the corresponding hormone and that a given endocrine effect occurring naturally in the body was dependent upon the ratio existing between the hormone and antihormone concentrations

Collip's observations have been confirmed repeatedly by other experimenters. But there has been a difference of opinion as to the nature of the inhibitory substances. The problem is one of extraordinary complexity for experimental investigation. From several later observations, however, e.g., that rats do not develop antihormones to implantation of anterior lobe tissue of their own species and antigonadotrophic substances are not formed in the blood of women injected with human chorionic gonadotrophin, it is most probable that the effect of these so called antihormones represents a form of antigen antibody reaction due to contaminating foreign (antigenic) protein

Augmentation of the action of the hormone after repeated injections has also been observed. The augmenting substance which develops in the serum of an injected animal is called a prohormone. The augmenting action may precede the antagonizing or antihormone effect

The Physiology of the Neurohypophysis

An active extract of the pituitary was first obtained in 1894, by Oliver and Schafer who described its effect in raising the blood pressure. Howell, 3 years later, showed that the posterior lobe alone contained the pressor principle. The extract has been used in medicine for many years under such commercial names as *Pituitrin*, *Infundin*, *Infundibulin*, etc., or as the official solutions of the British and United States pharmacopoeias (B.P. and U.S.P.) 'Much of our knowledge regarding the pharmacological actions of posterior pituitary principles has been derived from work using crude whole extract of the posterior pituitary. The single extract may be fractionated into two extracts which contain in a nearly pure form the vasopressor or antidiuretic hormone and the oxytocic hormone (marketed as *Pitressin* and *Pilocin*,

respectively, see p 984) *Pitressin* and *Pilocin* have largely replaced *Pituitrin* in clinical use, and even more highly purified or synthetic compounds are being used for research purposes. However, an account of the actions of the whole posterior lobe extract will first be given

THE ACTIONS OF WHOLE POSTERIOR PITUITARY EXTRACT

These fall into 8 main groups

1 **CIRCULATORY** The blood pressure is raised, the systemic arterioles and capillaries both undergoing constriction. Marked pallor of the skin results. An initial depressor effect, or a pressor succeeded by a depressor effect, may precede the main rise in blood pressure. Repeated injections invoke smaller and smaller pressor responses (tachyphylaxis) and may even result only in a depression of the blood pressure (inversion effect). This depressor effect is cardiac in origin as indicated below. Posterior lobe extract causes constriction of the coronary and pulmonary vessels but dilates the cerebral and renal vessels. The dilator effect upon the two last mentioned sets of vessels is a passive one being caused by the rise in systemic blood pressure. The heart is slowed by posterior lobe extracts if the vagus nerves are intact, the effect being a reflex result of the blood pressure rise, but increased cardiac rate occurs if the nerves have first been cut. Some dilatation of the heart and weakening of its beat occur in the dog, rabbit and, with large doses, in the cat. The coronary constriction and the weakening effect upon the cardiac muscle cause a reduced cardiac output and a fall in pressure in the pulmonary artery (dog and rabbit). These experimental results indicate that commercial extracts are of no value *clinically* as a means of strengthening the action of a failing heart but may actually exert a deleterious effect. The fall in blood pressure which follows repeated injections of posterior pituitary extract (inversion effect) is due according to Melville and Stehl, to the weakening of the heart and is not of vascular origin. The portal venous pressure is reduced by posterior pituitary extract as a result of constriction of the splanchnic vessels.

2 **RESPIRATORY EFFECTS**, e.g., increased rate of breathing, alternating at times with periods of apnea, are produced by the extract, but they are secondary to the effects on the circulation

3 **PLAIN MUSCLE**, in general, is stimulated by whole posterior lobe extract. This action differs from the smooth muscle stimulating action of adrenaline in that it does not parallel the action of the sympathetic nerves, smooth muscle, re

* The official solution of U.S.P. (XIII) *Posterior Pituitary Injection* is an aqueous solution of the principles of the posterior lobe of the pituitary of 'healthy domesticated animals used as food by man'. It has a specific activity (oxytocic, antidiuretic, or pressor) of 10 posterior pituitary units per cubic centimeter. A *Posterior Pituitary Unit* (B.P., U.S.P., or International) is the potency of 0.5 mg. of the Posterior Pituitary Reference Standard

ceiving motor innervation from the parasympathetic, is excited as well. The muscular walls of the intestine, gall bladder, ureter and urinary bladder (detrusor and trigone) are excited. Peristalsis in the human small intestine and to a less extent in the colon is stimulated, but the tone is unaffected. Sometimes the smooth muscle of the bronchioles is stimulated, but this is due to contamination of the extract with histamine and is not specific.

4 UTERINE The stimulating effect of posterior pituitary extract upon the isolated virgin guinea pig's uterus was demonstrated by Dale in 1909, and termed the *oxytocic effect*. It is used as a means of assaying the potency of pituitary extracts. Some highly purified preparations exert an oxytocic effect in a dilution of 1 part in 2,000,000,000. The effect of these extracts upon the uterine muscle is antagonized by the hormone of the corpus luteum (see p. 1088). The oxytocic effect varies with the species, and, as a consequence of the interplay of other hormones, especially of the luteal hormone, with the phases of the sexual cycle (e.g., period of estrus, pregnant or nonpregnant state of the uterus). An interrelation between the actions of adrenaline and posterior pituitary extract is indicated by the fact that if the nonpregnant uterus of the cat is first treated with pituitary extract, adrenaline causes contraction instead of the usual relaxation (p. 1026). The human uterus is most sensitive at the end of pregnancy, and the extract is used as an obstetric aid to produce uterine contraction after the expulsion of the placenta and so to prevent or check postpartum hemorrhage.

5 MAMMARY Lactation consists of two main processes. First, milk formation or secretion which is intimately related to the anterior pituitary gland (p. 977), and second a process known as milk ejection, which is controlled by the posterior pituitary gland. Ott and Scott in 1910, first showed that injection of posterior pituitary extract increased the amount of milk obtainable from the cannulated udder of the goat. This action of the extract, causing an active expression of the milk present in the lactating breast or udder, has been confirmed in many species including man. Much discussion centered at one time around the question of the contractile element concerned. In many forms plain muscle exists only around the larger ducts in the mammary gland, and it was difficult to understand how milk contained in the alveoli could be expressed. The histological studies of Richardson have now established that a specialized contractile tissue,

FIG 56 15 Section of part of a lobule of the mammary gland of a goat, fixed in the distended state, showing the myoepithelial cells stained with silver. (From Richardson.)

composed of myoepithelial cells (see fig. 56 15), is extensively distributed around the alveoli and ducts of the mammary gland and there can now be little doubt that this is the effector element stimulated by posterior pituitary extract. In order to demonstrate the action of posterior pituitary extracts on the mammary gland it is necessary to cannulate the nipple or teat (to overcome the sphincter action of this structure). Very small doses of extracts (of the order of 0.001 unit) are then effective in exciting milk ejection.

6 KIDNEY (Antidiuretic hormone, ADH) The action of posterior pituitary extracts upon renal function was discovered by Magnus and Schafer in 1901, but they described only a *diuretic effect*. The diuresis, however, is of brief duration and may be preceded by anuria due to ureteral spasm; this early diuretic action is due to the rise in general blood pressure and the passive dilatation thereby, of the afferent glomerular vessels. The important and specific renal effect is, however, an increase in the reabsorption of water and as a consequence, a reduction in urinary flow. In anesthetized animals the specific antidiuretic action is absent, diuresis due to the vascular factors

is the outstanding effect. Posterior lobe extract postpones for several hours the diuresis induced in normal animals by water drinking, and reduces the polyuria of diabetes insipidus. Associated with the antidiuretic effect is an increase in the percentage of sodium and chloride in the urine and, as a result of a reduction in the tubular reabsorption of these electrolytes, an increase in their total excretion (see also ch. 34).

The antidiuretic principle is an essential factor in the maintenance of the water balance of the body, being secreted when the need for water conservation arises. For example, the quantity of the hormone in the urine, which reflects presumably its concentration in the blood stream, is increased in dehydrated states but decreased in hydremia (Gilman and Goodman). In man, it is through a more active tubular reabsorption rather than by a reduction in the filtration rate through the glomerulus that the kidney plays its part in conserving water.

It is only in mammals and birds that posterior pituitary extract exerts any effect upon tubular reabsorption. And, as compared with mammals the antidiuretic action of the extract in birds is feeble. Only these two classes secrete a hypertonic urine, and their nephrons alone possess a thin segment of Henle's loop. It is thought, therefore, that this part of the renal tubules is the site of action of the antidiuretic hormone (see also ch. 34). However, the hormone is not without effect upon the water exchange of amphibia and reptiles. Frogs, for example, immersed in water increase their body weight if injected with posterior pituitary extract (*Brunn effect*) as a result of the uptake of water through the skin; they also lose water readily in a dry environment if treated with the extract. This effect⁴ is due to a principle in pituitary extracts other than ADH, it is closely associated with the oxytocic principle but does not seem to be identical with the latter. It is called the *water balance principle* and can be prepared from the pituitaries of mammals as well as from those of amphibians.

7 METABOLIC EFFECTS Reduced tolerance for sugar, diminution in hepatic glycogen, hyperglycemia, glycosuria, and a fall in the basal metabolic rate follow the injection of posterior lobe extract. The effect of insulin is antagonized. That is to say, the pancreatic hormone produces less

effect upon the blood sugar and a greater amount is required to produce hypoglycemic convulsions if its administration has been preceded by an injection of posterior pituitary extract. This extract also causes an increase in liver fat. The effects on carbohydrate and fat metabolism are probably nonspecific, and, therefore, do not represent physiological actions.

8 MELANOPHORE EXPANDING (DISPERSING) PROPERTY The skins of many cold blooded animals contain peculiar cells with branching processes and mobile pigment granules whose movement toward the periphery of the cell or toward the center is under hormonal influence. Such cells have been given the general name of *chromophores*. Those containing black pigment (melanin) are known as *melanophores*, and those with red or yellow pigment are called *erythrophores* or *xanthophores*, respectively.

Hogben and Winton showed that posterior pituitary extracts caused the pigment granules in the melanophores of the frog to become dispersed throughout the bodies and branching processes of these cells. This results in darkening of the skin. Thus, the injection of a small dose of posterior pituitary extract into a frog causes its skin to become almost coal black as a result of the melanophore reaction. On the other hand, after hypophysectomy, owing to the disappearance of the pituitary hormone from the circulation, the pigment granules gather near the center of the cells and the skin becomes pale. Hypophysectomized tadpoles have instead of the usual dark brown or green color, a silvery appearance. The changes in color which certain amphibia, reptiles and fish undergo in order to blend into the color of their surroundings is largely due to variations in the concentrations of the pituitary hormone in the blood or to the balance between the concentrations of the melanophore-expanding principle and adrenaline. Blinding a frog deprives it of its adaptive power.⁵ Nervous impulses arising in the

⁴ The phenomenon of light influencing structure and function through the mediation of a retino-hypophyseal mechanism is not peculiar to cold blooded animals. The work of a number of experimenters indicates that the well known association of the seasonal periods with morphological changes (e.g., color and texture of hair or plumage) and with the sexual cycles of certain mammals and birds as well as with the migration of birds, is due in part at least to light acting upon the anterior pituitary through the medium of retinal impulses. Rowan, for example, was able to induce sexual activity in crows and canaries at any desired time of the year by varying the periods of their exposure to artificial light; it is also well known that the

⁵ It is not seen in fish or reptiles, but in the latter the extract exerts a renal effect, but one different from that induced in mammals, namely, a reduction of the filtration rate.

retina are believed, therefore, to govern the liberation of the melanophore expanding principle. The production of melanin in the skin of the frog is said to be stimulated by this principle.

In most animals, the melanophore-expanding principle is elaborated by the *pars intermedia*.¹ Cultures of tissue from the *pars intermedia* alone yield this principle, whereas, cultures of the neural part of the pituitary and unpurified extracts of the latter always contain it as a contamination. But it is possible to prepare it free from antidiuretic, pressor, and oxytocic effects. Moreover, the melanophore dispersing action of extracts from different parts of the posterior lobe does not run parallel with the pressor, oxytocic and antidiuretic properties. These factors argue for the melanophore effect being due to a separate and distinct hormone. Zondek has given the name *intermedin* or the *chromatophorotropic hormone* to this principle. It has been suggested that the melanophore expanding principle also causes the migration of the melanin granules in the pigment layer of the retina (ch 73) and is, therefore, a factor in dark adaptation of the eyes of higher vertebrates but the experimental evidence in respect to such a function is conflicting. Nor is there any definite evidence that any relationship exists between this hormone and the occurrence of retinitis pigmentosa. It is natural that it should also be suspected of playing a role in cutaneous pigmentation in the human subject but few observations have been reported which

might connect this principle with either normal or abnormal pigmentation in man. It has, indeed, been suggested that intermedin and adrenocorticotrophic hormone are one and the same substance. This hypothesis would explain the occurrence of pigmentation in Addison's disease, when the atrophic adrenal cortex allows increased release of ACTH. However, melanophore-expanding activity and adrenocorticotrophic activity have been largely separated into different fractions of pituitary extracts. The interesting suggestion has been made that the amino acid sequence of the polypeptide molecules of these hormones partially overlap, thus affording a possible explanation of the melanophore-dispersing activity of ACTH.

Fractionation of the Posterior Lobe Extract Oxytocin and Vasopressin

Considerable quantities of histamine may be present in commercial pituitary extracts which have not been carefully purified. Indeed it was believed for a time by some (Abel and associates) that the plain muscle stimulating and depressor effects were due simply to histamine. Abel also maintained that the other effects (pressor and antidiuretic) were due to a single hormone. The work of Dudley, and especially of Kamm and his associates has shown that the specific effects are not due to histamine and that there are at least two distinct active principles in a posterior lobe extract. From the crude extract Kamm and his associates have isolated two relatively pure fractions, one containing mainly vasopressin (the vasopressor or antidiuretic hormone) and the other mainly oxytocin (oxytocic hormone). They are marketed commercially as *Pitocin* and *Pitressin*. These are white amorphous powders freely soluble in water. However, van Dyke and colleagues obtained a noncrystalline material of protein nature from posterior lobe extracts which, from electrophoretic ultracentrifuge and solubility studies, seems to be a pure substance free from contaminating material. It possesses oxytocic and pressor activities in the same ratios as in the crude extracts. A significant advance was made by du Vigneaud and his team. Taking advantage of such modern techniques as countercurrent distribution between immiscible solvents, chromatographic separation on paper, or starch columns, they obtained highly purified preparations of vasopressin and oxytocin from beef material and were able to establish the structural formulas of these compounds. These are as follows

domestic fowl will lay regularly in winter if its period of exposure to light is lengthened by artificial means. Cognate experiments have been carried out upon mammals, ferrets, hedgehogs and raccoons. The seasonal onset of estrus in the ferret has been shown to be conditioned by the length of the day, and optic nerve section or hypophysectomy abolishes the phenomenon. The sexual cycles are abolished of course by hypophysectomy (lack of gonadotrophic hormone) but their periodicity in relation to the length of exposure to light is lost after optic nerve section alone. The extreme sensitivity to light of the pigeon with respect to the time of egg laying is extraordinary. The pigeon lays a pair of eggs in the morning, the second of the pair being laid with the regularity of clock work, half an hour after the first. Lengthening or shortening the period of exposure to light alters the duration of the interval between the laying of the first and second eggs of the pair.

¹ In those species such as the chicken, porpoise and whale which do not possess a *pars intermedia* the melanophore dispersing principle is found in extracts of the anterior lobe, none is present in the posterior lobe.

Structure of oxytocin and vasopressin (oz)

Each hormone contains eight amino acids, six of which (aspartic acid, cystine, glutamic acid, glycine, proline, and tyrosine) are common to the two. The isoleucine and leucine in oxytocin are replaced by phenyl alanine and arginine. It is of interest that in hog vasopressin lysine replaces the arginine of beef vasopressin. The molecular weight of oxytocin is 1007 and of beef vasopressin is 1084. Both these compounds have been synthesized by du Vigneaud and his group and the synthetic compounds have been found to be identical with the natural products in biological and chemical tests.

The preparation of highly purified and synthetic oxytocin and vasopressin has made possible the analysis of the physiological activities of whole posterior pituitary extract, described above, in terms of these two compounds. It seems clear that oxytocin is responsible for the action of pituitary extracts on uterine muscle and in the mammary gland, whereas vasopressin acts on the blood pressure and water excretion by the kidney. There are no good grounds for believing that the pressor and antidiuretic activities are due to two different substances. It is of interest that vasopressin has some slight oxytocic activity (uterine stimulating and milk-ejecting activities) and oxytocin has slight pressor and antidiuretic actions. This is so even with the highly purified preparations and appears to be due to the similarity of molecular structure of these hormones.

Although the term *oxytocic hormone* and *vasopressor hormone* are applied to these two pituitary fractions, it is not yet certain that these compounds are hormones in the sense that they are secreted individually and separately into the blood stream. The possibility cannot be ruled out that they are secreted as part of a larger protein molecule which constitutes a single hormone with multiple activities. The evidence in support of this latter view is that physiological stimuli which evoke secretion of vasopressin or antidiuretic hormone (injection of hypertonic saline) also seem to excite release of oxytocic hormone, and stimuli

evoking release of oxytocic hormone (suckling) also result in an antidiuresis. However, if both hormonal activities are secreted together, then they are liberated in ratios different from those observed in standard whole posterior pituitary extract. Electrical stimulation of the nerve supply to the neurohypophysis, injection of hypertonic saline, and suckling have all been found to result in the release of 1 part antidiuretic activity to about 50 parts of oxytocic activity, as compared with standard extracts.

THE CONTROL OF, AND THE FUNCTIONS OF, THE NEURAL LOBE

The functional activity of the neurohypophysis is entirely dependent on its nerve supply from the hypothalamus. This innervation is described above (see p. 959); it consists of a large number of unmyelinated fibers (100,000 in man) arising from the supraoptic and paraventricular hypothalamic nuclei and possibly other nuclear groups. These fibers converge to the pituitary stalk and end in all three parts of the neurohypophysis, the median eminence, the infundibular stem, and the infundibular process. This latter point is of much significance when earlier studies are considered, for section of the pituitary stalk clearly does not denervate the whole neurohypophysis. The upper end of the stalk and the median eminence of the tuber cinereum, which constitute about 13 per cent of total neurohypophyseal tissue, remain intact and innervated. The statement that neurohypophyseal function is dependent on its nerve supply is based on the facts that, first, a lesion placed in the supraopticohypophyseal tract in the hypothalamus results in loss of posterior pituitary activity, atrophy of all three parts of the gland, loss of extractable activity from the gland, and disappearance of neurons from the supraoptic and paraventricular nuclei. Second, electrical stimulation of the supraopticohypophyseal tract results in rapid discharge of posterior pituitary hormone as shown by an increase in uterine activity, milk ejection, antidiuresis, increase in intestinal peristalsis, possible

* Position of free amino group

a slight increase in blood pressure, and an increased excretion of antidiuretic material in the urine.

The physiological actions of the neurohypophysis are suggested by the responses excited by injection of small doses of posterior pituitary extract, they are confirmed as potential activities of the gland when similar responses are observed to follow electrical stimulation of the supraopticohypophyseal tract, they are established as physiological functions if they are abolished by denervation, or removal of the entire neurohypophysis, and they occur after physiological stimuli such as suckling.

1 ANTIDIURETIC ACTION. Very small doses of posterior pituitary extract, or purified vasopressin, are effective in inhibiting a water diuresis. In the rabbit about 0.1 to 1 mU/min is sufficient in this respect. Electrical stimulation of the supraopticohypophyseal tract in the conscious animal, by the remote control method, is also effective in inhibiting a water diuresis. The magnitude of the antidiuretic response varies with the strength and duration of the stimulus and can be very closely matched, in both the effect on water and chloride excretion, by injection of an appropriate dose of vasopressin.

It has long been known that a lesion in the floor of the third ventricle may be followed by the clinical condition of *diabetes insipidus*, in which large volumes of hypotonic urine are excreted each day (see p. 922). Ranson and his colleagues were able to produce a similar picture in cats and monkeys by placing bilateral electrolytic lesions in the supraopticohypophyseal tract in the hypothalamus. Their cats developed a permanent polyuria of 300 to 500 ml of urine per day (normal urine output for the cat is about 100 ml per day), which could be reduced to normal levels by replacement therapy with posterior pituitary extracts. After killing these animals they found that the greater number of nerve fibers in the neural lobe of the pituitary had disappeared, that the neurohypophysis was shrunken and hypercellular, and that extracts of these atrophic glands possessed greatly diminished pressor, antidiuretic, and oxytocic activity, though the melanophore activity was normal. This latter observation may be correlated with the normal *pars intermedia* found in these animals. Previous to this study it had been found by other workers that pituitary stalk section in the monkey did not lead to *diabetes insipidus*, though it did in the dog. On these grounds it was argued that denervation of the neural lobe was not essential to the onset of dia-

betes. However, Fisher and coworkers in a later study showed that stab wounds placed in the median eminence of the monkey resulted in a marked polyuria, and suggested that pituitary stalk section in this form left intact sufficient neurohypophyseal tissue in the still innervated median eminence to prevent the onset of diabetes. It may be pointed out that animals deprived of the *pars distalis*, as well as the neurohypophysis, develop only a slight polyuria if any at all. The *pars distalis* exerts a general diuretic effect which is necessary for the development of a marked polyuria. This may be observed in human patients with an expanding lesion in the sella turcica. Destruction of the neurohypophysis results in *diabetes insipidus* but further development of the lesion may destroy the *pars distalis* with amelioration of the diabetes.

The reflex release of antidiuretic hormone in response to physiological stimuli has been studied particularly by Verney and coworkers. Emotional excitement and the osmotic pressure of the blood are prominent factors in this category. Emotional stress produced in a variety of ways (exercise, loud noise, pain) was found to be associated with an antidiuresis of the same type as that following injection of posterior pituitary extract. Prior removal of the posterior lobe of the pituitary or section of the supraopticohypophyseal tracts reduced the response to about 0 per cent of its previous magnitude. In early work, Verney formed the view that the diuresis which follows the drinking of water was due to inhibition of the posterior pituitary gland. If this inhibition was mediated by a reduced osmotic pressure of the blood then injection or slow infusion of *hypertonic* sodium chloride especially into the arterial supply of the hypothalamo-hypophyseal region, would be expected to cause discharge of antidiuretic hormone. Such was found to be the case. For example, injection of 20 cc of 0.343 M NaCl in 25 seconds into the carotid artery produced a marked inhibitory response on the course of a water diuresis. A similar injection made intravenously had little effect, and the response to the carotid injection was markedly reduced by previous removal of the neural lobe. It is likely that the sensitive osmoreceptors lie in or near to the supraoptic nuclei in the hypothalamus. By slow infusions of hypertonic solutions into the carotid artery, Verney showed that changes of only 1 per cent in the osmotic pressure of the blood are effective in exciting release of about 1 microunit per second of antidiuretic substance. Such changes in osmotic pressure are within the range of the

falls reported in water diuresis in man. The dog has been found to liberate about 1 to 5 millunits of antidiuretic hormone per hour, and under the influence of an emotional stimulus discharges 5 to 10 millunits of hormone. For further information see the review by Verney (1947).

2 PRESSOR ACTION. Much larger doses of vasopressin are required to elicit a pressor than an antidiuretic response. Electrical stimulation of the supraopticohypophyseal tract in the conscious animal excites a slight increase in blood pressure of the same type as that following injection of vasopressin. However, the fact that hemorrhage and fainting appear to stimulate secretion of the vasopressor hormone supports the view that this hormone plays a physiological role in maintaining the blood pressure.

3 ACTION ON INTESTINAL PERISTALSIS. Again, large doses of vasopressor hormone are required to elicit an observable increase in intestinal peristalsis. However, electrical stimulation of the nerve supply to the neurohypophysis evokes a clear increase in peristalsis in the colon of the conscious rabbit. Although posterior pituitary extracts have long been used in man for the treatment of paralytic ileus, there is little evidence in the human that the posterior pituitary normally plays a physiological role in regulating intestinal motility. In this respect, Cushing's observation that patients with tumors that have destroyed the neurohypophysis are "notably victimized by chronic constipation," is of interest.

4 HYPERGLYCEMIC ACTION. Both vasopressin and oxytocin cause hyperglycemia, but which one will have the greater effect depends largely on the species. In rabbits vasopressin has the greater hyperglycemic action, whereas in dogs oxytocin is more effective. The dose necessary to induce this effect is very large. No equivalent hyperglycemic action has been obtained by electrical stimulation of the neurohypophysis. It is unlikely that the posterior pituitary plays a physiological role in regulating the blood sugar.

5 OXYTOIC ACTION ON THE UTERUS. The discovery of the oxytocic (swift birth) action of posterior pituitary extracts led, as it was bound to do, to the theory that the elaboration and discharge of a principle by the pituitary constituted an important factor in the birth mechanism. Such a view received tacit acceptance until it was found that many forms, including mice, rats, rabbits, guinea pigs, and others, delivered their young after hypophysectomy. However, Fisher and coworkers noted that six out of seven cats, suffering from diabetes insipidus consequent to hypo-

thalamic lesions, had serious difficulty in parturition. They suggested that the reports of successful delivery after hypophysectomy might be due to the fact that neurohypophyseal tissue in the pituitary stalk and median eminence had been left intact by the operation. A further study by Fisher and his colleagues showed that slightly less than one third of a number of guinea pigs, in which the neurohypophysis had been completely denervated by hypothalamic lesions, could undergo normal parturition. Similar, somewhat discordant, findings have been reported for human patients with diabetes insipidus. It seems then that in the absence of neurohypophyseal function other factors may compensate and result in apparently normal parturition in a proportion of cases.

Electrical stimulation of the neurohypophysis or its nerve supply has been found to result in increased uterine contractions in postpartum and estrous rabbits. Haterius and Ferguson showed that electrical stimulation of the pituitary stalk in anesthetized rabbits, 2 to 8 hours after delivery, resulted in increased uterine activity. Ferguson later showed that this response was still obtained even if all the tissues of the neck were crushed except the carotid arteries, jugular veins and a flap of skin. In a more recent study by Harris it was found that electrical stimulation of the supraopticohypophyseal tract in the conscious, estrous rabbit evoked increased uterine activity. The magnitude of the response varied with the intensity and duration of the stimulus. The pattern of the uterine response could be matched more nearly by intravenous injection of an oxytocic extract than by an injection of whole posterior pituitary extract. Maximal stimulation was found to be equivalent to the injection of 200 to 500 millunits of the oxytocic fraction. Cross (1958) has recently found that labor may be induced in anesthetized rabbits at term by injection of 50 to 200 millunits of oxytocin or by electrical stimulation of the supraopticohypophyseal tract. From his experiments Cross concludes that the secretion of oxytocin may well play a part in initiating labor and may be secreted during the course of labor under the influence of nervous reflexes initiated by distension of the uterine cervix, as first suggested by Ferguson. The studies of Caldeyro-Barcia and coworkers on the reactivity of the human uterus to synthetic oxytocin infused intravenously, lend indirect support to the views that the oxytocic hormone forms part of the mechanism controlling uterine activity during normal labor. Also in favor of this view is the observation of Gunther who noted milk ejection from the

nipple of a woman during parturition. The mammary expulsion of milk coincided with the labor pains and afforded sound evidence of an increased concentration of oxytocin in the blood at these times.

The suggestion has been made that oxytocic hormone is released by a nervous reflex excited by the act of mating and that the resultant increase in uterine motility normally plays a part in the transport of seminal fluid up the female reproductive tract. Data relating to this view may be summarized as follows:

- 1 The ascent of spermatozoa in the genital tract of many forms (rat, rabbit, guinea pig, dog, sheep, and cow) occurs too rapidly to be accounted for in terms of sperm motility.

- 2 An increase in uterine activity has been found to follow mating or mechanical stimulation of the external genitalia or cervix of the uterus.

- 3 Evidence that oxytocin is released by the act of mating or by manipulation of the vulva or cervix uteri is afforded by the milk ejection that has been observed to follow these stimuli.

- 4 Fitzpatrick and Hughes have observed an increase in oxytocic activity in jugular vein blood of cows consequent to manipulation of the uterus or cervix.

The evidence is suggestive that the oxytocic hormone normally plays a role in seminal transport but further work involving assays of oxytocin before and after coitus and investigations of any disabilities in sperm transport in animals after disturbance or denervation of the neurohypophysis are required.

6. MILK EJECTION ACTION. As with the oxytocic effect on the uterus, milk ejection may be produced in the lactating mammary gland by administration of very small doses of oxytocin that seem within a physiological range. As recounted above, there has long been evidence that the transfer of milk from mother to suckling young involves an active squeezing out of milk from the mammary tissue by the maternal organism. Petersen was the first to suggest that reflex stimulation of posterior pituitary secretion was involved in the process. Definitive evidence that this is so came from experiments in sheep, goats, and rabbits in which it was demonstrated that electrical stimulation of the supraopticohypophyseal tract results in milk ejection. Conversely, it was found that following denervation of the neurohypophysis by the placement of hypothalamic lesions in lactating rabbits, the young obtained only a small fraction of the normal quantity of milk. However, if the mother

animal was injected with oxytocin just prior to suckling, the milk obtained by her young approximated the normal amount. From this and other evidence, there can be no doubt that the sensory stimuli associated with suckling and probably conditioned stimuli as well reflexly excite the neurohypophysis to discharge oxytocic hormone. This hormone in turn causes contraction of the specialized myoepithelial tissue in the mammary gland, so that a positive ejection of milk occurs.

There is much evidence that a similar mechanism occurs in the human. It is well known that embarrassment, worry, or fright at the time of nursing may inhibit the flow of milk to the baby. This inhibition may, however, be overcome by injection of oxytocin. Haeger and Jacobsohn have observed striking increases in milk yield to follow injection of oxytocin into women with poor lactational performance but with engorged and painful mammae. It is of interest that after a single injection of oxytocin, lactation proceeded normally without the need of further injections in the majority of cases.

In summary, it may be said that posterior pituitary hormones play a physiological role in regulating the excretion of water by the kidney and the ejection of milk from the lactating mammary gland. In all probability, the oxytocic activity is of importance in parturition and may also be concerned with the transport of seminal fluid in the female reproductive tract. It is possible that neurohypophyseal secretion is one of the factors regulating intestinal motility and in maintaining a falling blood pressure. The hypoglycemic action of posterior pituitary extracts is of pharmacological interest only.

The melanophore-expanding principle (present in posterior pituitary extracts but a secretion of the pars intermedia of the pituitary) plays an important role in lower forms (fishes, amphibians) in regulating the expansion of melanophores and erythrophores in response to retinal nervous reflexes.

Assay of Posterior Pituitary Hormone

Assays of posterior pituitary hormones are performed with regard to their antidiuretic, vasopressor, or oxytocic activity. Since the vasopressor and oxytocic hormones have overlapping activities, no assay method is entirely specific, though suitable corrections may be made for the overlapping activity. For further details, see the review by van Dyke and coworkers (1955).

- 1 **Antidiuretic assays.** The unknown standard extract are administered to rats or dogs during a water diuresis, and the antidiuretic response

measured. Probably the method of choice involves the use of the trained dog, given water by stomach tube, and the extracts by intravenous injection. This is a specific and sensitive method, and will detect 0.25 millunit of antidiuretic hormone.

2 Vasopressor assays In the past assay of the pressor potency of pituitary hormone has frequently been performed on the dog or rat, but the anesthetized rat now seems the method of choice. The extracts are injected intravenously, about 4 millunits of vasopressin produces a definite pressor response.

3 Oxytocic activity The classical method involving the use of the isolated guinea pig uterus *in vitro* is suitable for assay of material of high potency. The depressor action of oxytocin on the blood pressure of the fowl has been widely used as the basis of an assay method but is relatively insensitive. Probably the most sensitive and reliable method is that devised by van Dyke and his colleagues in which the milk ejection response of a cannulated teat duct of an anesthetized rabbit is employed. The threshold dose is of the order 2 to 3 millunits in this preparation.

The results of all assays should be expressed in terms of the international standard. One international unit is the antidiuretic, pressor or oxytocic activity present in 0.5 mg. of the international standard preparation.

THE FORMATION AND FATE OF NEUROHYPOPHYSIAL HORMONES The fact that the neurohypophysis lacks glandular cells has long posed the problem as to the cellular site of formation of the hormones. For a long time it was believed that the cells of the pars intermedia migrated posteriorly into the neurohypophysis and liberated posterior pituitary hormones. That this is not so is shown by the facts that such forms, such as the porpoise and whale, in which the neural lobe is separated from all parts of the adenohypophysis by a thick connective tissue septum, show the usual activities of neural lobe extracts (except melanophore-expanding activity), and also that animals with an atrophic neurohypophysis due to a hypothalamic lesion show a loss of extractable activity although the pars intermedia appears normal. It was then suggested that certain rather specialized cells in the neurohypophysis (pituicytes of Bucy, or the parenchymatous glandular cells of Gersh) secrete neurohypophyseal hormones. However, the data regarding the secretory nature of these cells were controversial, and the evidence that material rich in posterior pituitary activity could be extracted from the hypothalamus was difficult to explain since such cells do not exist in this region.

An attractive view, which has received wide

acceptance in the last 10 years, holds that the hypothalamo-neurohypophyseal unit acts as a *neurosecretory mechanism*. E. and B. Scharrer have for many years investigated the possibility that neurons in the central nervous system secrete hormone into the blood stream. There was formerly more evidence to uphold this thesis in invertebrates than vertebrates, but in 1949, Bargmann demonstrated that the cells in the paraventricular and supraoptic nuclei, and their nerve fibers sweeping through the basal hypothalamus, pituitary stalk, and neural lobe, may be selectively stained by the Gomori chrome alum hematoxylin method. Striking histological pictures have been obtained in many forms in which cell groups and nerve tracts are deeply stained in contrast to surrounding neural structures. The general view is that the stainable material seen in these neurons is either neurohypophyseal hormone or some carrier material closely linked with the hormone, and that it is found in the cell bodies in the hypothalamic nuclei and transported down the axons to be liberated into the blood vessels in three parts of the neurohypophysis. There are no reasons to doubt that these neurons function also as do other nerve cells, and that the rate of discharge of hormone from the nerve terminals into the vascular system is regulated by nervous impulses in the same nerve fibers. It is unlikely that the hormone can be discharged from any part of the neuron except the nerve terminals existing in the neurohypophysis, since lesions in the nerve tract above the median eminence uniformly result in diabetes insipidus and since the permeability properties of the blood vessels of the neurohypophysis are so markedly different from those of the hypothalamus proper. The evidence relating the stainable material to hormonal activity has been mainly concerned with the antidiuretic function. In different forms, and in the same form under different conditions of dehydration or exposure to stress, there is a correlation between the amount of stainable material and the content of vasopressor hormone. The relationship with oxytocin is less clear, since it has been established that there is very little oxytocic activity in extracts of hypothalamic tissue. It is possible that oxytocic hormone is formed during the transport of neurosecretory material into the neural lobe itself. The neurosecretory view of the origin of posterior pituitary hormones affords an obvious explanation for the lack of secretory cells in the neurohypophysis and for the presence of hormonally active material in hypothalamic extracts.

Although at one time it was thought that the hormones of the posterior pituitary, passed up the pituitary stalk and into the third ventricle, it is now believed that they are secreted into the capillaries of the gland and into the venous system directly. The form in which the hormones are transported in the blood is unknown, but it is possible that they are secreted as polypeptides and become linked to the plasma protein. The hormonal activities of injected extracts disappear from the blood stream within a few minutes, and evidence exists that a major part of this inactivation occurs in the liver and kidneys (Heller, 1957). A further portion (about 25 per cent) of the activity of administered hormone, or of the hormone discharged from the neurohypophysis by electrical stimulation, appears in the urine, it is impossible to say though, whether this represents the unchanged hormone or a biologically active metabolite.

Disorders of the Pituitary in Man

Derangements of pituitary function may take the form of overactivity or of deficiency. In the former case tumors composed of functioning endocrine tissue are frequently the cause of the disorder, in the latter, atrophy or degeneration of the specific secreting cells, either primarily or as the result of mechanical pressure by tumors, may be responsible. A pituitary tumor of the anterior lobe may be composed of any of the cellular elements of the gland, *chromophobe*, *acidophil*, or *basophil* adenomas. Squamous-celled growths (cranopharyngeomas) may also arise from epithelial rests (remnants of Rathke's pouch) near the root of the infundibular stalk. As a result of the confined position of the pituitary within the sella turcica the entire gland is likely to suffer from pressure effects when one of its parts becomes enlarged. For this reason and on account of the proximity of other important structures, e.g., hypothalamus and optic chiasma, and the proclivity of tumors to invade or press upon neighboring structures the manifestations of a pituitary tumor are not always referable simply to the part of the pituitary originally involved. Any function (growth, sex, water elimination or the metabolism of carbohydrate or fat) presided over by the pituitary hypothalamic mechanism may, therefore, be disturbed by a lesion in this region. Nevertheless the site wherein the tumor arises and the nature of the cells of which it is composed do very often determine the predominant features of the condition, and certain fairly well defined groups of symptoms (syndromes) are rec-

ognized. To these may or may not be added symptoms referable to pressure upon or to irritation or destruction of, nearby nervous structures.

The following is a short classification of pituitary diseases.

I Anterior lobe

A Overactivity

- 1 Acromegaly
- 2 Gigantism
- 3 Pituitary basophilism (Cushing's disease)

B Deficiency

- 1 Dwarfism
- 2 Pituitary cachexia (Simmonds' disease)
- 3 Aerometria

II Posterior lobe deficiency or hypothalamic lesion

A Diabetes insipidus

III Anterior lobe deficiency together with posterior lobe deficiency or hypothalamic lesion

A Dystrophia adiposo genitalis (Frohlich)

- 1 Infantile or juvenile type
- 2 Adolescent or adult type

ACROMEGALY

This condition was first described by Pierre Marie in 1885. It is due to the excessive elaboration of the growth hormone during adult life, i.e., after the usual age of full skeletal growth (fig. 56-16). An adenomatous tumor of the anterior lobe composed of acidophil cells is responsible for the hypersecretion. The characteristic features of the condition are: (a) Overgrowth of the bones of the hands, feet and face. Of the latter, the mandible, nasal bones, and supraorbital ridges are especially involved (fig. 56-17). The feet and hands are greatly increased in size, the latter being usually broadened and the fingers thickened, under the X rays, the terminal phalanges appear tufted, thus resembling a wheat sheaf in shape. Bowing of the spine (kyphosis) is common. The soft tissues of the nose, lips, forehead, and scalp are thickened, the latter being thrown into folds or wrinkles (bulldog scalp). There is a general overgrowth of body hair. (b) Atrophy of the gonads and suppression of the sexual function (amenorrhea in women, impotence in men). (c) Moderate increase in the urinary excretion of 17 ketosteroids and corticoids with reduced excretion of gonadotrophins. In the earlier stages, however, there may be evidence of increased sexual function. (d) Enlargement of the viscera (splanchnomegaly). The tongue, lungs, thymus,

heart, liver, and spleen are greatly enlarged. The thyroid, parathyroids, and adrenals may show hypertrophy or adenomatous growth. Hyperthyroidism may be present in the early stages (e). Glycosuria and hyperglycemia are common, and a condition indistinguishable from diabetes of pancreatic origin may be present. The metabolic rate may be raised from 10 to 70 per cent, the

specific dynamic action of protein is not altered (p 787)

GIANTISM

Giantism is due to a pituitary lesion of a similar nature to that responsible for acromegaly, but the condition arises in preadult life, i.e., before ossification is complete (fig 56 18). A general overgrowth of the skeleton results and the production of persons of enormous stature, 7 or 8 feet or more in height. The limbs are usually disproportionately long. The viscera are not enlarged.

FIG 56 16 Acromegaly together with enlarged stature—acromegalic giantism (From Cushing and Davidoff)

FIG 56 18 Giantism

FIG 56 17 Skulls of a normal person (left) and of an acromegalic (right) (From Cushing and Davidoff)

out of proportion to the frame unless, as is sometimes the case, the gigantism is accompanied by the characteristic features of acromegaly, as may occur after adolescence

CUSHING'S DISEASE CUSHING'S SYNDROME

This is a rare disease. Its main features are (a) Obesity of the trunk (especially of the abdomen), face, and buttocks, but not of the limbs, these latter show some wasting (fig 56 19). The fattening of face leads to rounding of the facial contours which obscures the bony structure, producing the so-called "moon face." There is, thus, a redistribution of body fat, which is mobilized from the limbs and deposited in the regions mentioned. The fatty deposits are frequently tense, tender, and painful. Purplish striae, due to distension, are present over the lower abdomen. (b) Polycythemia with cyanosis of the face, hands, and feet, pigmentation of the skin, and excessive growth of hair. Women may grow a mustache or a beard. (c) Loss of mineral from the bones, leading to osteoporosis, softening or brittleness. The softening often involves the dorsal vertebrae, and causes kyphosis, which with the deposition of fat in the interscapular region gives the appearance known as "buffalo neck." (d) Systolic hypertension. (e) Suppression of sexual functions. (f) Hyperglycemia and glycosuria and in some cases increased urinary excretion of nitrogen. (g) Atrophy of testes or ovaries, and hypertrophy of the adrenal cortex with signs of hypersecretion of its hormones. (h) Increased urinary excretion of 11 oxycorticosteroids, and often of 17 ketosteroids, high uric acid creatinine ratio. (i) Leucopenia, lymphopenia, low blood potassium, and retention of sodium chloride with increase of body fluids and a tendency to edema.

The disease as originally described by Harvey Cushing (1932) was associated with a basophil adenoma of the adenohypophysis.^{*} It has since been found that the syndrome may arise either as a result of a pituitary tumor (excess ACTH production and stimulation of the adrenal cortex) or from primary hyperplasia or tumor of the adrenal cortex. The manifestations, it will have

^{*} Susman found, however, that in the postmortem examination of a large number of pituitaries, small basophil adenomas were present in 31 per cent though no sign of basophilism was observed during life. Crook also states that a basophil adenoma or a general increase in basophil cells is an inconstant finding in Cushing's syndrome but that hyaline degeneration of these cells (with or without adenoma) is invariable.

FIG 56 19. On left at 20 years of age, on right, 5 years later at height of the disease. (From Cushing and Turney.)

been observed are in either case referable for the most part to excessive adrenocortical secretion. Sometimes Cushing's disease is restricted to cases associated with a pituitary tumor, and Cushing's syndrome applied to the condition due to primary adrenal tumor or hyperplasia.

DWARFISM

The arrested skeletal development which results from deficiency of the growth hormone of the anterior pituitary is spoken of as the Loran type of infantilism (fig 56 20). These dwarfs are usually, though not invariably, undeveloped sexually. They do not show deformity or, as a rule, mental inferiority, and are generally not unattractive in appearance. Sometimes, however, they are wizened and except for their diminutive stature appear older than their years (progeria). The condition may then be considered the counterpart of Simmonds's disease, but commencing before puberty. The anterior lobe dwarf at adult age may be no more than 3 or 4 feet high. During infancy and childhood, the ossification centers, as observed by radioscscopy, appear normal and dentition is not delayed. The relative proportions of the different parts of the skeleton are not far from normal though they tend toward those characteristic of childhood, the head being large relative to the body. Some encouraging results have been reported from the treatment of this type of dwarfism with anterior pituitary extracts of primate origin.

FIG 56-20 Infantileism due to anterior lobar deficiency. Age 21 years. Man on right is 5 feet 7 inches tall. (From L. Seer.)

PITUITARY CACHEXIA (SIMMONDS DISEASE)

This rare disease was first described by Simmonds of Hamburg. It is due to atrophy or degeneration of the anterior lobe. The main features of this disease form a picture which may best be described as that of a premature and rapidly developing senile decay (fig. 56-21). They are largely referable to severe depression of activity of the adrenal cortex and other target organs, e.g., gonads and thyroid as a result of deficiency of the trophic hormones of the pituitary.

The characteristics of the disease are as follows: (a) *General appearance* (loss of axillary and pubic hair; hair of the head prematurely gray and sparse; loss of teeth; skin of face wrinkled and dry; often great emaciation; smallness of hands and feet; and shrunken appearance of the facial features); (b) *anemia*; (c) *low metabolic rate and hypoglycemia*; (d) *amenorrhea or impotence*; (e) *mental deterioration*; muscular weakness; death in coma; (f) *atrophy of the gonads* and a general smallness of the internal organs (*splanchnomecristia*); (g) *reduced urinary excretion of gonadotrophins*; 11-oxycorticoids and 17 ketosteroids, and depression of

protein bound iodine of the blood and (h) *acute adrenal insufficiency may occur*.

The disease most commonly follows childbirth in which there has been severe hemorrhage with peripheral circulatory collapse. It is likely that the hypophyseal portal blood supply in some way becomes obstructed thus accounting for the necrosis and fibrosis found on postmortem examination of the pituitary. Milder manifestations of the disease developing after childbirth have been described by Sheehan, which are now referred to as *Sheehan's syndrome*.

DIABETES INSIPIDUS (see also p. 985 and ch. 34)

Diabetes insipidus is a condition in which large quantities of urine of very low specific gravity, 1.002 to 1.006, and low chloride content are excreted. In an ordinary case the daily output of urine is 4 or 5 liters, but daily amounts several times these figures have been reported. A corresponding increase in the fluid intake occurs and thirst is often intense. The condition frequently accompanies tumors of the pituitary or hypothalamic region and is essentially due to lack of posterior pituitary hormone through damage to the hypothalamo-neurohypophyseal unit. As described above (p. 985), Fisher, Ingram, and Ranson were able to duplicate this state experimentally and showed that either damage to the neurohypophysis or denervation of the neurohypophysis by means of a hypothalamic lesion were equally effective in evoking this condition.

It will be recalled (ch. 34) that only about 15 per cent of the glomerular filtrate is reabsorbed by the nephron distal to the proximal convoluted

FIG 56-21 Pituitary cachexia. On left patient aged 42 years; on right the same woman at the age of 34 years. (From Zondek, *Diseases of the Endocrine Glands*, by permission of Edward Arnold & Co. London.)

tubule ("facultative" reabsorption) and upon this fraction alone is the action of the antidiuretic hormone exerted, the reabsorption of water by the proximal tubule ("obligative" reabsorption) is not altered. Therefore, a limit is set to the increase in urine output even though ADH be completely absent. If, say, the glomerular filtrate amounts to 180 liters daily, at least 150 liters must be reabsorbed under all circumstances, leaving less than 30 liters as the maximum amount of urine which could be produced.

The failure of total hypophysectomy to produce diabetes insipidus is due to the loss of the anterior pituitary gland. This was first pointed out by von Hann from his findings at human autopsies, and confirmed by the experimental work of Richter. It seems that the anterior lobe, through its general metabolic effects, exerts a diuretic influence, and that in the absence of this action posterior pituitary deficiency is not revealed by the development of polyuria.

In diabetes insipidus the ingestion of large quantities of water of a temperature below that of the body necessitates readjustments in the heat regulating mechanisms. Vasoconstriction of the skin vessels occurs, the extremities are often cold and may be cyanotic, and the subject is very sensitive to cold. The vasoconstriction is apparently a compensatory measure for heat conservation. Shivering and a rise in the metabolic rate may also result, the food intake is then, as a consequence increased.

Administration of posterior pituitary extract is the only available means for the control of diabetes insipidus and, as mentioned below, this is not successful in some cases. The whole extract (or the vasopressin fraction) may be given by injection or by means of pledgets of absorbent cotton soaked in the solution and inserted into the nose. The polyuria of nephritis is not influenced by this medication. Water intoxication may occur in diabetes insipidus if posterior pituitary extract is administered and the patient is requested to maintain the usual fluid intake. The urea clearances are normal as a rule.

The fundamental mechanisms concerned in the polyuria of diabetes insipidus appear to be allied in nature to those underlying the diuresis of water drinking in normal persons. But the thirst and the consequent excessive ingestion of water experienced by subjects of diabetes insipidus is not primary, as in the water diuresis of normal persons, but is secondary to the polyuria and the resulting tendency toward dehydration: the deprivation of water carried to the limit of endurance

does not prevent the excretion of large quantities of water.

The results of Richter's work upon rats, in which diabetes insipidus was produced by partial hypophysectomy or a stab wound in the floor of the third ventricle, indicate that in the experimental condition polyuria is also primary. He states that polyuria preceded polydipsia and that animals deprived of water continued to excrete large quantities of urine.

About 10 per cent of cases, classed as diabetes insipidus, do not respond to postpituitary preparations, or do so very poorly. Such cases are congenital or show a familial tendency, and are thought to be due to an inherent defect of the renal tubules with respect to the renal absorption of water—a persistence, it would seem, of the infantile incapacity of the tubules to concentrate the urine.

Polyuria, simulating in some ways diabetes insipidus, occurs in chronic nephritis (ch 35) and in psychogenic polydipsia. The polyuria in chronic nephritis is not corrected by pituitary extracts and in polydipsia thirst is primary: the urine volume is reduced and the specific gravity of the urine is raised by rigid deprivation of water: the polyuria is simply a normal diuretic response to water drinking.

DYSTROPHIA ADIPOSO-GENITALIS

Dystrophia adiposo genitalis, as its name suggests, is a condition in which obesity, sexual infantilism, and dwarfing (if the condition occurs during the growing period) are the essential features. It is due to a lesion of the anterior lobe of the pituitary, which accounts for the sexual immaturity and dwarfing, and of the hypothalamus. The experiments of Smith with hypophysectomized rats and of other investigators, point to injury of the hypothalamus as being chiefly responsible for the obesity. Marked obesity is also a feature of certain hypothalamic disorders in man unassociated apparently with any disease of the pituitary itself. Dystrophia adiposo genitalis appears in two forms according to the age at which it develops, the infantile or prepubertal and the adolescent or adult.

THE INFANTILE OR PREPUBERTAL TYPE, FROLICHER'S SYNDROME (fig 56 22). This type may occur in children of any age before puberty. It may be the result of an inherent defect of the pituitary, of atrophy of the secretory cells by pressure (e.g., by tumors), injury (e.g., a penetrating wound), or of some infectious disease. Polyuria and a high sugar tolerance are frequent accompaniments of

FIG 56 22 Male aged 8 years Hypopituitarism following whooping cough, with characteristic growth and sex defects and obesity, Frohlich's syndrome (From Gardiner Hill)

FIG 56 23 Extreme case of obesity, due to pituitary or hypothalamic disease (From Timme)

the disease. The subjects are lethargic or somnolent and often of subnormal intelligence. They usually have voracious appetites and especially a craving for sweets. The "fat boy" of *Pickwick Papers* was undoubtedly an example of this condition. The younger the age of the child at which the disease commences the greater, obviously, will be the degree of stunting. When the dwarfing is of high grade, this combined with the obesity

makes a very striking picture. These subjects are human counterparts of Smith's rats in which the pituitary was destroyed (and the hypothalamus presumably injured) by chronic acid injections. Since obesity and an *apparent* sexual infantilism may occur in normal adolescent boys, the diagnosis of Frohlich's syndrome in such cases should be applied only to those patients with proven hypothalamic damage.

THE ADOLESCENT OR ADULT TYPE Male subjects of this condition are often effeminate in disposition and appearance. The excess fat has a feminine distribution, the adiposity being noticeable chiefly in the mammary region, buttocks, thighs, and over the mons veneris. The hair over the pubis and in the axillae is sparse or absent, the skin of the face and the body is smooth, soft, and hairless, the hips are broad. In female subjects the obesity is often extreme, a weight of 300 pounds being not very unusual (fig 56 23). In both sexes the feet and hands are small and "pretty," the finger tips being slender and tapering with narrow pointed terminal phalanges. The extremities thus give a picture the reverse of that seen in acromegaly. The basal metabolic rate is often subnormal and sugar tolerance increased. Diabetes insipidus is a common, and narcolepsy (p 1231) an occasional, accompaniment.

THE THYROID GLAND

Development, Histology, Blood, and Nerve Supply

Very early in its evolutionary history the thyroid had a digestive function, a function lost long since but which its ontogeny recalls. The gland is developed from a single median outgrowth of hypoblast derived from the ventral wall of the primitive pharynx at the level of the first visceral cleft. This extends downward. Its lower end bifurcates and enlarges to form the isthmus and lateral lobes of the thyroid. Its upper end gives rise to the foramen cecum of the tongue. The intervening portion, the *thyroglossal duct*, normally disappears but sometimes persists and may give origin to accessory thyroids or to the so-called *thyroglossal cysts*.

The *thyroid tissue* is composed of cuboidal epithelial cells arranged in a single layer around spaces roughly circular or ovoid in shape and fairly uniform in size. These spaces, variously known as *follicles*, *vesicles*, *acini*, or *alveoli*, contain a homogenous gelatinous material, the *colloid substance*, which is the stored secretion of the gland. Connective tissue fibers support the alveolar walls and form *septa* which divide the gland into smaller masses. The cells lining the alveoli contain numerous mitochondria and a well defined Golgi apparatus. Studies with the electron microscope have shown that the inner (luminal) end of these cells possess cilia and a brush border. These are characteristic features of cells engaged in absorption or secretion. When the gland becomes active the Golgi apparatus hypertrophies and droplets of colloid appear in its proximity. Other histological changes typical of increased activity in the thyroid are, increase in the cell height of the epithelium, increase in mitotic figures, decrease in amount of colloid in the follicles with a tendency to become basophilic rather than acidophilic in staining properties, and an increase in vascularity. The maximal normal weight of the human thyroid is, according to Marine, from 20 to 35 grams or around 0.4 gram per kilogram of body weight. The thyroid tissue of the early fetus consists of masses of epithelial

cells showing little or no arrangement into acini. The latter appear about the fourth month but are small and contain little colloid. Functional activity first appears in the fetal gland at about this time.

The *blood supply* comes from the superior and inferior thyroid arteries, chiefly the former. The blood flow is profuse, the blood passing with little resistance from the arterial to the venous side through a wide capillary bed. The flow amounts to from 3.5 to 6 cc. per gram of tissue per minute, or about 5 liters per hour for the whole gland. The gland is richly supplied with *lymphatics* which drain lymph spaces surrounding the vesicles.

The *nerve supply* of the thyroid is derived from the *vagus* and the *sympathetic nerves*. The sympathetic fibers leave the spinal cord between the second and fifth thoracic segments and pass to cell stations in the superior and middle cervical ganglia, where they are relayed to the gland through the superior laryngeal nerves and along the blood vessels. It is probable that the thyroid nerves are purely *vasomotor* in function and influence the activity of the gland indirectly, namely, by altering its blood supply. Control of thyroid activity is exerted mainly, if not exclusively, by the *thyrotrophic hormone* of the pituitary (p. 963).

An Outline of Thyroid Function

Some of the first experiments on the thyroid were performed in 1836 by Schiff, who found that in dogs death followed its removal, from the symptoms preceding death it is now apparent that this was due to removal of the parathyroids (ch. 59). As in the case of some other ductless glands, clinical observations gave the first hint concerning the functions of the thyroid. Hilton Fagg in 1871, reported a case of *cretinism* (p. 1000) and ascribed it to absence or atrophy of the thyroid. Three years later, Gull described the condition which today is known as *myxedema* or *Gull's disease*, but called it the *cretinoid state in adult life*. Horsley, some years later, removed the gland from monkeys and produced conditions

resembling human cretinism and myxedema. Later experiments upon other species have established the fact that the thyroid secretion is absolutely necessary for the *normal growth and development* of young animals, and for maintaining the *normal level of metabolism* of animals of all ages. Magnus-Levy, in 1895, demonstrated that thyroid deficiency was associated with a greatly reduced metabolism and that treatment with desiccated thyroid restored the metabolic rate to the normal level or above. Complete thyroidectomy reduces the basal metabolic rate by from 40 to 45 per cent in about 8 weeks after the operation. Thyroidectomy in lambs, young rabbits, goats, or calves has been shown to cause retarded skeletal growth and arrested sexual development (fig 57 1). Apathy, lack of vigor, thickening of the skin, and a striking reduction in basal metabolism result in both young and full grown animals. In young cattle, increase in bulk but not in height is a notable feature, the animals appearing short legged and of a broad, stocky build. Other effects of thyroid removal in the young are delay in the ossification of the epiphyses of the long bones, poor growth of hair, failure in thymic involution, and subnormal intelligence. The administration of thyroid extract to young animals shortly after thyroidectomy prevents these otherwise inevitable results. In full grown animals the effects of thyroid removal can be corrected by thyroid administration at any time after operation.

The effects produced upon lower orders by thyroid removal and by thyroid feeding are even

FIG 57 1 Triplet kids. Center animal normal, right and left hand animals thyroidectomized at 20 days of age. Photograph taken 13 weeks after operation. (From Sutherland Simpson.)

FIG 57 2 The effect of removal of the thyroids upon the development of tadpoles. A, Thyroidless tadpoles, B, normal frogs of the same age as A. (From Allen, redrawn.)

more striking. Gudernatsch removed the thyroids from tadpoles, keeping a number of young animals of the same hatching as controls. The thyroidectomized larvae grew somewhat larger in size but did not metamorphose, the controls developed into frogs within the usual time (fig 57 2). Metamorphoses of the thyroidless creatures could be induced to proceed at the normal rate by thyroid feeding.¹ Also, the time required for the normal larvae to metamorphose completely could be shortened (from 104 to 20 days) by feeding thyroid tissue. Swingle has shown that inorganic iodine alone will produce similar effects (p 1005). The effect of the thyroid hormone upon the axolotl is extraordinary. This animal is allied to the frog but is purely aquatic in its habits. It has in its adult form, a finned tail, gills, and four short limbs, resembling somewhat an enormous tadpole which has undergone partial metamorphosis. Thyroid feeding causes the axolotl to lose its fin and gills, develop air breathing organs, and forsake the aquatic life for which Nature had designed it (see also ch 57).

In growing birds (chicks) and mammals, a stimulating effect of the thyroid hormone on growth has been demonstrated. Acceleration of growth has also been observed in a twin child suffering from hyperthyroidism.

It is now known that the function of the thyroid gland is to extract iodide ions from the blood, combine them with a protein (thyroglobulin)

¹ This effect has been made use of to assay the potency of thyroid preparations or to determine the activity of a particular thyroid gland (Gudernatsch test).

stored in the colloid of the alveoli and to liberate thyroxine and allied compounds from this protein for secretion into the blood. The study of these reactions has been greatly aided by the use of radioactive iodine. The isotope most generally used is I^{131} (half life, 8 days). Injection of a tracer dose of I^{131} adds such a minute amount of iodine to the circulation that for all practical purposes the iodine metabolism remains unchanged but, together with such techniques as paper chromatography, it allows quick and accurate analysis of the different iodine containing compounds in the gland or body fluid. Unlike the other endocrine glands, the thyroid stores large amounts of hormone. It has been calculated that the human gland stores a 3 months' supply of thyroxine. Knowledge of the function of the thyroid in man has been derived largely from studies of clinical cases of hypothyroidism and hyperthyroidism, and for this reason a description of these states precedes the account of experimental studies of thyroid physiology.

Goster

Many abnormal thyroid states are accompanied by a visible swelling in the neck due to enlargement of the gland. Goster is a generic term which may be applied to almost any noninflammatory and nonmalignant enlargement of the thyroid gland. The following is a short classification.

- A. *Simple goster*. These are unaccompanied by constitutional features. They are subdivided upon a histological basis into three groups
 1. Colloid (diffuse)
 2. Parenchymatous (diffuse)
 3. Adenomatous (nodular)
- B. *Gosters associated with a deficiency of the thyroid hormone* (hypothyroidism)
 1. Cretinism
 2. Myxedema
- C. *Gosters associated with an excess of the thyroid hormone* (hyperthyroidism)
 1. Exophthalmic goster
 2. Toxic adenoma

Diffuse Colloid Goster

The alveoli are large, distended with colloid and lined by low cuboidal or flattened epithelial cells. There is no hypertrophy or hyperplasia of the latter (figs 57.3 and 57.4). The iodine content per gram of gland tissue is low but as a rule the total quantity in the enlarged gland is not far from normal. Colloid goster may become converted into, or result from, the following type (see also pp 1007)

FIG 57.3 Photomicrograph of a human sample of colloid goster

Diffuse Parenchymatous Goster

Hypertrophy and multiplication of the cells lining the alveoli with great reduction in the amount of colloid material are characteristic features of this type. The alveolar cavities are of various sizes and shapes and often almost obliterated by infoldings of their walls. The epithelial cells are high columnar instead of the normal cuboidal type. The iodine content of the gland is low, usually much less than 0.1 per cent of its dried substance. Exhaustion of the gland and atrophy of its secretory elements with an increase in fibrous tissue may result, or, as mentioned above, the goster may change to the colloid type especially after iodine administration (fig 57.4). Partial thyroidectomy in animals as first shown by Halsted results in regeneration of the thyroid remnant to produce the foregoing histological picture of diffuse parenchymatous hypertrophy. This observer also showed that removal of the thyroid from pregnant bitches led to parenchymatous goster in the puppies.

Adenomatous Goster

As a result of the formation of isolated tumor-like masses of thyroid tissue (adenomata) the glandular enlargement is asymmetrical or nodular. The minute structure of the adenoma may resemble a section of colloid or parenchymatous goster or it may undergo cystic changes. Again, the alveoli may be unusually small, contain little colloid and resemble fetal thyroid tissue (fetal adenoma). The iodine content of the nodule may be normal or high while that of the rest of the gland, which may also show diffuse colloid or parenchymatous changes, is usually low.

FIG. 57.4 Upper photograph, microscopical appearance of the gland in exophthalmic goiter showing hypertrophy and hyperplasia (parenchymatous goiter) before the administration of iodine. Lower photograph, appearance after involution had occurred from iodine administration (colloid goiter). (From Rienhoff.)

The simple enlargement of the thyroid which sometimes occurs at puberty or during pregnancy may be either of the colloid or parenchymatous type. A certain degree of thyroid enlargement at these times is physiological. The enlargements seen in goiter districts (endemic goiter) or occurring sporadically may show the features of any of the three types. Either of the first two forms may end in exhaustion atrophy (p. 1007).

Hypothyroid States

CRETINISM

A cretin is a type of dwarf for which deficiency or absence of the thyroid secretion in infancy or early childhood is responsible (fig. 57.5). Among the typical features of the condition are (a) retarded and abnormal skeletal growth, (b) arrested sexual development, (c) mental deficiency varying in degree but often amounting to complete

idiotcy (deaf mutism is common), (d) the facial features are coarse and appear bloated, the skin is dry, thick, pasty, and often deeply wrinkled, the nose is broad and its bridge depressed, the tongue is enlarged and appears between the thickened and usually parted lips, (e) the supraclavicular fossae are filled with pads of fat, (f) closure of the anterior fontanelle which normally occurs before the 20th month is postponed for several years, the epiphyses of the long bones fail to ossify at the usual time, and (g) the basal metabolic rate is depressed by from 20 to 40 per cent below the normal.

Endemic cretinism is much less common today. In the past it was seen most frequently in districts where goiter was prevalent (in the valleys of the Alps, Pyrenees, Himalayas, etc.) and was usually the result of atrophy and degeneration of the secretory epithelium of a goitrous gland. Some of the worst cases of cretinism appear, however, in

FIG 575 Upper photograph (left) cretinism in an infant (right) same child after treatment with thyroid extract (From J Huxley) Lower photograph a cretin aged 10 years (From McCarrison after Thomson)

infants, either in these districts or elsewhere, who are not goutous. The condition is then due to (a) prenatal or early postnatal atrophy of the thyroid (b) to its congenital absence, or (c) to its destruction by some inflammatory condition. A large percentage of the gouterless cretins in a gouter district are the result of hypothyroidism in one or both of the parents.

Although the majority of cretins are apathetic and sluggish a very few are highly excitable, the *nerveous cretinism of McCarrison*.

MYXEDEMA (GULL'S DISEASE)

Myxedema is the result of thyroid deficiency in adults or older children and corresponds to the cretinism of infants and younger children. It follows atrophy or destruction of the thyroid from whatever cause, or may result from an operation in which too much of the gland has been removed (*operative myxedema* or *cachexia strumipriva*). The chief characteristics are (a) low metabolic rate (-20 to -40) (b) a thick puffy appearance of the skin the hair is dry brittle and sparse the facial features sometimes give the subject a mongoloid look (fig 57 6) (c) apathy lethargy slow cerebration though general intelligence is retained (d) increased body fat and hypercholesterolemia (e) greater susceptibility to cold and (f) cardiac dilatation and low voltage electrocardiograms. The edemalike appearance of the skin was thought by Ord who suggested the term myxedema to be due to the accumulation of mucin in the subcutaneous tissues. The thickening of the skin is not due to a true edema nor is it

FIG 576 Left myxedema right same subject after 3 months treatment with thyroid extract (From Murray)

the result of the accumulation of mucin but, according to Boothby, to the deposit of a semifluid albuminous substance containing over 13 per cent of protein

Hyperthyroid States, Thyrotoxicosis

EXOPHTHALMIC GOITER (GRAVES', PARRY'S OR BASFORD'S DISEASE)

In Graves' disease there is nothing in the histological appearance of the thyroid to distinguish it with certainty, from a simple goiter. The gland usually shows a picture typical of parenchymatous goiter, i.e., hypertrophy and hyperplasia (p. 999), its iodine content is low. The blood iodine is elevated. After iodine administration the gland tends to assume the histological appearance of colloid goiter (fig. 57.4 and p. 1006). The blood supply of the gland is greatly increased; the rush of blood through the superior thyroid arteries often producing a loud bruit or a distinct thrill. In addition to the thyroid enlargement the chief features of the fully developed condition are

- 1 Accelerated pulse (100 to 160 per minute) and increased circulation rate (50 per cent or more above normal)
- 2 Cardiac dilation and hypertrophy
- 3 Myocardial failure
- 4 Auricular fibrillation in 20 per cent of cases
- 5 Flushing of the skin and normal or low diastolic pressure with high systolic pressure (i.e. high pulse pressure)
- 6 Nervous excitability
- 7 A fine involuntary tremor
- 8 General muscular weakness
- 9 Protrusion of the eyeballs (exophthalmos) and other ocular signs e.g. widening of the pal-

pebral fissure (Dalrymple's sign) due to retraction of the upper lid; infrequent winking (Stellwag's sign); weakness in convergence of the eyes (Moebus); tremor of the closed lids (Rosenbach); lid lag (von Graefe); i.e. failure of the lid to follow the eye smoothly upon looking down; absence of wrinkling of the forehead when eyes are rotated upward (Joffroy); and difficulty in eversion of upper lid (Gifford). There is frequently edema of the conjunctiva (chemosis) and upper lid and palsies of ocular muscles may occur (fig. 57.7).

6 Metabolic rate increased to varying degrees up to 80 per cent above normal. As a result of the increased activity of the heat dissipating mechanisms the skin is hot and moist. Increased tolerance to cold and lowered tolerance to a high environmental temperature.

7 Dissipation of the fat stores; wasting.

8 Nitrogen and calcium excretion are increased (rarefaction of the skeleton may be demonstrated by X rays in many cases).

9 Disturbance of carbohydrate metabolism is common as evidenced by hyperglycemia, glycosuria and reduced sugar tolerance. Hepatic glycogen stores are reduced.

10 The thymus is enlarged in 80 per cent of cases and hyperplasia of lymphoid tissue in general is found.

11 Subjects of hyperthyroidism are especially susceptible to oxygen deficiency. Work is performed less economically and dyspnea occurs upon exertion (ch. 33).

12 Thyroid crises. During the course of exophthalmic goiter intense exacerbation of the symptoms may occur accompanied by nausea, vomiting, diarrhea, dehydration, high temperature, a great increase in heart rate, erythema, extreme nervousness, thrashing about in bed, muscular weakness and sometimes delirium or coma. Treatment of this condition with cortisone has been successful.

A DISCUSSION OF THE PATHOGENESIS OF SOME OF THE FEATURES LISTED ABOVE

The tachycardia is not dependent upon nervous connections but appears to be due to a direct and persistent effect of the hormone upon the cardiac muscle. The excised heart of an animal given thyroxine (p. 1015) in excess beats at the increased rate when perfused or transplanted to the body of another animal. Also fragments of heart muscle of a 2-day old chick embryo pulsate at a more rapid rate when thyroxine is added to the nutrient fluid. The high pulse pressure seen in hyperthyroidism is due to the general vasodilation combined with an increased stroke volume. The increased circulation rate is chiefly the result of the higher metabolic rate.

FIG. 57.7 Typical case of exophthalmic goiter showing characteristic facies. (From Crile.)

Cardiac failure and thyrotoxic disease The association of cardiac failure with hyperthyroidism has led to the idea that the thyrotoxicosis is a cause of myocardial disease. But organic disease of the heart is not as common in Graves' disease as has been generally supposed. When cardiac failure does occur it is in the great majority of instances due to disease of the heart which had existed, though often without symptoms, before the development of thyrotoxicosis. The greater cardiac work (increased cardiac output) resulting from the higher metabolism, it is believed by encroaching on cardiac reserve, merely reveals a hidden cardiac condition or aggravates a pre-existing manifest heart lesion.

Exophthalmos The pathogenesis of exophthalmos in Graves' disease has been a puzzling question for years. Exophthalmos refers to a forward displacement of the eyeball in the bony orbit, and must be distinguished clinically from simple retraction of the upper lid which results in the same staring or frightened expression. The existence, and degree of, exophthalmos is established with special instruments (e.g., Hertel's exophthalmometer) which measure the distance at which the most forward point in the cornea lies anterior to the outer bony margin (external canthus) of the orbit. The distance in normal persons ranges from 14 to 16 mm., whereas in Graves' disease it may be over 25 mm. Two questions are posed by exophthalmos, (a) what are the general factors responsible for producing the changes in the orbit in Graves' disease? and (b) what are the pathological changes in the orbit which result in protrusion of the eyeball?

There is sufficient evidence to state quite confidently that exophthalmos is not an effect of the thyroid hormone itself. Exophthalmos cannot be produced in animals by large and repeated doses of thyroid hormone, nor can it be induced in man by this means.² Furthermore, severe thyrotoxicosis may be present in the absence of exophthalmos (see toxic adenoma, p. 1004). Conversely, efficient treatment of a thyrotoxic state (by thyroidectomy or administration of goitrogenic drugs) may result in alleviation of all signs of the disease except that the exophthalmos fails to improve or becomes worse in about 40 per cent of cases and becomes extremely severe in about 1

per cent. Administration of thyroid hormone to these cases occasionally induces an amelioration of the exophthalmos. Although repeated doses of thyroid hormone do not evoke exophthalmos, administration of thyrotrophic hormone readily induces this state in normal animals (guinea pigs) or thyroidectomized animals and even to a greater degree in the latter. Whether this effect is due to the thyrotrophic hormone itself, or to an exophthalmos-producing substance (EPS) closely associated with it has been discussed above (p. 965). Dobyns and Wilson have produced exophthalmos in the fish *Fundulus* by injection of sera from patients with progressive exophthalmos (see also ch. 56). The relationship of pituitary secretion to the exophthalmos of Graves' disease is also implied by the recent findings that hypophysectomy, or section of the pituitary stalk, may be beneficial in otherwise intractable and progressive cases.

The mechanism causing the actual proptosis or forward displacement of the eye must now be considered. One of the earliest theories was based on the contractile power of *Mueller's orbital muscle* situated at the back of the orbit or of the smooth muscle in the *fascia bulbi*. The tone of these muscles was thought to be increased as a result of the thyroid hormone having sensitized them to the action of circulating adrenaline. This view cannot be accepted, however, since (a) thyroid hormone does not induce exophthalmos, (b) *Mueller's muscle* in the human is a mere vestige and incapable of contraction powerful enough to produce this effect, and (c) the exophthalmos does not disappear after death as it would do if it were solely due to increased muscle tone. It is more likely that exophthalmos both that induced experimentally by injection of thyrotrophin and that seen clinically in the human, is due to an increased bulk of the retro-ocular tissues. Smelser found in animals an increased bulk of the extrinsic ocular muscles and retro-ocular fat, due mainly to accumulation of fluid. The dorsal lacrimal gland (Harderian gland) which is not present in man, was enlarged. Pochin and others, in post-mortem studies on the human, have found an increased bulk of periorbital tissues, this was due largely to an increase of fat and mucopolysaccharides, and to an edema not associated with an excess of water in the tissues. The extraocular muscles were found to be swollen, edematous and infiltrated with fat and lymphocytes. The lacrimal gland was enlarged. Although the above changes occur predominantly in the muscle of the

² Prolonged treatment with the thyroid hormone as for obesity may set up a thyrotoxic state, and exophthalmos sometimes develops as part of the syndrome. The exophthalmos, however, is not due to a direct effect of the administered hormone but has the same pathogenesis as that of spontaneously developed Graves' disease.

eye they also occur, to a minor extent, in skeletal muscles

In summary, the suspicion is very strong that a principle derived from the hypophysis is responsible for the increased volume of the orbital tissues, and thus for the exophthalmos occurring in Graves' disease

Malignant exophthalmos is a very severe, and intractable form of exophthalmos, accompanied by ocular palsies. Brain prefers to call this condition *exophthalmic ophthalmoplegia*. The exophthalmos and weakness of the ocular muscles may be unilateral. The signs and symptoms of thyrotoxicosis are often mild, or, as after thyroidectomy, absent, in some cases, this severe form of exophthalmos occurs without evidence at any time of thyroid involvement. Proptosis of the eyeball is extreme, and drying of the corneal surface, ulceration or optic nerve injury is likely to result. The muscular weakness has been thought to be due to a coincident myasthenia gravis (which is not uncommonly associated with thyrotoxicosis), but its failure to be influenced by prostigmine disproves this supposition. It is probably due to stretching, and to infiltration and eventual fibrosis, of the muscles themselves.

Retraction of the upper eyelid is produced in a manner quite different from that which causes exophthalmos, being often present when the latter is absent. It is thought to be due either to increased tone of Mueller's palpebral muscle, which in conjunction with the levator palpebrae superioris elevates the upper lid, or to lessened opposition of striped muscle antagonists (orbicularis oculi) weakened by the action of excess thyroid hormone. The increased tone of Mueller's palpebral muscle is attributed to the action of the thyroid hormone in sensitizing this smooth muscle to adrenaline. Such action of the thyroid hormone upon sympathetically innervated structures is well known. Another example is the dilation of the pupil which occurs in hyperthyroid patients, but not in normal persons, when adrenaline is instilled into the conjunctival sac (Loewi's sign). The other lid signs are apparently due to a disorder of those muscles which constitute the lid closure mechanism and are thus probably due to excess thyroid hormone and not to the thyrotrophic principle.

The general muscular weakness seen in thyrotoxicosis is of two types. One type is an associated but independent muscular dystrophy which has become aggravated by the thyrotoxicosis. In the other category the weakness of the muscles is the direct effect of the thyrotoxicosis, in this type

there is, as a rule, little muscular wasting. In both forms there is a defect in creatine-creatinine metabolism (p 781), in the second, but not in the first, thyroidectomy, or the administration of iodine or of thiouracil abolishes the creatinuria.

TOXIC ADENOMA

A simple adenomatous goiter (p 1000) may undergo increased functional activity and produce the features of pure hyperthyroidism, i.e., those produced by the administration of thyroid extract in excessive amounts. The association of a benign secreting tumor (an adenoma), with signs of increased glandular function, may be seen not only in the thyroid but also in the case of the anterior pituitary (acidophile adenoma causing gigantism or acromegaly), the adrenal cortex (Cushing's syndrome), the parathyroids (hyperparathyroidism), or the pancreatic islet tissue (hyperinsulinism).

Although many intermediate states of hyperthyroidism are seen clinically which show features of both Graves' disease and toxic adenoma, it is believed by most authorities that the two extreme conditions may be distinct. Graves' disease commonly occurs in young girls, the whole thyroid gland becomes diffusely enlarged and hyperactive, and exophthalmos is a prominent feature. Toxic adenomatous or nodular goiter on the other hand, often has its onset in elderly patients, the adenoma itself may be the only actively functioning part of the gland (the rest of the gland is often atrophic), eye complications are very rare, and the dominant signs are cardiac disturbances.

It may be mentioned here that hyperthyroidism can be, though rarely is due to malignant tumors, carcinomata of the thyroid. Secondary metastases in bone may maintain a hyperthyroid state even after complete thyroidectomy.

ETIOLOGY OF HYPERTHYROID STATES

The etiology of adenomatous toxic goiter is akin to the etiology of any benign tumor formation, though why some adenomata remain non-secretory and are termed 'simple' whereas others become functionally active and give rise to thyrotoxicosis, is unknown. The typical case of toxic nodular goiter is, then, explicable in terms of a small localized tumor or tumors in the thyroid gland which are autonomously secreting excess thyroid hormone. The raised concentration of thyroid hormone in the blood inhibits thyrotrophin secretion so that the remaining areas of the thyroid are inactive and atrophic. The absence of exophthalmos may also be explained

on the grounds that the pituitary is not hyperactive in this condition

The etiology of Graves' disease is unknown, but there is suggestive evidence that the immediate cause of the hyperthyroidism is a rise in the blood level of thyrotrophic hormone. The sudden diffuse enlargement of the thyroid which occurs, implies that some external stimulus has impinged upon the gland. This stimulus is unlikely to be nervous in type, since the thyroid appears to lack a secretomotor nerve supply. Of the blood borne stimuli the most likely would appear to be an increased concentration of TSH. Direct data on this point were, until recently, absent since assay methods for measuring the blood concentration of TSH lacked the necessary sensitivity. In the last 10 years, however, improved methods have been used and several different groups of workers have found an increased blood level of TSH in some cases of Graves' disease. This is not a constant finding in all cases, and curiously seems to be related more to the degree of exophthalmos present than the hyperthyroidism. Recent work suggests that the thyrotrophic hormone found in some of these cases may have an abnormal action on the thyroid. It has been pointed out that a raised blood concentration of TSH in the presence of an increased concentration of thyroid hormone implies an extrathyroid defect in the feed back mechanism. It should be mentioned that some authorities do not agree that the hyperthyroidism of Graves' disease is to be explained as a disorder of the anterior pituitary. Werner points out, for example, that patients with active toxic diffuse goiter are uniformly responsive to the administration of thyrotrophin which would not be expected if a large excess of endogenous TSH were already present and maximally stimulating the gland.

A striking feature in the history of patients with Graves' disease is the frequency with which an emotional shock is reported preceding the onset of the condition. Studies have been made of the type of individual and type of emotional disturbance involved. It has been found that hyperthyroidism tends to develop in individuals who are highly dependent on their personal relationships with maternal or protective figures, and that it develops when this relationship is seriously threatened. It has been proposed that such psychological trauma might activate the hypothalamo-anterior pituitary mechanism since it has been shown that lesions placed in the anterior hypothalamus of animals result in decreased secretion of thyrotrophin and decreased

thyroid activity, and that electrical stimulation of the same hypothalamic region results in increased thyroid activity in rabbits. Another factor which has been considered in respect to Graves' disease concerns the activity of the adrenal cortex. Marine pointed out that thyrotoxicosis in the human is often associated with signs of adrenal cortical underactivity (lymphoid hyperplasia and a large thymus) and a small adrenal cortex. It has since been observed that Graves' disease occurs more frequently in patients suffering from Addison's disease than in normal persons may follow X ray damage to the adrenals, and is associated with a low or normal level of urinary adrenal steroids. The surprising feature is that the urinary excretion of adrenal steroids in Graves' disease is not greatly increased since the emotional and physical state of these patients would appear to be a strong stimulus to adrenal cortical activity.

From the above discussion it may be tentatively proposed that emotional trauma in the presence of a relative adrenal cortical deficiency, evokes increased discharge of thyrotrophin, thyroidal overactivity and thus the condition of Graves' disease. Such a view does not exclude nutritional, genetic, or other factors from playing a role. The available data are at the moment inadequate to draw any definite conclusion.

Iodine Metabolism

NATURAL OCCURRENCE OF IODINE Since iodine forms an essential part of the thyroid hormone it may be readily appreciated that a deficiency of iodine in the diet leads to disturbances of the thyroid gland, particularly to the development of goiter. Burnt seaweed or sponge, both of which are rich in iodine, have been employed in the treatment of goiter from the days of Hippocrates. Following the discovery of the element in the early part of the 19th century, its administration for the cure of many ills but especially of goiter, became the vogue. But as a result of its indiscriminate use, the true value of iodine was lost sight of. Studies of the geographical distribution of cases of goiter again indicated the importance of iodine. Goiter is not seen along the seaboard. The sea contains an inexhaustible supply of iodine which has been leached from the soil. Sea water contains about 0.02 mg. of iodine per liter, fresh water, as a rule, very much less. The further away from the ocean and the more mountainous the country, the lower is the concentration of iodine in food and water and the higher in consequence is the incidence of goiter.

The accompanying schema modified from

Lunde shows the distribution and circulation of iodine in Nature

To Marine and his associates is due the credit for establishing the value of iodine in the prevention of goiter. They found that iodine or sea food prevented the thyroid enlargement in brook trout hatcheries. Marine and Kimball carried out experiments upon a large number of school children in Akron, Ohio, where goiter was endemic. They showed that of the group of children given iodine (2 grams of sodium iodide in 10 daily doses twice a year) those who developed goiter amounted to only a small fraction of the number of goitrous individuals in a control group in which the iodine intake was not increased above that of the general population. The employment of small amounts of iodine in goiter districts such as Switzerland, New Zealand, Derbyshire in England, and in parts of the United States and Canada has proved to be a preventive measure of the utmost value. Many preparations of table salt have this essential added in a proportion of 1 part in 10,000 or so. Once goiter has become established iodine administration is of much less value but, as already mentioned, a hyperplastic parenchymatous goiter may be converted thereby to the less severe colloid type. The ingestion of iodine in much larger amounts than those mentioned above may induce hyperactivity in a simple goiter.

Iodine in the form of Lugol's solution² (10 to 40 minims daily) produces temporary amelioration in cases of exophthalmic goiter, and for this reason is used together with antithyroid drugs, in the preparation of patients for partial thyroidectomy. The amount of colloid in the gland increases and the vascularity decreases (fig. 574). Such treatment has markedly improved the operative mortality and almost eliminated the risk of a postoperative thyroid crisis. The bene-

ficial action of iodine in Graves' disease has been a puzzling problem and more than one theory has been proposed to account for it. It is possible that iodine inactivates thyrotrophin or interferes with the action of thyrotrophin on the thyroid or that it inhibits a proteolytic enzyme involved in the release of thyroxine from the gland.

IODINE REQUIREMENTS AND METABOLISM The following figures, quoted by Ruggs, are representative for the normal adult: daily intake of iodine 150 μ g, urinary excretion, 144 μ g per day, and fecal excretion, 6 μ g per day. Iodine is readily absorbed from the gastrointestinal tract and through the skin. The normal concentration of inorganic iodine in the serum is 1 μ g per 100 cc.

Studies on the metabolic path of iodine have been greatly aided by the use of radioactive iodine. Physiologically negligible amounts of the latter may be administered too minute in themselves to affect the metabolism of iodine in the body and the pathway of the isotope in the organism followed with ease by use of the sensitive counters and scaling equipment available. Following administration of tracer doses of I^{131} it has been found that radioactive iodine distributes in the blood and extracellular fluids and is accumulated by the thyroid and excreted by the kidney. After oral administration the blood concentration reaches a peak in 1 hour and then declines exponentially, the rate of fall depending on thyroid activity and renal excretion. Both the thyroid and the kidney remove I^{131} from the blood at a rate dependent on the plasma concentration. The amount excreted by the kidney varies with thyroidal activity. After thyroidectomy or administration of antithyroid drugs the renal excretion of I^{131} may reach 98 per cent of the administered dose. On the other hand, in hyperthyroidism the thyroid may accumulate a greater proportion of I^{131} than the kidney. Iodide is also normally concentrated and secreted by the salivary glands and gastric mucosa, but little of this finds its way into the feces since it is reabsorbed in the intestines. After incorporation in the thyroid gland into hormonal form it is secreted as part of the hormone molecule, a proportion of which will be degraded in the tissues with liberation of iodide. This iodide will then recirculate a second time, and is again partly accumulated by the thyroid and partly excreted by the kidneys.

A deficiency of iodine in the diet leads to the development of simple goiter. The deficiency may be (a) an absolute deficiency in drinking water and food, (b) a relative deficiency, the iodine

² Iodine 1 gram, potassium iodide, 2 grams water 30 cc.

of the food being sufficient for the elaboration of the amount of hormone required under the ordinary circumstances of life but insufficient under more exacting conditions, e.g., puberty, pregnancy, excessive protein of the diet, etc., and (c) it is also possible that certain microorganisms in the intestinal tract may reduce the quantity of iodine absorbed from the food, this would explain McCarrison's observations upon the relationship between the incidence of goiter in India and infected drinking water. It is more likely, however, that infected water, if it does sometimes play a part in the production of goiter, acts in some other way than by merely interfering with the absorption of iodine.

The quantity of iodine in the normal human thyroid is about 2 mg. per gram of dried tissue, the average total store in the gland is from 10 to 15 mg. A content below 1 mg. per gram of dry gland, according to Marine, is indicative of definite thyroid abnormality, in severe parenchymatous goiter, either simple or exophthalmic, it may be as low as 0.25 mg. or less per gram. In colloid goiters the general level is higher. Marine considers all goitrous enlargements, as examples of "a compensatory work hypertrophy," brought about by iodine deficiency. (The demands made upon the gland to produce its hormone without an adequate iodine supply results in hypertrophy and hyperplasia, or adenomatous growth, and in some instances, final exhaustion and atrophy. The different types of simple goiter are looked upon as stages in a process which is responsive to the iodine supplies, the gland sometimes passing several times through a cycle of hypertrophic, hyperplastic, and colloid changes, or the cycle may end in atrophy. The successive stages are represented in the following scheme after Marine. According to Rawson the thyroid may, in some instances, become restored to normal from the colloid goitrous state.

UPTAKE OF IODIDE BY THE THYROID GLAND The thyroid gland was shown some years ago by Marine to have a remarkable affinity for iodine. Though constituting only about 0.05 per cent or so of the body's entire iodine content. The rest of the body's iodine store is contained mainly in the skeletal muscles. The entire blood contains less than a milligram. Marine observed that when the thyroid was perfused with a solution of potassium iodide, relatively large quantities of iodine were taken up by the gland and could not be removed by subsequent washing. This result was not obtained by the perfusion of other organs, e.g., spleen, kidney, etc. The selective action of the intact thyroid for ingested iodine was also demonstrated. Over 18 per cent of iodine fed to normal animals was recovered from the gland, the fetal gland also stores iodine fed to the mother.

If a smaller tracer dose of I^{131} (2 to 4 μ c) be administered to an animal such as a rabbit an immediate, slow, steady increase of I^{131} in the thyroid gland follows and reaches a peak after about 30 hours. The I^{131} is taken up from the blood in the inorganic (iodide) form converted into organic compounds and stored as thyroglobulin. If diiodotyrosine or thyroxine is injected instead, then the uptake of iodine by the thyroid is delayed and occurs only after the organic compound is degraded and iodide released. The partial visualization of these processes has been made possible by the use of the radioautographic technique. Radioiodine in contact with a photographic emulsion acts upon it to give a dark mark when the emulsion is spread upon a microscopic section of thyroid tissue which has taken up the isotope. The latter's position in relation to the histological structure can be observed (fig. 57-8). Leblond and Gross used this technique to investigate the site of I^{131} in the thyroid at various time intervals after injection of the isotope into rats and guinea pigs. It was found that with animals on a high iodine diet the radioactivity in the thyroid was mostly present in the epithelial cells at 1 hour and in the colloid at 24 hours after injection. If the animals were placed on a low iodine diet, or thyroid activity was increased by injection of thyrotrophin, the deposition of radioactivity in the colloid was much accelerated since it was found there as early as 2 minutes after injection. These results imply that the chemical conversion of iodide to thyroglobulin occurs with rapidity in the thyroid gland. Two main steps may then be recognized in the formation of hor

FIG. 57.8 Radioautographs of rat thyroids stained with hematoxylin and eosin. The location of radioactivity is indicated by the accumulations of black granules. In these sections the radioactivity is present as radioactive iodine incorporated in the thyroglobulin molecule. *A*: Thyroid of a rat sacrificed 1 hour after injection of radioiodine. In most of the follicles the radioactivity is arranged in the form of rings because the newly formed radioactive thyroglobulin is present in the epithelium of the thyroid follicle. *B*: Thyroid of a rat sacrificed 24 hours after injection of radioiodine. The photographic reaction is present over the colloid of the thyroid follicles and eating that the thyroglobulin formed in the cells at 1 hour is deposited in the colloid some 24 hours later. (From Leblond and Gross, in *Essays of Dr. C. P. Leblond*.)

more in the thyroid. First the accumulation of inorganic iodide from the blood stream by thyroid cells. This avidity of the gland for iodine occurs against a concentration gradient and is said to be due to an *iodide trapping mechanism* on the part of the gland. And second the conversion of the iodide into organic combination and storage as thyroglobulin. These two processes may be separately and individually blocked by different pharmacological agents. Thiocyanates, perchlorates and other anions block the iodide-trapping activity of the thyroid, whereas various thiocarbonamides and other compounds (see pp

1012-1013) do not interfere with the iodide-concentrating ability of the thyroid but do inhibit the organic binding of the iodide (therefore, any iodide taken up by the gland is not converted into hormonal form but remains as inorganic iodide). The use of an antithyroid drug of this latter type makes it possible to measure the iodide trapping ability of the thyroid. After blocking organic binding by administration of a drug such as propylthiouracil a dose of I^{131} is given and 1 hour later the animal is killed and the concentration of I^{131} measured in the serum and in the thyroid. The ratio of thyroid:serum I^{131}

concentration (T/S ratio) gives a measure of the ability of the gland to accumulate iodide. Blockage of organic binding is necessary, otherwise part of the I^{131} accumulated by the thyroid would be secreted as hormone and lost to the gland. Typical values for the T/S ratio in the rat are about 50 in the normal animal, 250 for the animal under the influence of excess thyrotrophin, and about 2 after hypophysectomy.

THE FORMATION OF THYROID HORMONE

A glycerine extract of sheep's thyroids was first employed successfully by the English physician George Murray in 1891, for the relief of myxedema. The thyroid tissue itself when given by mouth was shown subsequently to be physiologically active. Brumann in 1896, discovered that iodine was an important constituent of the thyroid extract. By acid hydrolysis of thyroid tissue, and later by peptic digestion, he obtained a brownish powder containing 10 per cent of iodine and possessing the physiological activity of the whole gland. He believed that the iodine was present in organic combination and named the compound *iodothyron*. It was shown subsequently by Oswald (1899) that the active iodine constituent was attached to a protein, *thyroglobulin*, which is the chief component of the colloid material filling the alveoli of the gland. Thyroglobulin contains both diiodotyrosine and thyroxine joined to the protein molecule by peptide linkages. It is looked upon as the storage form of the thyroid hormone.

The active principle of the thyroid was isolated in crystalline form by Kendall in 1919. He named the substance *thyroxin*^{*} and found that it contained 65 per cent of iodine and an amino group. Harington and Barger in 1927, established the chemical form of thyroxine and effected its synthesis. It was found to be constituted of 2 benzene rings united by an oxygen bridge, and to contain four atoms of iodine and an amino acid (alanine) side chain. The synthesis required a number of separate steps.

3,5-Diiodo-4-(4'-methoxyphenoxy)benzaldehyde contains iodine atoms in the same positions as two of those in natural thyroxine.

3,5-Diiodo-4-(4'-methoxyphenoxy)benzaldehyde

^{*} Now spelled *thyroxine*

This compound having been prepared, the amino group was attached by condensation with hippuric acid. The resulting compound was boiled with NaOH in alcohol and then with acetic anhydride and hydriodic acid. The product of these procedures, 3,5-diiodothyronine, readily takes up 2 additional atoms of iodine with the formation of thyroxine, when treated with a concentrated solution of iodine in potassium iodide (see formula).

Synthetic thyroxine possesses physiological properties identical with those of the natural product.

3,5,3'-Triiodothyronine has also been found to be physiologically active. It has in fact greater activity than thyroxine in preventing thyroid-induced goiter in rats and in stimulating oxygen consumption in various forms. Gross and Pitt-Rivers in 1932, produced strong evidence that this compound was identical with an unknown factor previously found to be present in rat thyroid and blood. These same workers managed to isolate triiodothyronine from the thyroid. In simultaneous and independent studies Roche and coworkers were able to synthesize 3,5,3'-triiodothyronine and also to detect its presence in hydrolysates of rat thyroid tissue. These studies have been confirmed and triiodothyronine has now been identified in the thyroid of the human and other forms, in human blood and in the venous blood from the thyroid of the sheep, horse, and calf. There can be no doubt that it should be included with thyroxine as a hormone secreted by the thyroid gland.

3,5-diiodothyronine

Thyroxine (3,5,3',5'-tetraiodothyronine)^{*}

Thyroxine is formed in the thyroid gland from diiodotyrosine.

^{*} The numbering of the positions in the thyroxine nucleus is shown below.

Di iodotyrosine

This compound is formed in the body from tyrosine (fig 57 9) and certainly represents a stage in the synthesis of thyroxine, when added to slices of surviving thyroid tissue di iodotyrosine is converted to thyroxine. Di iodotyrosine itself has only slight physiological activity. Most of the organic iodine in the thyroid is in this form, a much smaller part being present as thyroxine. Four separate processes (see fig 57 9) or steps are required for the synthesis of thyroxine, (a) the concentration of iodide in the gland, (b) the oxidation of iodide to elemental iodine, (c) the combination of iodine with tyrosine, and (d) the oxidative coupling of di iodotyrosine molecules, forming a diphenyl ether with the loss of one alanine side chain. The thyrotrophic hormone (TSH) of the pituitary gland appears to be neces-

sary for all four steps. The mechanism responsible for the oxidative reactions, second and third steps, is not definitely known, but the most probable theory which has been proposed is that both the iodination of tyrosine and the coupling of two molecules of di iodotyrosine are effected through an enzyme system in which *peroxidase* plays an essential part. Fine granules in the thyroid cells which give the histochemical reaction characteristic of peroxidase have been described by Dempsey. The enzyme has not, so far, however, been extracted from thyroid tissue, but in support of this theory is the fact that such antithyroid drugs as thiourea and thiouracil inhibit peroxidase action. An experiment performed by Keston is of great interest and suggests the type of reaction that may take place in the thyroid gland. When radioactive iodide was added with xanthine to milk and the mixture incubated, thyroxine containing the isotope was formed. The xanthine oxidase in the milk, acting presumably upon the xanthine, liberated hydrogen peroxide which in

FIG 57 9 Diagram depicting the steps in hormone synthesis, storage, and secretion by a thyroid cell (From Rosenberg and Astwood)

the presence of milk peroxidase oxidized the iodide to iodine which was introduced into tyrosine groups. Thyroxine was then formed by the coupling of diiodotyrosine molecules. If thiourea were added before incubation no thyroxine was formed.

Additional evidence for the peroxidase theory is afforded by the observation of Harington that hydrogen peroxide hastens the *in vitro* iodination of protein (see below).

Other enzyme systems, e.g., cytochrome and tyrosinase, have been suggested as playing the chief role in thyroxine synthesis, but this is unlikely, for the cytochrome system is not inhibited by thiourea or thiouracil. Tyrosinase has not been demonstrated in thyroid tissue nor does the inhibition of its action by thiourea derivatives run parallel with the antithyroid activity of these drugs.

The formation of triiodothyronine in the thyroid could be effected by the coupling of one

3 5 3' triiodothyronine

molecule of monoiodotyrosine with one molecule of diiodotyrosine, or by the removal of iodine from thyroxine.

For further information on the thyroid hormone the monograph of Pitt-Rivers and Tata may be consulted.

EXTRATHYROIDAL SYNTHESIS OF HORMONE

It has been suggested that tissues in the body, other than the thyroid gland, can manufacture small amounts of thyroid hormone. Such a view was suggested on the grounds that thyroidectomized rats fed on a high iodine diet show a slightly higher consumption of oxygen than similar animals on a low iodine diet. It was also claimed that thyroxine could be isolated from tissues of thyroidectomized animals. However, these findings have not been substantiated. Although certain tissues, such as that of the lactating mammary gland and the gastric mucosa, concentrate iodine and may contain a fraction of this in organic form, it is to be doubted whether compounds with the activities of thyroid hormone are formed in this manner. Such a possibility is of little practical significance, since complete thyroidectomy is followed by myxedema.

The Iodination of Protein and the Artificial Synthesis of Thyroxine

The remarkable discovery was made some years ago that the iodination of casein, serum protein, and other proteins, followed by hydrolysis, yielded crystals of thyroxine possessing the characteristic physiological activity. The first experiments in which the *in vitro* synthesis of thyroxine was demonstrated were performed by Abelin. His results were published in a series of papers from 1934 to 1938. His claim was not, however, generally accepted until the same result was obtained by Ludwig and Mutzenbecher in 1939. They gave an account of the method, a clear chemical description of the product obtained, and described its physiological property. It was also shown that a small amount of thyroxine was formed spontaneously simply by prolonged incubation in alkaline solution. These findings were soon confirmed by Harington and Rivers and in several other laboratories. Iodinated protein causes all the physiological effects of thyroid extract, relieves myxedema, and in large doses induces thyrotoxicosis.

The Storage and Release of Thyroid Hormone

It is likely that the iodination of tyrosine in the thyroid gland occurs when the amino acid is incorporated in protein rather than when it is in the free state. Studies of the iodine-containing compounds in the thyroid gland after injection of I^{131} , suggest that thyroxine is first produced as the bound form in thyroglobulin and that the free hormone is formed subsequently. The characteristics of the thyroglobulin molecule may in some way facilitate the formation of hormonally active triiodothyronines as end groups in the protein molecule, and their attachment in loose surface bonds may be related to the regulation of the rate of hormone secretion.

Thyroglobulin has a high molecular weight (about 650,000), a fairly constant amino acid composition, but an iodine content that varies with the functional state of the gland from which the protein was extracted. Recent studies indicate that even within the thyroid gland of a single animal the thyroglobulin is not completely homogeneous. If different thyroglobulins exist it is possible that they are the products of different follicles in a gland, that are in varying states of functional activity.

The fact that the thyroid hormone is stored in combination with a protein and that simpler molecules, thyroxine and triiodothyronine, form

FIG. 57-10. Cells of the thyroid of a rat which had been injected 22 hours previously with the thyroid stimulating hormone (TSH) of the pituitary. The intracellular droplets of colloid are increased in number and are collected toward the basal part of the cell from where they are discharged into the capillaries. The first effect of TSH within 30 minutes or so is to cause an increase in intracellular colloid which is accumulated toward that part of the cell abutting on the follicular lumen. The reversal of the direction of the movement of the droplets, i.e. from the free to the basal part of the cell commences in about 6 hours after the administration of TSH. *c*: Colloid in lumen of the follicle; *c*: capillary; *E*: erythrocyte in capillary. (From De Robertis.)

the circulating hormone leads to the question whether a proteolytic enzyme exists in thyroid tissue by which the thyroglobulin is broken down to permit the smaller thyroxine molecule to enter the circulation. Such an enzyme has been demonstrated by De Robertis in the colloid of the gland and was found to increase in activity by 100 per cent in thyrotoxicosis and to be reduced in hypothyroidism. The thyrotrophic hormone of the pituitary activates this enzyme as the researches of De Robertis have demonstrated. Within a few minutes after the injection of TSH, droplets appear in the cells lining the alveoli of the gland. These intracellular droplets appear to be different in composition from the colloid of the alveoli and are believed to be composed of smaller molecules derived from hydrolysis of the latter (fig. 57-10).

Pharmacological Agents and Hormone Synthesis

In 1928 Chesney and his associates observed that rabbits which were on a diet of cabbage became goitrous. Other members of the *Brassica* family, e.g. cauliflower, Brussels sprouts etc., are also goitrogenic. Rape seed was also found by Kennedy and Purves to cause goiter in man. Cases of goiter in man resulting from a diet containing a large proportion of cabbage have been reported. A characteristic of vegetables of the *Brassica* family is their relatively high content of

cyanogen compounds. Taking this hint Marine and his associates gave various cyanides to rabbits and obtained a marked thyroid enlargement. Methyl cyanide was especially effective. The thyroid hyperplasia was accompanied by exophthalmos. Marine suggested that the goitrogenic effect of cyanides was dependent on their property of depressing tissue oxidations, increased thyroid function being a compensatory effect instituted to oppose this action. The effect of cyanide on the thyroid more probably reflects the fact that the iodide trapping mechanism requires energy. *In vitro* studies with surviving thyroid tissue showed that cyanide inhibits this mechanism.

The goitrogenic activities of the above food stuffs fall into at least two classes. The goitrogenic action of a cabbage diet may be inhibited by administration of iodide, whereas the goitrogenic action of brassica seeds is not reversed by iodide but can be inhibited by thyroxine administration.

It has been mentioned above (p. 1008) that the chemical processes concerned in the synthesis of hormone in the thyroid gland may be blocked at two separate points by different pharmacological agents. (a) Thiocyanates inhibit the process by which the thyroid gland extracts iodide ions from the blood. The goitrogenic action of thiocyanate is inhibited by iodide administration. (b) Drugs such as thiouracil block the process by which the gland binds iodide into organic combination. The

goitrogenic action of these drugs is not inhibited by iodide administration but is reversed by giving thyroxine

1 **THIOCYANATES AND THE IODIDE TRAPPING MECHANISM** Potassium thiocyanate is a more recently discovered goitrogen than the cyanide compounds of Marine. It is a normal metabolite and, it will be recalled, is excreted in the saliva. Its action on the thyroid was first observed by Barker in two patients under treatment with the drug for hypertension. Goiters developed in these cases. In rats, thiocyanate inhibits the uptake of iodide by the gland and thereby causes goiter. The primary action of this drug appears to be on the iodide trapping mechanism. In spite of its avidity for iodide, the normal thyroid gland contains very little inorganic iodide since the iodide is rapidly incorporated into organic form. If this organic binding is blocked with a drug such as propylthiouracil, inorganic iodide accumulates in the thyroid. In such a gland, which has accumulated a quantity of inorganic I^{-} , thiocyanate evokes a prompt discharge of I^{-} through the inhibitory effect it exerts on the iodide "pump" of the gland. Chronic administration of thiocyanate results in reduced iodide uptake by the thyroid, a reduced rate of hormone synthesis, a fall in blood level of thyroid hormone and, thereby, an increased secretion of TSH and the development of a goiter. It is of interest that the uptake of iodine and the rate of synthesis and release of hormone may be returned toward normal values in the thiocyanate treated animal by increasing the iodine intake. Presumably, the increased concentration of iodide in the blood allows sufficient halogen to enter the gland by diffusion. Other anions, such as chloride, perchlorate, hypochlorite, iodate, periodate, biiodate, and nitrate have a similar effect on the thyroid to thiocyanate.

2 **ANTITHYROID DRUGS AND THE ORGANIC COMBINATION OF IODIDE** In 1941, Mackenzie and co-workers reported the goitrogenic action of sulfa guanidine, and in 1943, the same group, and also Astwood and his colleagues, gave an account of the effects of some sulfonamides and thioureas on

the thyroid. Because of the possible clinical significance of such compounds a great deal of work was undertaken to find antithyroid drugs that are nontoxic. Over 100 drugs possessing antithyroid activity to varying degrees have now been discovered. In general they fall into two groups, those with a thiocarbonamide grouping (thiourea, thiouracil) and those with a substituted benzene ring (*p*-aminobenzoic acid, sulfonamides, phloroglucinol).

These antithyroid drugs inhibit the synthesis of thyroid hormone by preventing the binding of iodide ions into organic compounds. This results in an increased concentration of inorganic iodide, and a fall in hormone content of the gland. A fall in concentration of thyroid hormone in the blood follows, with a consequent increased rate of secretion of pituitary thyrotrophin and all the anatomical and histological changes in the thyroid normally produced by excess TSH. That the goitrous and hyperplastic changes in the thyroid produced by antithyroid drugs are mediated by the pituitary is shown by the fact that they do not occur in hypophysectomized animals and that they are inhibited by simultaneous administration of exogenous thyroxine. The degree of inhibition is quantitatively related to the dose of thyroxine, and measurement of the least amount of thyroxine that prevents hyperplasia of the thyroid gives a method for estimating the normal daily secretion of thyroid hormone. Thyroxine and allied compounds are thus said to possess *antigoitrogenic properties*. However, the direct action of antithyroid drugs in blocking iodide-combining activity and their indirect goitrogenic action should be clearly distinguished. There is no evidence that these compounds affect the other actions of the thyroid such as the iodide trapping mechanism or the release of preformed thyroid hormone. It has been suggested by Pitt-Rivers that the thiocarbonamide group of antithyroid drugs exert their direct effect by keeping the iodine in the gland in a reduced state. However, this view could not account for the action of the sulfonamides or resorcinol compounds, and it is now generally believed that all the antithyroid drugs act by inhibiting the peroxidase enzyme system in the thyroid.

A species difference exists in the action of the drugs of the benzene derivative class. Whereas the members of the thiocarbonamide group appear effective in all forms, those of the benzene group are active in the rat and mouse but much less so in the chick and human.

Rawson and his associates have produced evi

2 Thiouracil

dence that the thiol compounds have a further direct effect on thyroid tissue, that is that they augment the action of TSH on the gland. The thyroids of rats given thiouracil for only 24 hours showed hyperplasia at the end of this period yet no fall in the blood level of protein bound iodine occurred. This finding would be compatible with the observed augmentation of the action of TSH already in the circulation. Further, TSH and thiouracil given simultaneously to cockerels produced a greater increase in acinar cell height than TSH alone.

Antithyroid drugs are used clinically either on a short term basis to prepare a thyrotoxic patient for operation or on a long term basis in an attempt to control hyperthyroidism without recourse to surgery or radioactive iodine treatment. However it should be remembered that prolonged treatment with these compounds [such as propylthiouracil or methimazole (1-methyl-2-mercaptoimidazole)] does result in rare cases in toxic effects such as agranulocytosis and that even though the remission of the thyrotoxic state has been induced for several years by drug therapy cessation of administration results in recurrence of hyperthyroidism in about half the cases.

THE SECRETION AND TRANSPORT OF THYROID HORMONE

It has been mentioned above that thyroxine is formed in the thyroid gland as part of the thyroglobulin molecule. Only a small part of the thyroxine in the gland is in the free form (less than 1 per cent) and this probably represents the immediate source of serum thyroxine. The secretion of hormone from the gland to the blood seems to involve an enzymatic proteolysis of thyroglobulin in the gland with liberation of free thyroxine which enters the blood stream. The rate of release of hormone from the thyroid is very largely regulated by pituitary thyrotrophin and present data indicate that the first effect of TSH on thyroid function is to increase the rate of release of hormone. Studies on the radioactive content of thyroid vein blood have shown that in such forms as the rabbit and cat this may occur in less than half an hour. From this evidence it might be suggested that the primary action of TSH on the thyroid is to regulate the release of thyroidal hormone and that the other effects are secondary to this. However, it should not be forgotten that TSH evokes thyroid hypertrophy when hormonal synthesis has been blocked with antithyroid drugs.

After the discovery of thyroglobulin and thyroxine in the thyroid gland it was thought that the hormone secreted into the blood might be a polypeptide. Harington discussed this possibility with the facts in mind that the physiological potency of whole thyroid substance did not seem explainable in terms of its thyroxine content (now explained by the presence of the more potent triiodothyronine in thyroid tissue) and that thyroid hormone in the blood is precipitated by protein precipitants (now explained by the binding of thyroxine to plasma protein, see below). Immunological studies showed that only in exceptional circumstances (associated with thyroid disease and damage) was thyroglobulin present in the circulation. In 1948 Taurog and Chaikoff showed that thyroid hormone labelled with I^{131} in the circulation behaved in an identical way to thyroxine added to the blood. It is now generally accepted that the thyroid hormone in the circulation is thyroxine together with a small amount of triiodothyronine.

The normal rate of secretion of thyroid hormone has been estimated in a variety of ways by measuring (a) the amount of thyroxine necessary to restore to a normal state the thyroidectomized animal or thyroidectomized or myxedematous patient (b) the smallest quantity of thyroxine to give a maximal depression of the thyroidal uptake of I^{131} or of the thyroidal release of I^{131} labelled hormone (c) the minimum quantity of thyroxine necessary to prevent enlargement of the thyroid or cytological changes in the pituitary after treatment with antithyroid drugs and (d) the rate of accumulation of iodide by the gland. The most direct method of assessing thyroid activity (the amount of hormone liberated per unit time) would be to measure the blood flow through the gland and the hormone content of the arterial blood passing to and the venous blood leaving the gland. Such measurements can be made but unfortunately the stress of the manipulations involved in anesthesia and manipulative trauma result in a rapid reduction of thyroid function. Average figures for the daily secretion of thyroxine are 0.2 to 5.2 μg per 100 grams of body weight per day in the chicken, rat, rabbit, goat, cow and man. In absolute figures the rat secretes about 8 μg of thyroxine per day, the rabbit about 18 μg per day and the human about 200 to 300 μg per day. The larger the animal the less hormone (on a weight basis) is secreted per day. This may be correlated with the fact that the greater the body weight the less the surface area of the body per unit weight and thus the less is the heat loss per unit weight. The amount of hormone secreted per day will of course vary widely in the normal animal.

according to environmental conditions. Thus, Dempsey and Astwood found that the normal rat secretes 9.5 μg of thyroxine per 100 grams of body weight per day at an environmental temperature of 1°C , 5.2 μg per 100 grams per day at 25°C , and 1.7 μg per 100 grams per day at 35°C .

The concentration of thyroid hormone in the blood is probably maintained at a more constant level than is the rate of secretion of hormone from the gland. This is because the blood level represents a balance between the rate of secretion and the rate of metabolism or excretion of the hormone. Iodine exists in the blood stream as inorganic iodide and as organically combined iodine. This latter is precipitated by protein precipitants and is commonly referred to as protein bound iodine (PBI). The PBI represents largely hormonal iodine and has an average value in the normal human of 4 to 8 μg per 100 cc of serum. In cases of hyperthyroidism this figure may rise to 20 μg per 100 cc or over, and in myxedema fall to 1 μg per 100 cc. It is important to note that misleadingly high figures are obtained if the patient has been treated previously with large quantities of iodide or with organic iodine compounds such as those used in X-ray diagnosis.

Thyroxine is carried in the blood stream bound to serum proteins. An α globulin has the highest binding affinity for thyroxine and is commonly referred to as thyroxine binding protein (TBP). If the amount of thyroxine in serum is raised, increasing amounts of thyroxine become bound to albumin. The "binding" of thyroxine to plasma proteins must be clearly distinguished from the peptide linkage uniting thyroxine to thyroglobulin in the thyroid gland. The fact that butanol extracts thyroxine from serum shows that only a relatively loose attachment between thyroxine and TBP occurs. The protein binding of thyroid hormones in serum may modify their peripheral action. It is possible that the lower affinity of TBP for triiodothyronine, than for thyroxine, may account for the faster, greater, and shorter lived physiological activity of triiodothyronine. Also conditions in which the plasma proteins are decreased or increased in amounts may affect the blood concentration of thyroid hormone. Thus in nephrosis low blood levels of TBP and PBI coexist, and during pregnancy the reverse is the case. In nephrotic patients signs of hypothyroidism are commonly present in pregnancy; a diet relatively low in iodine may result in goiter.

THE ACTIONS OF THYROID HORMONE

Many of the actions of thyroid hormone in the human were given at the beginning of this chapter when the clinical pictures of hyper- and hypothyroidism were described. The experimental investigation of the physiological effects exerted by the thyroid gland has likewise involved the study of hypothyroid states (produced by surgical or chemical thyroidectomy) and their repair, and hyperthyroid states (produced by administration of thyroxine or triiodothyronine). The qualitative effects produced by thyroxine and triiodothyronine are similar, but triiodothyronine acts more quickly, is usually (according to the effect studied) the more potent of the two compounds, and has a shorter lived action. The long latent period of action of thyroxine at one time gave rise to the view that thyroxine was not the hormone secreted by the gland. After it was established that triiodothyronine is a normal secretion product of the thyroid the possibility was considered that thyroxine was converted into triiodothyronine in the tissues, and formed, therefore, a "precursor" of the hormone. However, the evidence is now strong that both thyroxine and triiodothyronine are secreted by the gland and that both substances act as such at a tissue level.

1. **HEAT PRODUCTION, CALORIGENESIS** Magnus and Levy in 1895, first described the low oxygen consumption of patients with myxedema and showed that thyroid feeding raised the basal oxygen intake in the human. The effect of a single administration of thyroxine upon the basal metabolic rate is slowly developed but prolonged (fig. 57-11), it commences after a lapse of 12 to 48 hours, reaches its maximum in 8 to 10 days, and lasts for 5 or 6 weeks. Thyroxine brings about the combustion of a relatively enormous amount of material, 1 mg. causes the total CO_2 output to increase by some 400 grams and the heat production to increase by about 1000 calories. In the athyroid human the basal metabolic rate may be only one half the normal value, whereas in severe thyrotoxicosis it may be double. To maintain a normal basal metabolic rate in myxedema requires the daily administration of about 200 to 300 μg of l thyroxine.

In vitro studies of the oxygen consumption of tissues taken from animals rendered hyper- or hypothyroid show that these tissues have an increased or decreased exchange, respectively. Thus the calorogenic action of thyroid hormone is exerted directly on the cells rather than through the

FIG 57 11 Effect of thyroxine on a myxedematous patient (From Harrington)

nervous system. It should be noted that if thyroxine is added to the incubation medium containing tissue taken from a normal animal, no calorogenic effect is observed.

Such obvious mental changes are observed in Graves disease and myxedema that thyroxine might be expected to exert a marked effect on cerebral metabolism. However, this does not seem to be the case since the respiratory metabolism of tissue from the brains of rats rendered hyper-

or hypothyroid is normal. In this respect brain tissue behaves differently from other bodily tissues. Similarly, the cerebral oxygen consumption of thyrotoxic patients is not increased, although oxygen and glucose consumption of the brain has been reported as low in myxedema.

The various effects of the thyroid hormone upon the development and differentiation of skeletal nervous and other tissues cannot be explained by its property of increasing combustion in the cells. A substance such as dinitrophenol, which increases heat production, has no such action.

2. GROWTH AND DIFFERENTIATION. The earliest and clearest evidence that the thyroid is closely concerned with tissue differentiation came from the experiments of Gudernatsch in 1912. He showed that feeding thyroid tissue to frog tadpoles resulted in early metamorphosis and the production of small frogs. Later studies showed that thyroidectomized tadpoles fail to metamorphose and develop into abnormally large larval forms. The human cretin, besides showing retardation of growth, shows marked failure in the maturation of the skeletal and other bodily systems. The growth process is influenced both by growth hormone (STH) from the anterior pituitary and by thyroid hormone (fig 57 12), whereas the process of maturation and differentiation (formation of ossification centers in the epiphyses, eruption of primary and secondary dentition) is more solely influenced by the thyroid hormone. For example, hypophysectomized young rats treated with growth hormone show

FIG 57 12 Showing the effect of thyroid on growth. Above: 81-day-old cretin rat (50 grams) from a mother which had been treated with thiourea for the entire gestation period. Below: normal untreated animal (160 grams) of the same age. (From Goldsmith and associates.)

bony growth but abnormal development of epiphyses whereas treatment of similar animals with thyroxine results in slight growth of the bones but marked stimulation of epiphyseal development and bony maturation. The growth and development of the brain appears to be particularly dependent on thyroid hormone. The retarded mentality or imbecility of the cretin may not be completely reversible by treatment with thyroxine even though therapy is started in the first year of life. Experimental studies have shown that young animals rendered hypothyroid, surgically or with drugs, show impaired growth of the brain, decreased size of cortical neurones, a decreased density of the neuropile between the cortical neurones, and retarded myelination of cerebral nerve tracts.

3 METABOLIC PROCESSES. The increased basal metabolic rate typical of hyperthyroidism is associated with a normal fasting respiratory quotient. The ratio of the different foodstuffs metabolized remains within normal limits. Increased protein catabolism and an increased excretion of urinary nitrogen occurs in both hyper and hypothyroidism. The administration of small doses of thyroxine to hypothyroid animals results in protein deposition. This may be correlated with the increased growth which occurs in young hypothyroid animals under therapy. Creatinuria is typical of the hyperthyroid state. An increased concentration of blood lipid and cholesterol occurs with thyroid deficiency, and has some diagnostic significance in suspected cases of myxedema. An increased excretion of calcium, sometimes in association with osteoporosis, occurs in hyperthyroidism, this may, though rarely, result in bony fractures. In the absence of the thyroid hormone the conversion of carotene to vitamin A is impaired, possibly through defective intestinal absorption of carotene. The occasional failure of night vision in cases of myxedema may be thus explained. Administration of thyroid hormone to the lactating animal results in a temporary increase in milk yield and an increase in the fat content of the milk. It is probable that this action is mediated by an increased blood flow to the mammary gland and by stimulation of the metabolic processes of the glandular cells themselves.

THE CELLULAR ACTION, METABOLISM, AND EXCRETION OF THYROID HORMONE

The manner in which thyroxine exerts its effects on oxidative processes, growth, and differentiation, at a cellular level, is unknown. At

one time it was thought very probable that thyroxine, and other hormones, owed their effects to an action on enzyme systems. At the present time more attention is being paid to the possibility that the hormones act by modifying the permeability of cellular and subcellular (mitochondrial) membranes.

Our knowledge of the metabolism of thyroid hormones has increased rapidly since the introduction of radioactive iodine and radioactive thyroxine. Chromatography has allowed the separation and identification of the different labelled iodine compounds from body fluids and tissues and provided a useful analytical tool. After injection of radioactive thyroxine the blood concentration falls rapidly at first (as the hormone is distributed in the tissues) and then more slowly (as the hormone is metabolized and excreted). The half life of thyroxine in the blood is about 8 days in man, 4 days in the rabbit and guinea pig and only 18 hours in the rat. Thyroxine is taken up rapidly by the liver and bile and accumulates more slowly in the intestines, muscle and skin. These latter two tissues, though, ultimately contain a significant fraction of administered hormone owing to their large bulk. It is of interest that different parts of the brain and pituitary gland show a selective absorption of radioactive thyroxine and triiodothyronine. This occurs mainly in the nuclear areas of the brain (Ford and Gross), and especially in the neurosecretory nuclei of the hypothalamus (supraoptic and paraventricular nuclei) and in the neurohypophysis and pars distalis of the adenohypophysis. Although the total amounts of hormone taken up in these tissues is small the concentration of I^{131} triiodothyronine in the neural lobe of the rabbit pituitary may reach 40 to 50 times the plasma concentration. It is tempting to speculate that the hypothalamic and hypophysial uptake of these compounds is related in some way to the homeostatic effect exerted by the feed back mechanism of thyroid hormone over TSH secretion.

It has long been known that the liver concentrates thyroxine and secretes it in the bile. Although part of the thyroxine appears as such in the bile a greater part is conjugated in the liver with glucuronic acid and secreted as such. This is a process of some magnitude, after the injection of radiothyroxine into a rat, about half the radioactivity is found in the bile in the first 24 hours. The glucuronide is hydrolyzed by bacteria in the gut and free thyroxine liberated. The greater part of the thyroxine is then reabsorbed through the gut wall, once more to enter the blood stream, whereas the remainder is excreted in the faeces. The cycling of thyroxine through the liver gut, and back to blood is referred to as the enterohepatic circulation. The amount of thyroxine excreted in

the feces varies with the species studied, and expressed as a percentage of an administered dose, is approximately 65 per cent in the rat, 50 per cent in the rabbit, and 10 per cent in man. The remainder of a dose of radiothyroxine is largely deiodinated in the tissues and the radioiodide so liberated is shared between thyroid and kidney. The main excretory path of thyroid hormone in man is, thus, the kidney—the urine containing largely inorganic iodide as a degradation product of the hormone.

The Assay of Thyroid Hormone

Chemical assay A given extract of thyroid tissue may be assayed by determining its content of iodine bound in thyroxine according to the method of Harington and Randall. As indicated above the blood concentration of thyroid hormone is assayed by estimating the iodine in organic combination in the blood.

Biological assay Several biological criteria have been used in testing the thyroid potency of an extract, e.g., the rate of carbon dioxide production in mice, the rate of oxygen consumption in rats, the sensitivity of rats to oxygen lack, and the rate of metamorphosis of tadpoles as described by Gudernatsch. With the introduction of radioactive iodine a more detailed method became available. The thyroid activity of different compounds may be assessed by their ability to inhibit TSH secretion and therefore to inhibit the thyroidal uptake of I^{131} or release of I^{131} labelled hormone. A further method also involving the feed back mechanism employs the antithyroid drugs. After blocking the release of endogenous thyroid hormone with these drugs the least amount of an extract which prevents goiter formation is measured. Both these latter two methods assay hormone activity within the range of the normal daily secretion rate of the thyroid gland of the assay animal used.

The Measurement of, and the Factors Regulating, Thyroid Activity

The measurement of thyroid activity may be made by observations on the gland itself, by assessing the blood concentration of thyroid hormone, or the magnitude of the peripheral effects exerted by the hormone. The requirements vary somewhat according to whether the test is to be applied to the human or to the laboratory animal.

1. Thyroid uptake of iodine Following an injection of I^{131} (half life 8 days) or I^{125} (half life, 2.26 hours) the rate of uptake of the isotope by the thyroid gland is followed. For acute experiments on the laboratory animal this is most accurately assessed by killing the animal 1 to 2 hours after injection, dissolving the thyroid in alkali, and counting an aliquot of the solution. In

clinical studies the uptake is followed by external counting over the neck.

2. Urinary excretion of I^{131} Since an injected dose of iodide is mainly shared by the thyroid and the kidney, measurement of the excretion rate of I^{131} in the urine indirectly measures the thyroid accumulation of I^{131} .

3. Release of I^{131} labelled hormone from the thyroid The turn over rate of thyroid hormone in the normal human gland is too slow for this method to be of value in man. In the experimental animal the amount of radioactive hormone in the thyroid is followed by external counting over the neck. After correcting for the physical decay of the I^{131} , the rate of decline of radioactivity in the gland is related to the rate of secretion of thyroid hormone.

4. Thyroid histology Measurement of the average height of the acinar cells of the thyroid has been used to assess thyroid function in laboratory animals.

5. Blood hormone As mentioned previously estimation of the protein bound iodine (I^{127}) gives a measurement of the blood concentration of thyroid hormone. Following an injection of I^{131} the rate of rise of radioactive hormone in the blood may be followed. This method has been found useful in distinguishing suspected cases of hyperthyroidism.

6. Methods based on the peripheral action of thyroid hormone Measurements of the basal metabolic rate and the concentration of serum cholesterol or fasting serum creatinine are used clinically as indications of thyroid activity.

Many factors influence the activity of the thyroid gland. Some of these have been discussed elsewhere and will only be mentioned briefly below.

Iodine deficiency (see p. 1006). A deficiency of iodine in the diet leads to hyperplastic changes in the gland and, eventually, to a state of exhaustion atrophy. Between wide limits of iodine intake thyroid function proceeds normally. In the presence of excess iodine, however, the organic binding of iodine by the thyroid is inhibited for at least a temporary period.

Diet It has been claimed that a faulty diet, such as one containing an excess of fat or fatty acids, an excess of protein, or a deficiency of vitamins A or C, may lead to goiter in animals, and presumably, therefore, in man.

Thiocyanate, perchlorate, and the antithyroid drugs The effect of these compounds on thyroid function has been described on page 1013.

THE PHYSIOLOGICAL FACTORS WHICH REGULATE

THE THYROID GLAND in the normal animal on an adequate diet are its nerve supply, the thyrotrophic hormone from the anterior pituitary gland and possibly the steroid hormones from the gonads and adrenal cortex (fig 57 13)

1 *Nerve supply* The nerves to the thyroid probably supply only the blood vessels of the gland. The fact that transplanted thyroid tissue functions in an apparently normal fashion demonstrates the essential dependence of the thyroid on humoral, rather than nervous, factors. It is likely, though, that the vasomotor innervation acts to adjust the blood flow through the gland in accordance with its functional requirements. Soderberg has shown that acute changes in blood flow through the thyroid are reflected by changes in the rate of uptake of I^{131} and that stimulation of the nerve supply of the thyroid modifies in a transient fashion the secretory response of the gland to administered TSH.

2 *Thyrotrophic hormone* There can be no doubt that the main factor regulating thyroid activity is the thyrotrophic hormone. The control of the thyroid gland therefore becomes largely a problem of the control of TSH secretion by the anterior pituitary gland. The data relating to this topic has been given in chapter 56. In summary, the secretion of TSH by the adenohypophysis is maintained and regulated by the central nervous system acting through the hypothalamus and hypophyseal portal vessels of the pituitary stalk. In all probability the nervous system acts as an intermediary between environmental stimuli and pituitary and thyroid function. The stimulus of cold has been found to result in an increase of TSH concentration in the blood within 30 minutes after the beginning of cold exposure and this occurred despite a previous injection of thyroxine (Bottari). The time relations and the apparent independence from the feed back system afford strong evidence that the response is mediated by a nervous reflex. Similarly the evidence is good that environmental stimuli which cause emotional excitement or stress inhibit TSH secretion and thyroid activity by a central nervous mechanism. The secretion of TSH is also regulated by the blood level of thyroid hormone, although it is as yet undecided whether this exerts its effect directly on the pituitary gland or indirectly via the hypothalamus.

3 *Adrenal and gonadal steroids* Administration of corticoids (e.g., cortisone) or the adrenocorticotrophic hormone (ACTH) in small physiological doses inhibits thyroid hormone production. Since it has been found that similar treatment

Fig 57 13 Diagram to show the factors controlling thyroid function. Certain dietary factors (iodine intake) and drugs exert an action directly on the thyroid gland. The nerve supply is probably vasomotor in type and may modify the function of the gland by regulating its blood supply. The main physiological factor controlling thyroid activity is without doubt the thyrotrophic hormone. It is probable that environmental stimuli (cold stress) exert their effects via central nervous reflexes modifying thyrotrophin secretion from the anterior pituitary. The blood concentration of thyroid hormone (and probably of ovarian and adrenal cortical hormone) acts by in some way regulating TSH release.

does not modify the action of a given dose of TSH on the thyroid, it is likely that the adrenal corticoids act at a pituitary, rather than thyroid, level as depicted in figure 57 13. The thyroid enlargement which occurs in the human at puberty, and during menstruation and pregnancy, is strong evidence of a thyroid-ovarian relationship. However, studies in experimental animals have failed to reveal any marked change in thyroid function during the different phases of the estrous cycle, pregnancy, or after ovariectomy, although a slight decrease in thyroid activity has been seen after castration in male rabbits. The increased level of plasma protein bound iodine seen during pregnancy in the human is probably related to

changes in the plasma proteins, and the thyroxine-binding power of the plasma, rather than thyroid activity *per se*

THE ADRENAL (SUPRARENAL) GLANDS

DEVELOPMENT AND STRUCTURE

The mammalian adrenal gland, like the pituitary body and the thyroid parathyroid apparatus, consists of two parts which, though closely associated anatomically, have separate origins and are structurally different. The central part of the gland is called the *medulla*, the outer enveloping rim of tissue is known as the *cortex*. In certain fishes (*Elasmobranchis*) the two parts are present but not combined as a single gland. Tissue corresponding to the mammalian medulla, for example, is found as a number of small discrete masses on either side of the spine in association with the sympathetic ganglia (*chromaffin tissue*), whereas an elongated structure lying between the kidneys (*inter renal body*) corresponds to the adrenal cortex of mammals. In the amphibia and reptilia the two types of tissue have come together, but masses of cortical cells are intermingled with islets of medullary tissue and the two tissues are not segregated into a peripheral and a central zone, as in the mammalian adrenal.

In all animals the medullary tissue and the sympathetic ganglion cells have a common origin: they develop from primitive cell masses which have separated from the neural crest. Migrating from their sites of origin these masses of ectodermal cells undergo differentiation along two paths, some into sympathetic ganglion cells, others into *chromaffin tissue*. This latter term is derived from their reaction with chromic acid or its salts in which the cells are stained dark brown. Chromaffin or chromophil cells are also stained blue by ferric chloride and black by osmic acid. In the abdomen, on either side of the midline, a relatively large mass of chromaffin cells becomes enveloped by cortical tissue to constitute the adrenal medulla. Other smaller masses persist as accessory chromaffin tissue in association with the ganglia and plexuses of the sympathetic, and are called *paraganglia*. On the other hand, sympathetic ganglion cells may be found scattered among the cells of the adult adrenal medulla. The cortex is developed from mesoderm. It arises as a bud from the coelomic epithelium covering the inner side of the fore part of the mesonephros. The coelomic epithelium immediately behind this area gives rise to the germinal epithelium from which in turn the sex glands develop.

The medulla is composed of closely packed

groups of polyhedral cells containing chromaffin granules which are looked upon as the mother substance of the medullary secretion. The cell groups are separated by blood sinuses which empty into a central vein. The cells of the cortex are arranged in three zones. These are, from without inward, the (1) *zona glomerulosa*, in which groups of cells are arranged in a circular or oval pattern, (2) *zona fasciculata*, in which the cells are arranged in columns and (3) *zona reticularis*, which is composed of a network of cell cords (fig. 58.1). The cells of the cortex in a number of species contain fine lipid droplets which can be made apparent by a variety of histochemical or optical methods. Such lipid droplets appear to be associated with the secretion of the gland, but in some forms (e.g., the hamster, other hibernants and ruminants) these droplets are not visible microscopically.

The characteristic zonation of the adrenal cortex has led many workers to consider that the cells of the cortex originate at the periphery of the gland, in the *zona glomerulosa* just beneath the capsule or from the capsular cells. With increasing age the cells were believed to move inward through, and as constituents of, the *zona fasciculata* to the *zona reticularis* where cellular death and absorption ensued. More recent opinion favors the view that the three zones of the cortex reflect differing functional activities, although it is well established that following an almost complete adrenalectomy a few *zona glomerulosa* cells are able to regenerate a new adrenal cortex with the normal zonation.

The adrenal gland of the human fetus is proportionally some 10 to 20 times larger by weight than that of the adult. Most of the gland is comprised of an enormously enlarged reticular (or fetal) zone which is destined to involute soon after birth. The function of the fetal zone is not clear; it may be developed under the influence of chorionic gonadotrophin.

A sex difference in the size and histological appearance of the adrenal cortex has been demonstrated in animals. The glands are larger in women than in men, a difference which is enhanced when the smaller female body is taken into account. In animals, the adrenals of the female are reduced to the size of the male glands under the influence of testosterone.

FIG. 581 Section of the human suprarenal capsule *A*, medullary portion, *B*, zona reticularis, *C*, zona fasciculata, and *D* capsule. The zona glomerulosa is situated just beneath the capsule (From Maximow and Bloom)

BLOOD AND NERVE SUPPLY The adrenal is one of the most richly vascular organs in the body, receiving 6 to 7 cc. of blood per gram of tissue per minute. It is supplied by three small arteries which are derived respectively, from the inferior phrenic artery, the renal artery, and the aorta. These form rich plexuses in the cortex. The plexuses are continuous with the sinuses of the medulla which drain into the central vein of the latter. The right adrenal vein empties directly into the inferior vena cava, the left vein into the renal vein. The nerves are derived from the splanchnic nerves and the lumbar sympathetic chain, the fibers passing through a plexus (suprarenal) before entering the gland. These fibers are medullated and have no cell stations in their course. That is, they are entirely preganglionic, the medullary cell itself taking the place of the ganglion cell and postganglionic fiber, they differ thus from all other sympathetic pathways (see ch 71).

The Adrenal Medulla

Thomas Addison's report in 1855 (p. 1042), and the experimental work of Brown-Séquard in 1856, gave the first hints concerning adrenal function. The last mentioned observer showed that complete removal of the glands from rabbits caused death. Not until many years later was it shown that the effects described by these pioneer investigators were due to loss of the adrenal cortex. The French physiologist Vulpian, working at about the same time as Addison and Brown-Séquard, discovered that the medulla, unlike any other tissue, was stained blue-green by ferric chloride and that the blood of the adrenal vein sometimes gave a similar reaction. The staining reaction, it is now known, is characteristic of the internal secretion of the medulla (adrenaline). In 1894, Oliver and Schafer obtained an aqueous

extract from the medulla which upon injection caused a pronounced rise in blood pressure.

The active principle of the extract was obtained in pure form in 1901, by Takamine and by Aldrich. The substance has been given various names, *adrenaline* (or *adrenalin*), *epinephrine*, *adrenin*, and *suprarenin*; the first is most commonly used. More recently it has been established that the adrenal medulla contains a mixture of *adrenaline* and *noradrenaline* and may release these substances in different proportions in different circumstances. *Adrenaline* and *noradrenaline* possess a close structural relationship to *tyrosine* as may be seen from the following:

Tyrosine

Noradrenaline

Adrenaline or epinephrine

Since they may also be said to be derived from catechol they are termed *catecholamines*.

ADRENALINE OR EPINEPHRINE *Adrenaline* is a secondary alcohol, its full chemical name being 3,4-dihydroxy- α -phenyl β -methylaminoethanol. It was first prepared synthetically by Stoltz (1904) and later by Dakin (1905). *Adrenaline* possesses an asymmetric carbon atom so two isomers are possible (i.e., a *levo* and a *dextro*-rotatory form). The natural *levo* form is 15 times more powerful than the *dextro*rotatory form.

Adrenaline is probably synthesized in the adrenal medulla from the amino acid *phenylalanine*. However, although there are only five changes in the molecule involved in the process, there are 120 different ways of achieving the conversion with 30 possible intermediates. A likely pathway is that set out on the following page.

Evidence in favor of the following sequence is derived from a variety of experiments. Following the administration of isotopically labeled *phenylalanine* or *tyrosine*, radioactive *adrenaline* has been isolated from the adrenals. An enzyme system for the conversion of *phenylalanine* to *tyrosine* is known. With the introduction of a second hydroxyl group into the *tyrosine* molecule, *dihydroxyphenylalanine* is formed.

droxyphenylalanine (dopa) is produced which when decarboxylated by the enzyme dopadecarboxylase forms hydroxytyramine or dopamine. Dopa itself has been much studied and has been detected (like dopadecarboxylase) in the adrenal. Labeled adrenaline has been recovered from the adrenal after giving dopa- α - C^{14} or dopamine- α - C^{14} . The methylation of noradrenaline yields adrenaline and this step has been demonstrated in minced adrenal tissue and perfused glands (Bulbring).

INACTIVATION OF ADRENALINE Adrenaline disappears rapidly after injection due to its uptake by the tissues. The effects following subcutaneous injection are much less intense, though more prolonged, than those induced by intravenous administration. When given orally, adrenaline is inert. Adrenaline is rapidly inactivated in the body. Free adrenaline and noradrenaline are normally present in human urine, and according to von Euler, a 24 hour collection contains 5 to 10 μg of adrenaline and 30 to 60 μg of nor

adrenaline. The rate of excretion falls away during sleep. Minor amounts of noradrenaline and adrenaline may be conjugated physiologically with glucuronic acid, but the majority is oxidized or eliminated as metabolites. Outside the body adrenaline is much more stable in blood and tissue fluids than in Ringer solution, in which it undergoes oxidation to form a pink compound (*adrenochrome*). The substances in blood and tissue fluids which have a stabilizing or protective action upon the adrenaline molecule are reducing agents such as glutathione and ascorbic acid (Welch). It is significant that the adrenal gland is especially rich in these substances.

ACTIONS OF ADRENALINE AND NORADRENALINE

Although Oliver and Schafer discovered the pressor effect of an extract of adrenal medulla as long ago as 1894, not until nearly 50 years later was it discovered that the gland contained noradrenaline (arterenol, norepinephrine) as well as adrenaline. Noradrenaline or levarterenol present in adrenergic nerve trunks, sympathetic ganglia and the hypothalamus, and other parts of the brain, but absent in nerve free tissues such as placenta and bone marrow. Adrenaline and noradrenaline are present in the adult human adrenal medulla in the proportion of about 5 to 1, but the reverse proportion is obtained in children and very large amounts of noradrenaline (up to 90 per cent) may be found in some adrenal tumors (pheochromocytomas). It is probable, as noted earlier, that noradrenaline is the immediate precursor of adrenaline but in addition to its importance from this point of view, the substance has physiological functions of its own. For many years the properties of extracts of adrenal medulla have been studied with the belief that the only active principle present was adrenaline. The discovery of noradrenaline, therefore, revolutionized thought in this field, and only now are signs of order emerging. In what follows an attempt will be made to compare and contrast the properties of the two amines. In general it may be said that the main function of noradrenaline seems to be the normal control of the circulation, whereas adrenaline produces a variety of 'metabolic' effects useful in an emergency. Both agents act upon structures innervated by sympathetic nerve fibers and because of this are called (like certain other drugs) *sympathomimetic* (Barger and Dale).

1 VASCULAR EFFECTS Ordinary preparations of adrenaline (e.g., U.S.P. epinephrine) have a

pronounced pressor action causing widespread vasoconstriction. But adrenaline itself is by no means a general vasoconstrictor. Its overall effect upon the vascular system is vasodilatation, that is it decreases rather than increases the peripheral vascular resistance of the body as a whole. It constricts powerfully the arterioles and capillaries of the skin and the arterioles of the kidney, but dilates the vessels of the skeletal muscles and liver, and probably also of the coronary system. Thus vasodilator effect upon the muscles and liver overshadows the vasoconstrictor effects with a consequent decrease in the total peripheral resistance. The pronounced rise in blood pressure (fig 58 2), a true adrenaline effect, is due entirely to its increasing the cardiac output. The rise in blood pressure is confined to the systolic phase, the diastolic phase showing no change or a fall, an expression either of the absence of any increase in, or a reduction of the total peripheral resistance (see table 58 1)

Noradrenaline is an over all vasoconstrictor, causing an increase in the total peripheral resist-

TABLE 58 1

Effects of adrenaline and noradrenaline on blood flow (ml per min)
(After Barcroft modified)

	Before Adrenaline or Noradrenaline	During	
		Adrenaline	Noradrenaline
Liver	1500	3000	1500
Kidneys	1500	900	1200
Muscles	1000	2000	1000
Brain	750	900	675
Over all	4750	6800	4375

ance, and a hypertensive effect which is from 30 to 70 per cent greater than that of adrenaline. Noradrenaline constricts the cutaneous vessels but to a lesser degree than adrenaline the latter in man causing a much more pronounced pallor. Noradrenaline causes a reduction in blood flow through the brain of about 10 per cent whereas adrenaline increases it by 20 per cent or so.

2 HEART. Adrenaline (USP epinephrine) exerts a direct stimulating effect upon the myocardium. It increases the oxygen consumption of the heart and augments the cardiac output mainly by an increase in stroke volume, this being responsible for the rise in systolic pressure. These effects are apparently due to the action of adrenaline as such, for noradrenaline either has no effect upon the cardiac output or decreases it. Both drugs dilate the coronary vessels and increase the coronary flow. In animals with the vagus nerves intact, adrenaline slows the heart as a secondary effect of the hypertension (due to reflex inhibition—Marek's law) but causes cardiac acceleration after vagal section. In hearts protected from reflex inhibition by division of the vagus nerves or atropine, the force and rate of the heart are increased and conduction improved by both drugs. In man adrenaline accelerates the heart whereas noradrenaline causes bradycardia. Adrenaline also appears to increase the susceptibility of the ventricular muscle to the development of extrasystoles, or even of ventricular fibrillation.

3 RESPIRATION. After a short initial period of apnea the respirations are increased in rate and depth, both by adrenaline and noradrenaline. The apneic period is apparently secondary to the rise in blood pressure and is brought about through the carotid sinus mechanism.

4 SMOOTH MUSCLE. Adrenaline inhibits the

FIG 58 2 Lower tracing shows the effect of intravenous injection of 0.02 mg of adrenaline upon blood pressure. Upper tracing from the same animal shows the fall in pressure produced by the injection of 0.02 mg of adrenaline following a previous dose of 0.4 mg per kilogram of ergotamine tartrate. (From Geiling.)

FIG 58 3 Rabbit's intestine in Ringer's solution. At X, Ringer's solution plus adrenaline 1:100,000,000; at X', Ringer's solution substituted. Time 30 seconds (From Hoskins)

muscle of the stomach, intestine, bronchioles, and urinary bladder. Both the tone and movements of the intestine are inhibited (fig 58 3), the bronchioles are dilated. It excites the muscle of the splenic capsule, ureter, trigone and sphincter of the bladder, the retractor penis, and the pyloric, ileocolic, and internal anal sphincters. The uterus, whether pregnant or nonpregnant, is contracted in man and in many animals, but in the cat, rat, mouse, and guinea pig, the pregnant organ alone is contracted by adrenaline, the nonpregnant is relaxed. The contractions of the human uterus at term are often inhibited by adrenaline. Most of these effects are exhibited, though less strongly, by noradrenaline, with the exception of the excitation of the pregnant uterus of the cat upon which noradrenaline exerts a greater effect. As a result of the excitation of the radiating fibers of the iris (dilator pupillae) the pupil is dilated by adrenaline especially if the superior cervical ganglion has been previously excised. Mueller's muscle is stimulated and the eyeball protruded. Retraction of the upper eyelid is caused by the stimulation of its smooth muscle. The nictitating membrane of animals is retracted. Adrenaline also stimulates the erectorae pilae muscles and other smooth muscle fibers in the skin. After denervation the

sensitivity of some tissues to noradrenaline (e.g., the nictitating membrane of the cat) is greatly increased, whereas that to adrenaline is only slightly affected. This may be due to disappearance of amine oxidase from this tissue which destroys noradrenaline more rapidly than adrenaline.

5 SKELETAL MUSCLE Adrenaline postpones muscle fatigue and increases the tension developed in a twitch of skeletal muscle. It increases muscle tone, and may cause tremors or muscular twitching. The effects of noradrenaline upon muscle are much less pronounced. When the sympathetic supply to a muscle is excited during stimulation of the motor nerves, the contractions are increased. This effect is known as the *Orbeli phenomenon*.

6 CARBOHYDRATE METABOLISM Adrenaline administered by injection causes hyperglycemia and glycosuria. It shows an antagonism to insulin, relieving hypoglycemic convulsions. These effects, which are also shown by noradrenaline, but to a lesser degree, are due to the mobilization of sugar from the liver whose glycogen stores are thus reduced. The hyperglycemic effect is, therefore, greatest in well fed animals with an abundant hepatic store of carbohydrate, and of course is not obtained in hepatectomized animals. The glycogen of the muscles is also reduced by adrenaline. On the other hand, there is evidence (Himsworth and Scott) that the rate of removal of glucose from the blood by the tissues is accelerated. When administered to animals after a prolonged fast or in other conditions which deplete the hepatic glycogen stores, adrenaline causes an increase in liver glycogen. The latter is due to the breakdown of muscle glycogen to lactic acid which diffusing into the blood, is carried to the liver where resynthesis to glycogen occurs. There is a fall in the inorganic phosphate of the blood due apparently to the phosphorylation of glycogen and the formation of glucose monophosphate. If the adrenaline administration is continued the liver glycogen is converted in turn to glucose which passes into the blood, causing hyperglycemia, it is subsequently reconverted to glycogen in the muscles (Cori). The cycle may be represented in the following scheme:

Noradrenaline exerts little effect upon the concentration of lactic acid in the peripheral blood (Bearn *et al*)

7 GENERAL METABOLISM Oxygen consumption is increased by from 20 to 40 per cent, and CO_2 production by from 30 to 50 per cent; the respiratory quotient is, therefore, raised. In man the increase in the basal metabolic rate occurs within a short time after the subcutaneous injection of 0.5 cc of a 1:1000 solution, the temperature of the muscles rises. The effect of adrenaline upon heat production is known as its *calorigenic* action; it does not occur after removal of the liver (Sokolov)

Boothby and Sandiford attributed the latter effect largely to stimulation of cellular oxidations throughout the tissues of the body generally, and in a major degree to the hyperglycemia ("carbohydrate plethora"), and the increased utilization of carbohydrate, that is, to the specific dynamic action of glucose. The extent to which each of these factors contribute to the increased heat production is a controversial question, but the consensus favors increased carbohydrate utilization as the predominant factor (see Griffith). Cutaneous vasoconstriction leading to diminished heat loss and its effect upon metabolism, as well as increased muscular tone, are probably contributing factors. The calorigenic effect is not brought about through an action upon the thyroid since it is obtained after thyroidectomy. Moreover, the rise in metabolic rate commences within a few minutes and returns to normal within 2 hours or so, whereas the effect of thyroxine upon heat production does not commence for some hours and is prolonged for several days (p. 1015).

8 OTHER EFFECTS OF ADRENALINE (USP)

(a) Secretion of saliva, (b) lachrymation, (c) sweating in such animals as horses and sheep, but in most other animals the sweat glands, though innervated by the sympathetic, are not excited by adrenaline (see p. 1306). Sweating can be evoked in most human subjects by adrenaline or noradrenaline injected intradermally in very dilute solution, (d) contraction of the spleen (stimulation of the smooth muscle of its capsule and trabeculae) and consequent increase in the blood volume and in the red cell count (p. 517), (e) increase in the coagulability of the blood, (f) small doses increase the flow of urine as a result of constriction of efferent glomerular vessels (larger doses constrict both afferent and efferent vessels) and through reduction of the renal blood flow diminish the urinary flow (p. 546), (g) a fall, sometimes preceded by a rise, in the potassium

of the blood, (h) contraction of melanophores of certain cold blooded animals, e.g., frog and horned toad (Redfield)¹, (i) increased output of the adrenocorticotrophic hormone of the pituitary gland, (j) affects the transmission in nerve, (k) enhances or depresses, according to the dosage, the action of acetylcholine at synaptic junctions (ch. 71), and (l) intravenous injection of adrenaline causes arousal and anxiety in man, whereas injection of adrenaline into the cerebral ventricles gives signs of depression and drowsiness.

ASSAY OF ADRENALINE AND NORADRENALINE

The assay of adrenaline in blood, tissue fluids or extracts can be accomplished in many ways, and both biological and chemical methods are available. Since both adrenaline and noradrenaline are well established chemical entities, there is no international standard. All results are expressed in terms of the weight of pure amine.

With the growth of pharmacological knowledge, it has been realized that some of the earlier methods such as that concerned with the effect of adrenaline on the amplitude of the frog heart are not specific, and that it may be difficult to distinguish between adrenaline and noradrenaline. This difficulty is overcome by preliminary purification of the extract which increases both the specificity and the sensitivity of the final assay procedure. Adrenaline may be concentrated by adsorption on to aluminium hydroxide or an ion-exchange resin, whereas adrenaline and noradrenaline may be separated with the aid of paper chromatography and eluted from the paper prior to assay. In order to establish the relative concentration of adrenaline and noradrenaline in any extract, and in order to avoid the confusion introduced by interfering substances, it is advisable to use two or more methods in parallel.

BIOASSAYS. These include

Cat and rat blood pressure. An assay involving the pressor effect of catechol amines in the anaesthetized or spinal cat has long been used. The response to the sample and to standard solutions is measured and an attempt made to 'sandwich' the response of the unknown between a greater and a smaller dose of standard. The use of the hexamethonium treated rat provides a particularly sensitive preparation (Crawford and Outchourn), and whereas the blood pressure of both the cat and rat

¹ The contraction of the melanophores of the horned toad which results from adrenaline administration, also occurs when the animal becomes excited. Since in the latter instance the effect is abolished if the circulation to the melanophores is occluded, but not when the skin nerves are cut, the effect must be due to a chemical substance, presumably adrenaline, in the blood.

is more sensitive to noradrenaline than to adrenaline, that of the rat is particularly so. Amounts of noradrenaline of the order of 0.050 of 1 μ g can be measured with accuracy.

Rat uterus In this test the isolated rat uterus is suspended in a bath of modified Tyrode solution to which constant amounts of acetylcholine are added regularly. Contractions of the organ are induced which are readily inhibited by adrenaline. Unknown solutions are assayed by comparison of the effect observed with that produced by standard solutions. The rat uterus is much less sensitive to noradrenaline than to adrenaline and with good preparations less than 0.0001 of 1 μ g of adrenaline can be detected.

Vasoconstriction in rabbit ear The vasoconstriction induced by adrenaline in the perfused rabbit ear provides by far the most sensitive assay for adrenaline available. The vessels are sensitized by denervation and the diameter of the central artery measured microscopically at intervals. Adrenaline can be detected in a concentration of 10^{-11} grams per milliliter or less. The rabbit ear is also sensitive to 5-hydroxytryptamine but this effect can be blocked with lysergic acid diethylamide.

Intestinal muscle Catecholamines generally inhibit the smooth muscle of the gut and studies employing a segment of rabbit intestine were carried out over 40 years ago. Rat colon is particularly sensitive to noradrenaline, whereas the rectal caecum of the fowl is much better suited for the assay of adrenaline since it is able to detect 0.002 of a microgram.

CHEMICAL ASSAYS These are generally more convenient but less sensitive and specific than bioassays.

Colorimetric Colorimetric assays are based on the oxidation of adrenaline to the pink adrenochrome and other pink indole compounds or the use of adrenaline as a reducing agent. Thus arsenomolybdic acid is reduced by adrenaline to a blue compound.

FIG 584 Showing the effects of adrenaline upon the blood pressure and the uterus (*in situ*) of a pregnant cat before and after the administration of dibenamine. The intravenous injection of 25 mg per kilogram is indicated by the arrows (From Nickerson and Goodman.)

Fluorimetric The observation that adrenaline became fluorescent in alkaline solution was made by Paget in 1930, and an assay utilizing this fact was proposed 4 years later (Gaddum and Schild). In recent years, with a revival of interest in fluorimetric methods, new assays have been described. Though sensitive, these assays are as yet non-specific.

THE EFFECTS OF CERTAIN SUBSTANCES UPON THE ACTION OF ADRENALINE

A number of terms are used in the discussion of the action of drugs which interfere with the action of adrenaline and like substances. Thus the abolition of the effect of sympathetic stimulation is called a *sympatholytic* action whereas a drug which abolishes the excitatory action of adrenaline is called *adrenolytic*. The term *adrenergic blocking agent* may be applied to a drug which has either an adrenolytic or a sympatholytic action or both.

The first adrenergic blocking agents to be discovered were derivatives of ergot. *Ergotoxine* or *ergotamine* block the pressor effects of adrenaline and sympathetic stimulation but the vasodilator action is not interfered with. For this reason certain effects of adrenaline administration or of sympathetic stimulation appear to be reversed by the ergot alkaloids. Thus as just noted, only a depressor effect is obtainable with adrenaline if ergotoxine has been administered previously. Also, after ergotoxine adrenaline causes expansion of the melanophores of the frog instead of the usual contraction. The hyperglycemic response to adrenaline is abolished after treatment with ergot alkaloids. Ergotoxine is made up of three alkaloids: ergocristine, ergocryptine, and ergocryptine, which are derivatives of lysergic acid. These substances also markedly increase the motor activity of the uterus. This property is lost upon hydrogenation to respectively dehydroergocristine, crisatine and cryptine but the cardiovascular effects are little affected. The action on the capillaries, blood pressure and bronchioles of histamine and adrenaline are antagonistic, and adrenalectomized animals show an increased susceptibility to histamine administration. The blood concentrating effect of histamine administration is lessened or prevented by a previous injection of adrenaline. There is also some evidence that histamine increases the output of adrenaline from the medulla.

Other antagonists of adrenaline and of sympathetic effects have been discovered more recently. The β halo alkylamines (of which *dibenamine* and *dibenzylamine* are examples) possess particularly powerful adrenergic blocking properties (see fig 584). The blockade develops slowly, due to the *in vivo* formation of active intermediates but is then highly specific and persistent. Dibenamine and dibenzylamine reverse the pressor effect of adrenaline although, unlike ergotoxine, the hyper-

glycemic action of adrenaline is little affected. Nor are the inhibitory effects of adrenaline upon the virgin cat's uterus or the intestine modified by these drugs. Dibenamine (N,N dibenzyl β -chloroethylamine) and dibenzylamine (phoeoxy benzamine) have the structures shown below

Adrenergic blocking activity is also possessed by the *benzodioxanes*, or Fournéau compounds, such as 933F (piperoxan) and 833F (prosympal) and the imidazolines. Of the imidazolines, tolazoline (priscole, benzazoline, or priscole) and phetolamine (regitine, C 7337) are best known. The blockade produced by both series is relatively transient and they are useful in the diagnosis of pheochromocytoma.

Other compounds may be mentioned here which also block ganglionic transmission. Nicotine acts by depolarizing the ganglion cell, which it first stimulates and then paralyzes. The methonium compounds (hexa and decamethonium) compete with naturally formed acetylcholine for "possessions" of the ganglion cells, that is for the specific chemical receptors of the cell. Once in position, the postsynaptic membrane is stabilized and depolarization rendered more difficult. This ability of the methonium compounds depends upon their resemblance to acetylcholine, being also quaternary nitrogen compounds. The methonium compounds are useful clinically for the reduction of blood pressure and for their curarelike action.

ADRENALINELIKE SUBSTANCES

An extract containing *ephedrine* has been used in Chinese medicine for thousands of years, the pure alkaloid was obtained by Nagai, who gave it its present name, in 1887. The chemical resemblance to adrenaline may be seen in the formula

This alkaloid is closely similar to adrenaline in its action, causing bronchiolar relaxation, vasoconstriction, hyperglycemia, inhibition of intestinal muscle, and excitation of other smooth muscle. It has also a calorogenic action, its pressor effect (Curtis) is reversed by *ergotoxine* and reduced by cocaine. Ephedrine is about 100 times less powerful than adrenaline, but its effects are more prolonged. Because of its more lasting effect, it is often combined with adrenaline in commercial preparations. Unlike adrenaline, it is active when taken by mouth. According to the theory of Gaddum and Kwiatkowski, ephedrine exerts its action after a fashion analogous to that by which eserine enhances the action of acetylcholine (ch 71) namely, by inhibiting the oxidative deamination of adrenaline by amino oxidase. Tyramine is a sympathomimetic amine formed by the action of bacteria upon protein (decarboxylation of tyrosine). It is also secreted by the salivary glands of certain mollusks. It is chemically allied to adrenaline and resembles the latter in several of its actions, e.g., it elevates the blood pressure and stimulates the uterine muscle. Its structural formula is

Tyramine (1 (4' hydroxyphenyl) 2 amino ethane)

Amphetamine or *benzedrine* is a compound closely allied chemically to adrenaline, as shown in the following formula

Amphetamine (1-phenyl-2 aminopropane)

This sympathomimetic amine has also a stimulating action upon the mental processes somewhat like that of caffeine, inducing wakefulness, postponing mental fatigue, and relieving nervous depression.

A number of other sympathomimetic amines are known. Details of these should be sought in the review by Beyer and in current textbooks of pharmacology.

The skins of certain toads secrete substances (*bufotenine* and *bufotenidine*) similar in action to adrenaline, the secretion of these substances is increased during nervous excitement.

THE EMPLOYMENT OF ADRENALINE IN MEDICINE

Adrenaline is used (1) to staunch bleeding from accessible mucous surfaces (*epistaxis*, *hematemesis*) or from the skin. Because of its pressor effect it is of no value and may do harm in pulmonary hemorrhage and other forms of internal bleeding, (2) to shrink mucous surfaces, especially those of

the nose and is then frequently used in combination with ephedrine, (3) to relax the muscle of the bronchioles in asthma, the relief following its use is very striking, (4) to combat certain allergic conditions, e.g., serum sickness and to antagonize the effects of the histamine-like substances supposedly liberated in the skin in such conditions as urticaria and giant edema, (5) to stimulate the respiration or to resuscitate the heart which has ceased to beat, in the latter event it may be given by injection into the cardiac musculature. Adrenaline is of value in syncope due to Stokes Adams disease (p. 193). It should be mentioned that the administration of adrenaline during chloroform anesthesia is attended by the danger of inducing ventricular fibrillation (p. 200). (6) to enhance and prolong the action of cocaine and similar local anesthetics the vasoconstriction thus induced retards the absorption of these substances, thus prolonging their effects and reducing their toxicity. It is also used as an aid in spinal anesthesia, and (7) noradrenaline has been used in certain hypotensive states for its vasoconstrictor action.

THE REGULATION OF THE SECRETIONS OF THE ADRENAL MEDULLA

Under resting conditions the adrenal medulla releases very little secretion into the circulation, a recent estimate of the adrenaline equivalent for both adrenals in dogs is about 50 μg per kilogram per minute (Satake). On the other hand in states of stress (see emergency function below) or during stimulation of the splanchnic nerve, the output of pressor amine is greatly increased—to 50 to 75 μg per minute per adrenal in the dog. Lillott in 1912 found that the content of pressor amines of innervated adrenals fell on stimulation of the splanchnic nerve. More detailed information has been obtained in the dog (Houssay and Rapela) for the output of adrenaline and noradrenaline under various conditions. The output of adrenaline at rest was 10 μg per kilogram per minute and 400 μg per kilogram per minute after stimulation of the splanchnic nerve. The corresponding figures for noradrenaline were 2 μg at rest and 80 μg per kilogram per minute after the nerve stimulation. Clearly the discharge of catechol amines is markedly increased.

There is little doubt that the activity of the adrenal medulla lies under direct nervous control. Denervation of the gland suppresses the release of hormone and the content of hormone declines. Procedures which normally cause the discharge of medullary hormone are ineffective in the denervated gland. Such factors as a fall in pressure in the carotid sinus, emotional excitement, asphyxia, and a fall in blood sugar appear to act

reflexly upon the adrenal through centers in the diencephalon and midbrain. The location of these centers has been investigated by Ranson and Magoun. They found that electrical stimulation of various sites in the hypothalamus, midbrain, and medulla evoked signs of adrenal medullary activity, and it has since been shown by Vogt that these regions are characterized by a high content of noradrenaline. The diabetes which follows puncture of the floor of the fourth ventricle (Bernard) has been found to be due, at least in part, to increased adrenal medullary activity.

In simple terms the adrenal medulla may be considered to respond to a circulatory stress tending to lower the blood pressure by releasing largely noradrenaline which constricts the arteries and increases the peripheral resistance. Metabolic stresses, on the other hand, such as a sudden fall in the blood sugar level, are countered by the discharge of adrenaline which frees sugar from the liver and bars the uptake of sugar by the muscles. In order to respond appropriately to such stimuli it might be expected that a dual mechanism exists in the medulla for the release of adrenaline and/or noradrenaline. Information in favor of such a mechanism is accumulating. Measurement of the proportion of adrenaline and noradrenaline in adrenal vein blood has shown that the relative amounts change in accordance with the above concept. Scandinavian histologists have obtained evidence which indicates that some cells of the medulla contain mainly adrenaline, whereas others contain mainly noradrenaline. There may also be special islets of noradrenaline secretory cells. Chromaffin cell tumors in man may contain predominantly adrenaline or noradrenaline, and some exclusively noradrenaline. Further, it has been shown that electrical excitation of different regions of the hypothalamus may liberate preferentially adrenaline or noradrenaline.

Emotional excitement is a strong stimulus to sympathetic and adrenal medullary activity. Studies by Elmadjian and his colleagues on the human indicate that active, aggressive emotional displays are related to increased excretion of noradrenaline, whereas tense, anxious, but passive emotional displays are related to increased excretion of adrenaline in the urine. There also seems to be a relationship between the adrenal content of noradrenaline and the typical behavior in different species. Aggressive animals (cat, lion) have large amounts of noradrenaline in the adrenal medulla, whereas timid animals (rabbit, guinea pig) have little. The indication exists then,

that aggressive excitement leads mainly to an increased blood concentration of noradrenaline, and that emotion of a restrained or defensive type affects mainly the blood content of adrenaline.

The adrenal medulla is supplied by preganglionic sympathetic nerve fibers and the medullary cells themselves replace the ordinary ganglion cells. Because of this relationship, stimuli are transmitted to the medulla cholinergically. The pressor effect of splanchnic stimulation in cats, or of the close arterial injection of acetylcholine, can be almost completely abolished by large doses of nicotine, whereas pretreatment with the anti-cholinesterase eserine enhances the effect of such stimulation.

THE ROLE OF THE ADRENAL MEDULLA IN THE BODY

The adrenal medulla is not essential to life. In animals one adrenal may be removed completely and the medulla of the other excised without any apparent ill effect—the animal survives the operation indefinitely.

THE EMERGENCY THEORY OF ADRENAL FUNCTION. Cannon and his colleagues have furnished convincing evidence that the medulla liberates its secretion in significant amounts only under conditions which call for unusual effort on the part of the body to perform work, to prevent changes in its internal environment or to resist threatened dangers. In such times of stress the medullary secretion, it is believed, reinforces the sympathetic nervous system. Through this hormonal nervous cooperation, the several bodily reactions associated with such states of emergency are raised to maximal efficiency. Cannon and his associates employed the denervated heart as an indicator of adrenaline liberation. The operation for denervation comprised section of the vagi and removal of the stellate and second thoracic ganglia of the sympathetic chain, so that the heart was completely isolated from nervous control. Inasmuch as in their experiments any effect due to a change in the temperature of the blood was excluded, a pronounced acceleration of a heart so prepared was taken to be the result of a chemical substance carried in the blood stream. Fear, rage, pain, asphyxia, anesthesia, muscular activity, exposure to cold, stimulation of a sensory nerve, and several other conditions, caused within 10 seconds an increase in heart rate of from 20 to 40 beats per minute. Removal of the adrenals, their denervation, or ligation of the adrenal veins, prevented this effect. The conclusion, therefore,

is justified that the various conditions mentioned cause the reflex liberation of the medullary hormone. The denervated heart responds to as little as 1 part of adrenaline in 1400 million parts of blood. In some of Cannon's experiments, cats were frightened by the barking of a dog, the rate of the denervated heart increased by from 15 to 30 beats per minute. The cardiac acceleration was accompanied by pupillary dilation, erection of the hairs, and spitting. When motor activity, e.g., struggling in the animal holder, accompanied the emotional excitement, the cardiac acceleration was more pronounced (40 to 80 beats per minute). Even minor muscular movements without emotion, e.g., extending the legs, walking, or turning the body, caused an acceleration of from 5 to 20 beats per minute.

The hyperglycemia and glycosuria resulting from emotional excitement in man and animals is probably associated with the discharge of adrenaline, since it has been shown that the continued rise in blood sugar which occurs during the emotional reactions (sham rage) following removal of the cerebral cortex (p. 1239) is dependent upon the adrenals. The blood sugar continues to rise after this operation, though the glycogen stores of the liver are removed from nervous control by sectioning the hepatic nerves. On the other hand, the effect does not occur after removal of the adrenals, even though the hepatic nerves are intact. In those instances in which the emotional state does not follow the operation of decortication, the hyperglycemic effect also fails to appear. Puncture of the floor of the fourth ventricle or stimulation of the adrenal nerves also causes hyperglycemia after the hepatic nerves have been previously cut.

Though direct evidence is difficult to obtain it is reasonable to assume that besides the effects mentioned above, adrenaline when secreted into the blood stream brings about other actions which we have seen to be characteristic of its action when injected.

A recapitulation of the actions of the sympatho-adrenal system will show how useful these several actions are in fitting an animal for defense or flight, for attack or pursuit. (1) The rise in general blood pressure accompanied by dilation of the vessels of the contracting skeletal muscles, and of the coronary arteries, and the increased force and output of the heart, raise the circulatory system to a state of maximal efficiency. (2) Hyperglycemia indicates the mobilization of the carbohydrate stores of the liver; thus, an adequate supply of fuel for the active muscles is

ensured, muscular fatigue occurs less readily (3) Increased oxygen capacity of the blood is brought about by the discharge of red cells from the spleen (4) Bronchiolar dilation and an increase in the rate and depth of respiration permit an increased oxygen intake to supply the tissue cells, at the same time the level of oxygen consumption of the latter is raised (5) Shortened coagulation time of the blood lessens the danger from hemorrhage (6) Finally, the emotional manifestations of man and the fighting attitudes or defense reactions of various animals are sympathoadrenal effects, e.g., pupillary dilation, and, possibly, the startled expression due to contraction of Mueller's orbital muscle which retracts the upper eyelid, cutaneous vasoconstriction, acceleration of the heart, contraction of smooth muscle in the skin causing "gooseflesh" in man, and the erection of the hairs, quills or feathers of animals, sweating, salivary secretion (cat),² and the color changes of some cold blooded animals.

However, it is important to bear in mind that the above reactions are not *essential* to survival. In Cannon's studies, completely sympathetomized cats with denervated adrenal medullae lived entirely normal lives in the laboratory. Only when the animals were placed in an emergency situation did the effects of the operation become evident. Then the changes set out in the preceding paragraph were reduced in intensity or absent.

THE TONUS THEORY OF ADRENAL FUNCTION
It has been suggested that the medulloadrenal secretion maintains the sympathetic nerve endings in a state of sensitivity or tone and that the height of the normal blood pressure is dependent upon the continuous discharge of the hormone into the blood. Low blood pressure has been ascribed to adrenalin deficiency (so called hypoadrenalism) and essential hypertension to the liberation of adrenalin in excess (hyperadrenalism). But the evidence against such conjectures is conclusive; the theory has been entirely discredited. For example, if one adrenal is excised and the other cured or burned away, no fall in blood pressure occurs, so long as a sufficient amount of cortical tissue is left intact. Furthermore, we have seen that adrenalin does not increase the peripheral resistance (which is the basis of essential hypertension), and neither noradrenalin nor adrenalin is found in greater than usual amounts in the ad-

renals of hypertensive subjects. There are, however, certain types of hypertension, namely those associated with pheochromocytoma or adrenal hyperplasia, which are due to hypersecretion of the hormones of the adrenal medulla.

PHEOCHROMOCYTOMA AND HYPERPLASIA OF THE ADRENAL MEDULLA Pheochromocytoma is a tumor composed of chromaffin tissue arising either in the adrenal medulla itself or in an outlying collection of chromaffin cells (paraganglia, Zuckerkandl's organ). The secretion of one of these growths, or of a simple hyperplasia of the adrenal medulla, is a rare cause of hypertension, though not as rare as it once was thought to be. The hypertension may be due to the presence in the circulation of unusual amounts of adrenalin, or of noradrenalin, or of both hormones of which the tumor or hyperplastic medullary tissue contains excessive amounts. Noradrenalin rather than adrenalin is usually in greatest concentration and may constitute 90 per cent of the gland's hormone content. Both hormones have been found in excess in the urine of subjects of this type of arterial hypertension. The hypertension may be paroxysmal, with sometimes a violent onset, or the excessive secretion of the hormones may be continuous, the high blood pressure then being sustained and indistinguishable, clinically from essential hypertension. Hyperglycemia and glycosuria especially when the disease is paroxysmal, may occur, pallor, rapid pulse and profuse sweating usually accompany the attack. Peripheral circulatory collapse may ensue during a paroxysm which is thought to be analogous to the shock in animals which follows the injection of large doses of adrenalin, or hypotension and circulatory collapse may result from surgical removal of the tumor. This is attributed to the depressed tone of the vasomotor center, made evident only after the abolition of the excessive adrenal secretion. Adrenal hypertension can be distinguished from essential and other hypertensive states by means of Goldenberg's benzodioxane test. Benzodioxanes temporarily abolish, through their adrenergic blocking action, hypertension of adrenal origin but not that due to other causes. Alternatively, in cases of paroxysmal hypertension drugs which stimulate the adrenal medulla, such as histamine or methacholine, may be given in order to determine whether a paroxysm can be initiated.

SYPHATHIN

It has been mentioned that the *prompt* acceleration of the denervated heart does not occur in adrenalectomized animals during excitement, sensory nerve stimulation, etc. Cannon and his colleagues found, however, that a *slowly developing* acceleration of the denervated heart occurred during excitement or muscular activity though

² It is an interesting and perhaps a significant fact that in the cat, in which spitting is a defense reaction, sympathetic stimulation causes a profuse watery flow of juice from the salivary glands. In other animals sympathetic stimulation causes a scanty flow of viscid saliva, a watery secretion being caused by parasympathetic excitation.

the adrenals had been extirpated. The increase in heart rate took about a minute to develop, reached its maximum in about 3 minutes and then gradually subsided. Its occurrence was not prevented by the removal of all accessory adrenal tissue, by hypophysectomy or by the excision of the thyroid, parathyroids, or gonads, or by denervation of the liver. It was abolished, however, by removal of the sympathetic chains. It was also found that the characteristic slow acceleration of the heart occurred when the lower abdominal sympathetic chain was stimulated. The latter nerve contains fibers supplying the smooth muscle of the skin which are responsible for the erection of the tail hairs. Secretion of the denervated salivary glands, contraction of the micturating membrane, a rise in blood pressure and of blood sugar also resulted from the stimulation of the abdominal sympathetic. These effects as well as the cardiac acceleration occurred though the cord had been divided in the thoracic region, and the sympathetic chain above this level removed. A material originating in the hind part of the animal was evidently conveyed in the blood stream to the heart and other structures mentioned. Blocking the blood flow returning from the area supplied by the stimulated nerve or removal of the patch of skin prevented the cardiac response. As a result of these researches, Cannon and his associates concluded that during sympathetic stimulation a chemical substance resembling adrenaline in its action was liberated from the sympathetic endings supplying the smooth muscle of the skin. They named this substance *sympathin*.

Cannon and Rosenbluth found that *sympathin* and adrenaline showed certain differences in action. Preparations of adrenaline (e.g., USP epinephrine) exhibited both excitatory and inhibitory actions, whereas there appeared to be two types of *sympathin*, one which they named *sympathin F* (excitatory) was formed at the terminals of some sympathetic nerves such as vasoconstrictors, whereas the other type called *sympathin I* (inhibitory), was produced at other nerve terminals such as those in the small intestine. But *sympathin E* was found to be not purely excitatory, and *sympathin I* not purely inhibitory. This rather confusing state of affairs has been clarified by the discovery of the existence of two hormones of the adrenal medulla. *Sympathin E* is now considered to be noradrenaline, as first suggested by Baer, *sympathin I* is thought to be adrenaline itself. von Euler proposes that the qualifying letter *E* and *I* should be substituted by *N* (for noradrenaline) and *A* (for adrenaline).

It is clear that noradrenaline rather than adrenaline is the predominant humor liberated at nerve endings and in this context it is interesting to find that the excretion of noradrenaline in the urine is within normal limits in patients following bilateral adrenalectomy, whereas the content of adrenaline falls markedly.

The Adrenal Cortex

The cortex of the adrenal unlike the medulla is essential to life. Removal of more than about five sixths of this part of the adrenal causes death within a few days unless replacement therapy is instituted. Removal of the interrenal body of Clasmobranch fishes (p. 1022) is also fatal but comparative work on the amphibia is complicated by the difficulty of complete removal of the organ without serious damage to the kidney. Stewart and Rogoff found that the average survival time of dogs after complete double adrenalectomy was 10 days and the maximal time 15 days. They observed that pregnant or pseudopregnant animals survived much longer and suggested that some substance formed at this time substituted for the adrenal hormone. The substance in question is probably progesterone (p. 1036) and indeed it has since been shown that progesterone administration prolongs the life of adrenalectomized dogs, rats and ferrets. Numerous attempts were made to extract some substance from the adrenal gland which was able to maintain life and in 1927, Stewart and Rogoff and Hartman announced the preparation of suitable extracts. Both groups used watery extracts of the organ but in 1930 Swingle and Pfaffner demonstrated that with the aid of lipid solvents a very potent substance could be extracted from the cortex which maintained adrenalectomized animals indefinitely and could be used successfully in the treatment of patients suffering from a deficiency of adrenal cortical hormone (Addison's disease). At this time it was thought by Hartman that the adrenal cortex produced a single hormone, and he called this *cortin*. Subsequent work has established the existence of a number of active adrenal hormones which, since they are steroid compounds are termed *adrenal steroids*.

THE EFFECTS OF BILATERAL ADRENALECTOMY

During the short period of survival characteristic of the completely adrenalectomized animal, a variety of manifestations of adrenal cortical deficiency can be detected. These are also present in the patient suffering from reduced

FIG 58.5 Characteristic changes in metabolism, circulation, and blood concentration in a group of adrenalectomized animals following withdrawal of extract (From Harrop and associates)

adrenal function. There is a loss of appetite (particularly for fats), vomiting, diarrhea, rapid loss of weight, muscular weakness and prostration, pronounced diuresis until the later stages, a fall in body temperature, hypotension, and a reduction in the basal metabolic rate of about 20 per cent (see fig 58.5). The blood becomes concentrated (due to loss of plasma water) and shows a fall in the serum sodium and glucose, and a rise in nonprotein nitrogen, phosphate, calcium, and especially potassium. The urinary excretion of sodium is increased (pp 554-555) and that of potassium reduced. There is a reduced excretion of urinary nitrogen and other signs of renal failure. Although there is a spontaneous diuresis the elimination of ingested water is defective. The glycogen store of the liver and muscles is diminished. When placed in a cold environment the metabolic response of the adrenalectomized animal is less than normal and any form of stress is poorly met. Many of the above changes are detectable within 42 hours of the operation. Postmortem examination frequently shows congestion of the gastrointestinal tract and pancreas. There may be erosions in the mucosa of the stomach and intestine, and gastric ulcers may be observed; the gastric juice may lack hydrochloric acid—*achlorhydria*.

It will be seen that the adrenal cortex exerts an influence over a wide variety of bodily functions. As might be expected the individual suffering from adrenal cortical insufficiency is extremely susceptible to the damaging effects of a wide variety of stimuli such as changes in the environmental temperature, traumatic injuries, burns, severe muscular exercise, infections, and the ad-

ministration of toxic agents such as histamine and diphtheria toxin. Such stimuli may be grouped together as *stresses*. A supply of adrenal cortical hormones will greatly increase the resistance of an adrenalectomized individual to such noxious agents. The adrenal cortex also appears to be concerned in some way with the maintenance of the nutrition of certain nervous tissues; degenerative changes have been noted in autonomic ganglia (cervical, stellate, and celiac) following adrenalectomy, and almost complete loss of function of the vasomotor and cardiac accelerator nerves in adrenalectomized animals has been described. The relation of the adrenal cortical hormone to the development of renal hypertension is described in chapter 27, and the role of the adrenal cortex in lactation is mentioned in chapter 60.

Changes such as those outlined above can be prevented or reversed by the administration of adrenal cortical extracts, and even comatose animals can be restored to health. In treated adrenalectomized bitches, for example, heat will occur and pregnancy and lactation ensue normally. Adrenalectomized puppies given cortical extract will continue to grow.

The part played by adrenal hormones in salt and water metabolism merits a little more attention (see also ch 34). In adrenalectomized animals, as well as in human adrenal insufficiency, there is a marked reduction in total base due mainly to the loss of sodium, apparently through diminished reabsorption by the renal tubules, whereas the potassium concentration of the serum is raised above normal. The renal excretion of potassium is reduced and, perhaps most important, there is a shift of potassium from the intracellular to the extracellular fluids. In combination with an increased elimination of water by the kidney marked dehydration results. Under these conditions the administration of sodium chloride to adrenalectomized animals and a reduction in the potassium intake exert a remarkably beneficial effect. On the other hand, the withdrawal of salt from the diet increases the severity of the condition. The sodium rather than the chloride ion is the important factor.

The reduction of blood sodium was observed originally by Bauman and Kurland, and the effects of transfusions of saline in sustaining adrenalectomized animals were described by Stewart and Rogoff, and by Hartman, but the importance of sodium loss in the development of the symptoms was first pointed out by Loeb and his associates, and by Harrop. The value of a low potassium content of the diet in the survival of adro-

nalectomized animals was shown by Allers and his associates. Completely adrenalectomized animals can be maintained in good health without treatment by a cortical hormone if placed upon a diet low in potassium but high in sodium chloride and, in order to prevent the acidosis which otherwise develops, containing sodium citrate. The tendency to hypoglycemia is controlled by a high carbohydrate diet. These measures, however, do not completely restore an animal to a physiological state, for they are unable to withstand stress or to perform work with full efficiency.

THE PHYSIOLOGICAL ACTIONS OF ADRENAL CORTICAL EXTRACT

Extracts of the adrenal cortex contain a large number of steroids, of which only a minority are of importance physiologically. In view of the wide spectrum of activity of the adrenal steroids it is convenient to classify them into three groups according to the characteristic action of each steroid. These are

1 The *glucocorticoids*, which particularly affect carbohydrate metabolism

2 The *mineralocorticoids*, which are highly active in the control of mineral and water metabolism

3 The *androgenic corticoids*

Before examining each group in more detail it must be pointed out that representatives of each group possess overlapping activities. Thus cortisone, which is classed as a glucocorticoid, also acts on salt and water metabolism, and conversely, aldosterone, which is a highly potent mineralocorticoid, possesses very definite glucocorticoid activity. It is possible, as Bush has suggested, that the adrenal steroids could be grouped according to whether they are secreted under 'steady state' conditions independently of pituitary control, or as a stress function, being discharged in response to stress stimuli via pituitary adrenocorticotrophic hormone.

The *glucocorticoids* are characterized as a class by the presence of an oxygen atom at position 11 (see pp 1038-1039) either as a doubly bound oxygen or as an hydroxyl group. In the absence of this grouping there is little or no effect on carbohydrate, fat, or protein metabolism, whereas an hydroxyl group in addition at position 17, as in cortisone, enhances the activity of the steroid. The most important compounds in this group are cortisone (or Kendall's compound E), 17 hydroxycorticosterone (compound F), and corticosterone (compound B).

The fundamental action of the glucocorticoids

lies in the domain of glucose production and utilization. In the salt-maintained adrenalectomized rat there is apparently little abnormality in the storage of carbohydrate until a period of fasting is instituted, when hypoglycemia develops and the store of glycogen in the liver is rapidly depleted. Administration of adrenal steroids is followed by a large increase in liver glycogen. The glucocorticoids exert their effects in a variety of ways. There is an increase in the catabolism of tissue protein with the carbon fraction of the amino acids being used for the production of glucose. Because of this stimulation of gluconeogenesis the glucocorticoids exert a marked anti-insulin action. Administration of these corticoids exacerbates diabetes and will induce diabetes in the force-fed normal individual, the diabetes so produced is ameliorated by insulin only with difficulty. There are indications that cortical extracts decrease the amount of glucose that is utilized. The daily administration of cortisone to rats fed a high carbohydrate diet results in a severe hyperglycemia and glycosuria and the increased urinary nitrogen accounts for only a fraction of the glucose present in the urine (Ingle).

The glucocorticoids cause the mobilization of fat from the fat deposits and increase the fat content of the liver. Nothing more need be said here concerning the role played by the adrenal cortex in the metabolism of carbohydrate and fat inasmuch as these subjects have been dealt with in chapters 48 and 49.

The point of action of the adrenal hormones in the metabolic processes touched upon above is not clear. Studies on the enzyme content of various tissues, before and after adrenalectomy, indicate that a variety of enzymes may be reduced in amount, but it has not yet been possible to go much further than this.

Under stressful conditions there is an increased liberation of glucocorticoids. This action is mediated via the adrenocorticotrophic hormone of the pituitary and does not occur in the hypophysectomized individual. Whereas the glucocorticoids are highly active in increasing resistance to stress, the mineralocorticoids are relatively ineffective. Allied to their protective action in stress is the effect the glucocorticoids exert on muscular efficiency. One characteristic of adrenal cortical insufficiency is the early onset of muscular weakness and fatigue. Administration of cortisone restores the normal work performance of muscles.

The *mineralocorticoids* exert their most striking action upon the kidney, although there is increasing evidence for a generalized effect in the body,

possibly on cell surfaces. In the adrenalectomized animal there is an abnormally large excretion of sodium and chloride by the kidney and this phenomenon may be abolished by administration of adrenal cortical extract. Study of the individual steroids isolated from the cortex indicated, until quite recently, that desoxycorticosterone (desoxycorticosterone acetate = DOCA) was the most potent in the regulation of electrolyte metabolism. However, there always remained in the mother liquor of the extract an active, noncrystalline residue termed simply the *amorphous fraction*. Most of the biological activity effective in prolonging the life of adrenalectomized animals under low stress conditions remained in the amorphous fraction. In 1952 Simpson, Tait, Wettstein, Neher, von Euw, and Reichstein announced the crystallization of a new steroid from adrenal extracts which was from 30 to 100 times more active than desoxycorticosterone in promoting sodium retention and was effective in the rat in amounts of 0.1 μ g or less. Sodium retention in man can be demonstrated with doses of 100 μ g. Initially the compound was termed electrocortin, but following the determination of the structure of the steroid, the name *aldosterone* was suggested in 1954, and has since been generally adopted. Aldosterone is unique among the adrenal steroids in possessing an aldehyde group at position 18 (p 1039).

Among the "classical" adrenal steroids, *desoxycorticosterone* exhibits the greatest influence on the kidney. This compound increases the concentration of sodium in the body fluids, but reduces the concentration of potassium. It also reduces the intracellular concentration of potassium and increases that of sodium (fig 53.6) and with prolonged administration, the concentration

of sodium may nearly equal that of potassium. The administration of potassium almost completely corrects the abnormal quantitative relationship of these electrolytes. Through its action in causing sodium and water retention, the administration of desoxycorticosterone may be followed by a great increase in plasma volume and edema, especially if the intake of sodium is increased. With overdosage, more serious effects may result such as hypertension, dilation of the right ventricle, and pulmonary congestion. Death from cardiac failure has resulted from its clinical use. The rapid increase in plasma volume, and, as a result of this, the extra burden thrown upon the cardiovascular system are thought to be the most important factors leading to these ill effects. Although depression of the potassium concentration of the body fluids may be the lethal factor in some instances, Loeb and his associates have shown that administration of desoxycorticosterone to animals may lower the potassium level to the point where paralysis results. In dogs given desoxycorticosterone for several successive days, a condition resembling diabetes insipidus develops. The water intake, especially if salt is administered as well, is increased by from 6 to 10 fold. The output of urine rises accordingly and its specific gravity falls. The administration of potassium salts or a reduction in the sodium intake is undoubtedly of benefit in patients receiving large doses of desoxycorticosterone.

The actions of aldosterone differ in some respects from those of desoxycorticosterone. A comparison of the relative potency of the two hormones shows that aldosterone is about 20 times as active as desoxycorticosterone in maintaining life in adrenalectomized dogs, and about 5 times as effective in promoting potassium excretion in adrenalectomized rats. In the maintenance of sodium and potassium balance in human adrenal insufficiency, aldosterone is the more potent by a factor of 30 or so. Prolonged administration of aldosterone does not, at present appear to produce hypertension or edema though, like desoxycorticosterone, it results in chloride retention and increased potassium excretion.

The production, and function, of the *androgenic corticoids* produced by the adrenal gland has occasioned much controversy. Typical of the observations that must be taken into consideration is the fact that adrenalectomy disrupts sexual function. In the rat, for example, there is a loss of libido in the male and a suppression of the estrous cycles in the female. Since normal sexual activity is restored in animals given salt, it may be pre-

EFFECT OF DOCA UPON THE CONCENTRATION OF INTRACELLULAR Na AND K

FIG 53.6 The replacement intracellularly of potassium and sodium in the muscles of normal dogs under the influence of desoxycorticosterone acetate (DOCA). The effect is inhibited by the administration of KCl. (From Loeb.)

sumed that the adrenal steroids are not essential in reproductive processes. On the other hand, estrogens, androgens, and progesterone can be extracted from the adrenal cortex and are found not only in normal urine but that of eunuchs and of ovariectomized women. It is possible that the secretion of androgen by the adrenal is concerned in the persistence of libido after gonadal removal (p 1075).

Among numerous observations concerning the possible relationship of adrenal hormones to reproduction, the following are of interest here. Special cells (the cells of Stilling) appear in the adrenal cortex of the frog during the mating season. The ovaries of hypophysectomized tadpoles are increased in weight by injections of cortical extract. Stimulation of the adrenal cortex in the castrated rat by administration of adrenocorticotrophic hormone has been found to increase the weight of the accessory reproductive organs. In women the intermenstrual periods are said to be shortened by from 3 to 5 days by giving cortical extract (Hartman and associates). There is a marked increase in the excretion of adrenal androgens in both boys and girls at puberty. Sexual abnormalities are a striking feature of the syndrome associated with certain tumors of the adrenal gland (p 1043).

In view of the common origin of the genital organs and the adrenal cortex from the coelomic epithelium, and the closely similar chemical structure of the hormones derived from the two sources (see pp 989 and 1039), it is perhaps not surprising that the steroids produced may overlap in their activities. Further, it is important to note that the adrenal glands of immature mice contain an Y zone of cells with an acidophilic cytoplasm and prominent basophilic nuclei, it immediately invests the medulla. In the male, the X zone collapses as a result of the direct action of the androgens produced at puberty, if castration is performed, the X zone persists and may enlarge. In the immature female the X zone continues to develop up to puberty and can then persist for several months until it too disappears, possibly under the influence of androgen. The function of the X zone is not clear. A somewhat similar zone is distinguishable as the fetal cortex in the newborn human. In this case the greater part of the cortex at birth (apart from a peripheral layer of cortical cells which develops into the definitive cortex) is destined to involute and disappear in the first months of extrauterine life. Despite considerable research, the function of the fetal

cortex is also obscure although it is speculated that the cells produce androgen. According to Benirschke and Lanman, to cite recent workers, it would seem that the fetal cortex is trophically stimulated by chorionic gonadotrophin (p 1093), or possibly luteinizing hormone (p 971) from the fetal pituitary, and that upon withdrawal of this hormone at birth, involution occurs.

The adrenal cortex possesses spheres of influence additional to those described above. In the rat it has been found that desoxycorticosterone will restore the rate of growth of young adrenal ectomized rats to normal, and that the amorphous fraction is almost as active. Corticosterone and cortisone are not active in this respect and in general cortisone acts to suppress growth. Clinically cortisone has frequently been found to induce a negative nitrogen balance; this effect may be modified by increasing the diet and supply of protein. Administration of adrenal cortical hormone or the application of (stressful) stimuli leading to the discharge of cortical hormone produces a dissolution of lymphocytes and a fall in the lymphocyte count in the blood. There is also an eosinopenia. With high dosage of cortisone there is an atrophy of the thymus, spleen, and lymph nodes. There may be an increase in the titer of circulating antibodies in certain species. Recent work has emphasized the effects of the adrenal steroids, and particularly cortisone on mesodermal tissues. Inflammation of these tissues (connective tissue, synovial membranes, reticulum), which is prominent in the so called collagen diseases, is abruptly arrested by cortisone. Cortisone also delays wound healing by interference with the formation of granulation tissue and fibrosis. Desoxycorticosterone in contrast markedly stimulates the fibroblasts and ground substance. Cortisone also appears to inhibit the enzyme hyaluronidase and thus to decrease cell permeability.

OUTLINE OF THE BIOCHEMISTRY OF THE ADRENOCORTICAL HORMONES

There is good evidence that the adrenal cortical hormones are produced in the adrenal from cholesterol, which is in turn synthesized from acetate. This is indicated by the finding that when an adrenal gland is perfused with C^{14} labeled cholesterol, labeled corticosterone and 17 hydroxycorticosterone are produced. Additionally, incubation of adrenal slices, or perfusion of isolated adrenal glands with labeled acetate, results in the formation of labeled cholesterol and corticosteroid. It has been found that the

cholesterol content of the adrenal cortex is reduced by half by the injection of pituitary adrenocorticotrophic hormone, by trauma, or in states of stress (Long and associates). The fall is greatest some 5 to 6 hours after administration of ACTH and requires about 24 hours for the restoration of the normal level. No similar reduction in the cholesterol content of other organs has been observed to follow the injection of ACTH, so that the response appears to be specific to the adrenal cortex. An increase in liver glycogen accompanies the fall in adrenal cholesterol and is taken as an indication of the release of glucocorticoids.

The ascorbic acid content of the adrenal is reduced by 50 per cent or more by ACTH or by trauma. This finding has been much used as an index of the release of ACTH by various stimuli and forms the basis of an assay method for ACTH. In the rat, injection of ACTH results in a depletion of adrenal ascorbic acid which is maximal in about 1 hour. The concentration of ascorbic acid is rising in 3 hours and is restored to normal or above in 12 hours. The significance of ascorbic acid with respect to adrenal cortical function is, however, unknown, since in the guinea pig elaboration of the adrenal corticoids has been found to continue in the scorbutic animal, that is in the absence of ascorbic acid.

Analysis of extracts of ox glands has established the existence of between 20 and 30 steroids in the adrenal. Seven are of major importance although others are probably essential as intermediates in the synthesis of the discharged hormone. The seven biologically active corticoids are corticosterone, desoxycorticosterone, 11 dehydrocorticosterone, 17 hydroxycorticosterone (hydrocortisone), 17 hydroxy 11 dehydrocorticosterone (cortisone), 17 hydroxy 11-desoxycorticosterone, and aldosterone. Their formulas and the various synonyms, are illustrated in figure 58 I.

Corticosterone was isolated by Reichstein and his associates, and by Kendall and his colleagues, in 1937, and was later synthesized by the former workers. It is also known as Kendall's compound B. Desoxycorticosterone, lacking the hydroxyl group at carbon 11, was later synthesized by Steiger and Reichstein from stigmasterol but is present in minor amount in the adrenal.

The adrenal corticoids are included in the group of C_{21} -steroids, that is steroids with 2 methyl groups as well as a side chain of 2 carbon atoms at C_{17} . They also have a Δ^4 -3 ketone grouping believed to be essential for corticoid

activity and a characteristic α ketol ($-\text{CO}-\text{CH}_2\text{OH}$) grouping in the side chain attached at C_{17} . The oxygen component on carbon 11 appears to confer on the molecule activity in relation to carbohydrate metabolism, for such properties are minimal in desoxycorticosterone. Aldosterone is unique in possessing an aldehyde grouping at carbon 18.

As recorded earlier, the adrenal gland secretes steroids which exert an effect upon the genital tract. These include estrone, progesterone, 17 β hydroxyprogesterone, Δ^4 androstenedione-3 17 and adrenosterone (Δ^4 androstenedione-3 11, 17). The last three of these compounds are androgenic and the last two have a ketone group at position 17 and are known as adrenal neutral 17 keto steroids (17 KS). The 17 ketosteroids excreted in normal urine are adrenosterone, dehydroisoadrenosterone, and 11 hydroxyisoadrenosterone. Cortical steroids of both the 11 oxy and the 11 desoxy series are also excreted in the urine. These and the 17 KS are excreted in increased amount in adrenal tumors or following the administration of ACTH.

Adrenosterone is the most active androgen in the adrenal cortex, and has the formula

Adrenosterone

THE NATURAL CORTICAL HORMONE. The corticoid content of human adrenal vein blood has now been studied by a number of workers and it appears that the main constituents are hydrocortisone and corticosterone. Aldosterone is also secreted in low concentration but in a potent amount. The human, monkey, sheep and guinea pig secrete primarily hydrocortisone, the rabbit and rat primarily corticosterone, the dog and cat mainly hydrocortisone with some corticosterone, and the ferret, ox and cow a mixture of both in roughly equal parts. There is, however, a considerable variation within any one species. For further information on this subject see the review by Hechter and Pincus.

URINARY EXCRETION AND ASSAY. A wide variety of steroids may be isolated from human urine and it is well established that a number originate in the adrenal glands. They are excreted both in the free form and following conjugation with glu-

FIG 581 Formulas of adrenocortical principles

cronic acid to form water soluble glucuronides. Some may also be linked with sulfuric acid and excreted as sulfates. Before analysis of urine can be undertaken, it, therefore, becomes necessary to free the steroids from conjugation by hydrolysis with mineral acid or, better, by incubation with the enzyme β glucuronidase. The steroids can then be extracted from the urine and subjected to analysis by a variety of procedures.

For assay of adrenal corticoids, a selection may be made from a great profusion of both biological and chemical techniques. The information gained is often complementary, but with a growing under-

standing of the relationship between structure and function of the adrenal hormones, emphasis is now being given to chemical methods. The bioassays utilize effects such as the glycogen deposition induced in the livers of adrenalectomized mice, the action of adrenal corticoids in prolonging the lives of adrenalectomized rats subjected to cold, the fall in blood eosinophils induced by adrenal steroids in the adrenalectomized mouse, and elimination of radioactive sodium and potassium. A procedure based on the ability of corticoids to depress the ratio of $\text{Na}^{24}/\text{K}^{40}$ in the urine of adrenalectomized rats proved of great value in the studies of

Simpson and Tait which led to the isolation of aldosterone

In the chemical analysis of urinary steroids the neutral 17 ketosteroids may be studied or attention given to the reducing steroids formaldehydogenic steroids acetaldehydogenic steroids 17 ketogenic steroids total 17 hydroxysteroids Porter Silber chromogenic steroids and so on. In these procedures a fraction of the urinary steroids is examined in detail but the data obtained seldom permits presentation of the results in terms of a particular substance. With the use of paper chromatographic methods it is possible to identify individual steroids in extracts of urine but highly quantitative observations cannot yet be made. In the past much emphasis has been put on the analysis of urinary steroids for assessing adrenal cortical activity in the human patient. The recent introduction of radioactive hydrocortisone labeled with C^{14} in ring A has made possible a more direct method (Peterson and Wyngaarden Cope and Black) for measuring the rate of production of endogenous hydrocortisone.

The neutral 17 ketosteroids possess an oxygen atom attached at carbon 17 there is no side chain. They arise from precursors secreted largely by the adrenal cortex and testis and only in a minor degree by the ovaries. In men some two thirds of the neutral 17 ketosteroids are derived from the adrenal cortex. Following the appropriate extraction procedure the quantity of 17 ketosteroids is determined colorimetrically with the aid of the Zimmerman reaction. Here steroids containing the group $-CO-CH_2-$ give a purple color when treated with *m*-dinitrobenzene in the presence of alkali. The output of 17 ketosteroids is not constant throughout the life cycle. In both men and women it rises sharply at puberty reaches a maximum at about 25 years of age (Hamburger) and subsequently slowly declines. The mean output in healthy 25 year old males is 14 mg per day and in women of the same age 9 mg per day. In cases of tumors of the adrenal cortex the excretion of 17 ketosteroids is generally increased and values of more than 1000 mg per day have been found. In Addison's disease (p 1042) the output of 17 ketosteroids is usually abnormally low.

THE REGULATION OF ADRENAL CORTICAL HORMONE SECRETION

It is clear that the adrenal cortex, unlike the medulla is under humoral and not nervous control. This is indicated by the marked adrenal atrophy which follows removal of the hypophysis and the enlargement of the gland which is produced by administration of ACTH. However, the fact that complete adrenalectomy is fatal whereas hypophysectomy is compatible with life, shows that the adrenal cortex of the hypophy-

sectomized animal is functional to some extent.

1 Androgenic corticoids Little is known regarding the factors regulating the secretion of these steroids. Wilkins observed that the virilizing effects associated with adrenal cortical hyperplasia in young girls could be controlled by cortisone administration and suggested that the cortisone was acting by depressing the pituitary release of ACTH and therefore the adrenal cortical release of androgenic substances. Such a view implies a dependence of adrenal androgen secretion on ACTH.

2 Glucocorticoids The secretion of corticosterone and 17 hydroxycorticosterone is almost entirely dependent on the pituitary release of ACTH. Hypophysectomy markedly reduces the glucocorticoid content of adrenal vein blood whereas injection of ACTH gives a rapid and dramatic increase in the concentration of hormone in this blood. The regulation of secretion of the adrenal glucocorticoids becomes a question of the regulation of the secretion of pituitary ACTH (see ch 56).

3 Mineralocorticoid (aldosterone) Unlike other adrenal corticoids the secretion of aldosterone appears to be relatively free from hypophyseal control. Evidence in favor of this conclusion includes the following: (a) in the hypophysectomized rat, the output of aldosterone will vary in response to changes in the electrolyte intake; (b) in the hypophysectomized dog the secretion of aldosterone remains at about normal value whereas that of other steroids falls markedly; (c) similarly in hypophysectomized man the urinary aldosterone levels are nearly normal; (d) when cortisone is injected the adrenal output of hydrocortisone is depressed but not that of aldosterone. Nevertheless it is known that ACTH stimulates the production of aldosterone by the adrenal cortex although the mechanism concerned is obscure. It has been suggested that the secretion of aldosterone is controlled directly by the blood level of circulating electrolytes but Farrell points out that the secretory rate of aldosterone can be tripled during hemorrhage without any associated change in plasma electrolytes or even in the presence of increasing plasma sodium levels. Further ablation of the diencephalon in the dog results in a profound fall in aldosterone output without significant changes in serum electrolytes. This latter fact is in line with Farrell's view that the secretion of this steroid is controlled by a factor arising within the head, but not necessarily in the hy-

pophysis Rauschkoib and Farrell found that, in the dog removal of the head greatly depresses the secretion rate of aldosterone, but section of the nervous connections between the head and trunk is without effect if the vascular connections are intact. In later work, Farrell has produced suggestive evidence that some humoral factor originating in the region of the dorsal diencephalon is directly concerned with the regulation of aldosterone release.

Some Therapeutic Uses of Cortisone

Great interest has been aroused within recent years, and both laboratory and clinical research into the functions of the adrenal cortex have been intensified, by the dramatic discovery of Hench and his associates of the therapeutic value of compound E (cortisone) in acute rheumatism and rheumatoid arthritis. In acute rheumatism there is rapid reduction of fever, and of the swelling and pain in the joints, following the oral or parenteral administration of cortisone. The high sedimentation rate which occurs in this disease is restored to the normal by this steroid. Compound F (hydrocortisone) and the adrenotropic hormone of the hypophysis, ACTH (through its stimulation of the production and liberation of the cortical hormones), have a similarly beneficial effect. Rheumatoid arthritis is in most cases benefitted by these compounds, sometimes dramatically, but improvement as a rule is not sustained after treatment has been discontinued.

The adrenal steroids effect amelioration of these arthritic diseases though there is no evidence of adrenal insufficiency. Inasmuch as such large doses are required, much greater than are employed in the treatment of Addison's disease, it is not credible that these compounds act by correcting a hormone deficiency. That they act pharmacologically, rather than by replacement, there can be little doubt. In the dosage employed they appear to exert a specific effect upon the metabolism of the collagenous tissues (connective tissue fibers embedded in cement or ground substance containing hyaluronic acid) of joints, skin, arteries, and many other structures. The results of Opsahl's experiments may provide a clue to this action. She found that in mice, adrenal cortical extracts inhibited the enzyme hyaluronidase, as shown by a reduction of the 'spreading effect' of the enzyme. Compounds A, E and F exhibit this inhibiting action, but compound E was the most effective.

The therapeutic value of cortisone and dehydrocortisone has been investigated in a large number of diseases, many of them apparently quite unrelated to one another. The diseases upon whose course cortisone, dehydrocortisone or ACTH has been found to have a favorable effect though in many cases this has been slight or evanescent, can for the most part be grouped under three main headings as shown below.

Collagenous diseases (collagenoses)

Acute rheumatism (rheumatic fever)

Rheumatoid arthritis

Rheumatoid spondylitis

Psoriatic arthritis

Scleroderma

Periarthritis nodosa

Dermatomyositis

Allergic diseases or diseases due to abnormal sensitivity of cells

Bronchial asthma

Allergic rhinitis (hay fever)

Contact or atopic dermatitis

Urticaria

Lymphatic and myelogenous diseases

Acute and chronic lymphatic leukemias

Lymphosarcoma

Hodgkin's disease

Lymphoid thyroiditis (struma lymphomatosa)

Myelogenous leukemia

Sarcoidosis

Multiple myeloma

In the following list are a number of other pathological states in which ACTH or cortisone has been employed with variable success and which cannot be placed in any of the above categories: ulcerative colitis, acute inflammatory eye diseases, alcoholism with delirium tremens or Korsakoff's psychosis, chronic nephrosis, Waterhouse-Friderichsen syndrome, Loeffler's syndrome, and the adrenogenital syndrome.

Deleterious effects which may result from cortisone or ACTH treatment. A number of serious adverse effects may result from treatment with these agents. Prolonged cortisone therapy may lead to adrenocortical atrophy. Collapse and death from acute adrenal insufficiency may follow cessation of treatment. Several instances of the development of Cushing's disease (ch. 56), e.g., hirsutism, rounding of the facial contours, osteoporosis, kyphosis and hypertension have been reported from the continued administration of ACTH. Mental aberrations ranging from an exaggerated sense of well being (euphoria), moodiness or mild anxiety states to definite psychoses e.g., paranoia have been reported following cortisone therapy. Wound healing is apparently delayed by cortisone.

and resistance to certain infections is lowered. Hamsters can be infected with poliomyelitis virus by intraperitoneal injection, and develop a highly virulent form of the disease if pretreated with cortisone, but animals similarly injected but not receiving the hormone, could not be infected (Shwartzman). The spread of a tuberculous infection from a previously localized focus is thought to be a serious complication which may follow cortisone therapy. Peptic ulcers are not uncommon with prolonged treatment and perforation of the bowel in cases of ulcerative colitis has sometimes occurred.

DISEASE OF THE ADRENAL CORTEX IN MAN

Addison's Disease

The syndrome known today as Addison's disease was first described (in 1855) by Thomas Addison and ascribed by him to tuberculous disease of the adrenals. Experimental and clinical observations since that time have fully substantiated Addison's conclusion that the disease is due to adrenal involvement. Tuberculous disease of the gland is found, however, in only a proportion of the cases. It has also been shown that deficiency of the cortex and not of the medulla is the essential cause of the disease. The condition is most common between the ages of

30 and 50, and is found more often in men than in women. Its chief features, which closely resemble those seen in adrenalectomized animals, are (a) muscular weakness and languor, (b) low blood pressure and reduced circulation rate, (c) gastrointestinal disturbances, loss of appetite (anorexia), hypochlorhydria, and vomiting, (d) pigmentation of the skin and mucous membranes, bronzing, or tanning—a dirty brown cutaneous discoloration being a classical symptom of the disease, (e) lowered metabolic rate, subnormal temperature, sodium loss and a rise in serum potassium, reduced blood volume (plasma loss), dehydration, and loss of weight, (f) renal insufficiency with consequent rise in blood nonprotein nitrogen, (g) depression of the sexual functions, (h) hypoglycemia, which may be an immediate cause of death, (i) abnormal electroencephalogram slowing of α rhythm and reduced number of β waves, and (j) changes in the electrocardiogram, e.g., low voltage, flat or inverted T, prolongation of P R and QRS, and depression of RS T. The pigmentation of the skin may be so deep that the patient is mistaken for a mulatto, it is most pronounced in those regions—nipples, abdomen, etc., where the normal pigmentation is greatest (fig. 587). The palms of the hands and soles of the feet remain pale. The discoloration is

FIG. 587. Showing pigmentation of the skin together with patches of depigmentation in a patient with Addison's disease. (From Kepler.)

due to the excessive accumulation of the normal cutaneous pigment, *melanin*. This is deposited chiefly in the basal cells of the epidermis, but pigment granules are also found in the dermis. The change in pigment metabolism which causes the deposits is unknown.*

Addison's disease, unless treated with cortical hormone or with a diet of high salt and low potassium content is almost invariably fatal within from 1 to 3 years. The high salt, low potassium diet exerts an almost specific effect in adrenal insufficiency, but desoxy corticosterone acetate is most usually employed, it is given in oil or as pellets inserted subcutaneously. However, as already mentioned, there are certain disadvantages associated with the use of this corticoid, a marked antidiuresis and edema with sodium retention and loss of potassium occurs when a certain dosage is exceeded. A high sodium and low potassium content of the diet enhances the adverse effects. Nor does the desoxy compound constitute a complete replacement therapy, for the tendency to hypo-

glycemia during fasting and the EEG and ECG abnormalities are not corrected. Cortisone given with DOCA provides a more complete replacement therapy in Addison's disease.

Acute adrenal cortical hypofunction may be encountered following adrenal surgery or in patients with chronic adrenal insufficiency who have been subjected to a sudden stress. Bilateral adrenal hemorrhage may occur, most often in children, and the ensuing condition is known as the *Waterhouse-Friderichsen syndrome*.

*Tumors of the Adrenal Cortex Adrenogenital Syndrome Pseudohermaphroditism**

Tumors composed of cortical tissue which secrete an excess of androgenic compounds may arise in the adrenal itself or in aberrant collections of cortical cells (adrenal 'rests') which are found in the broad ligament of the uterus, in the neighborhood of the testes or in the retroperitoneal tissue of the abdomen or pelvis. Such growths or a diffuse hyperplasia of the adrenal cortex, may occur in children or adults and are associated with extraordinary abnormalities of development especially of the *accessory organs of sex* and of the *secondary sex characters* (p. 1072).

When cortical hyperplasia or a tumor composed of cortical tissue occurs in young children puberty appears prematurely. A male child of 4 or 5 years for example may show the sexual development of an adult (fig. 58-8). The testes and penis are enlarged, hair may appear upon the chest, pubis and face and there may be precocious sexual desire. Often there is also unusual muscular development or extreme obesity. There is early ossification of the epiphyses. Male children showing these characteristics have been described as resembling 'an infant Hercules (Herculean type of Weber) or a burly brewer's drayman' (Guthrie). Growth is rapid as a rule, but the epiphyses fuse early; young subjects of the disease, therefore, do not reach full stature.

In little girls the breasts hypertrophy, hair appears on the mons veneris and around the vulva, the uterus develops prematurely, the clitoris is hypertrophied, and there is sometimes precocious menstruation. In appearance such children re-

* Bloch found that sections of normal skin became deeply pigmented when placed in a dilute solution of 3,4-dihydroxyphenylalanine. Albino skin treated similarly remained unpigmented. Solutions of other aromatic compounds (e.g. tyrosine, tryptophane, pyrogallol, etc.) did not cause pigmentation of skin sections. Bloch concluded that dihydroxyphenylalanine, which he called *dopa*, was the precursor of melanin; the conversion being brought about by an oxidizing enzyme (*dopa oxidase*) in the skin. Until recently tyrosinase was present in potato fungi and other plants and which is capable of catalyzing the conversion of tyrosine to *dopa*. It has been believed to be absent from mammalian tissues. But since its discovery in animals this enzyme has been assigned the role of catalyzing the reactions, tyrosine to *dopa* and *dopa* to melanin (see Lerner and Fitzpatrick). Tyrosinase is now believed or thought to be identical with Bloch's *dopa oxidase* (see scheme below).

The reactions resulting in melanin production are inhibited by ascorbic acid and under certain circumstances by cortical steroids. So far the foregoing facts have not led to a satisfactory theory of the cause of the pigmentation in Addison's disease.

* Pseudohermaphroditism is defined as a condition in which the gonads of one sex only are present but the external genitalia combine features of both sexes so that from inspection of them alone it is difficult or impossible to determine the sex. In true hermaphroditism both ovarian and testicular tissues are present; it is an embryological aberration and not due to a hyperfunctional adrenal cortex (see also ch. 60).

semble stout little women. Women who are subjects of this disease become mannish in appearance and disposition (virilism, fig. 589). The voice deepens, menstruation ceases, the breasts atrophy, and hair may grow upon the chest, face and limbs; homosexuality is a common feature. The urinary excretion of androgens (17 ketosteroids)

FIG. 588 Enlarged abdomen and precocious sexual development of a boy aged 30 months. A mass palpated in the abdomen was probably a suprarenal cortical tumor. (From Rowntree and Ball.)

is increased several fold. In some adult female subjects, the virilism is accompanied by glycosuria and decreased sugar tolerance, due apparently to an increased production of glucocorticoids. This type is known as the Achard Tiers syndrome and was described by these authors as the "diabetes of bearded women." Adult male subjects of cortical tumors, as a rule, give no evidence of endocrine disturbances. In some, however, an exaggeration of the male characters is manifest, e.g., enlargement of the penis, a tendency to hirsutism, an increased sexual appetite. In others, the tumor secretes excessive amounts of estrogen when a certain degree of feminization is observed, e.g., enlargement of the mammae, atrophy of the testes, and a feminine distribution of fat.

It might be expected that with the increase in active adrenal cortical tissue, changes in electrolyte balance corresponding to those following injections of adrenal cortical hormone, namely a rise in blood sodium and a fall in potassium, would be found. But actually such changes occur only in a proportion of cases and are, as a rule, moderate in degree. On the other hand, there may be an associated depression of adrenal salt retaining factors with the appearance of Addisonian symptoms, due to atrophy of the opposite adrenal. Surgical removal of the tumor or hyperplastic tissue is the preferred treatment when possible. Sometimes as a result of atrophy of the normal

FIG. 589 Virilism due to adrenal tumor. On left, at age 23 years before the onset of the disease, on right, at age 35 years at the height of the disease. (From Lescher.)

adrenal tissue, acute cortical insufficiency develops after operation. In order to forestall such a crisis, treatment with a cortical hormone is instituted preoperatively. The administration of cortisone is sometimes successful in suppressing adrenal hyperplasia, the elevated blood level of this hormone tends to inhibit the output of ACTH and, as a consequence, to reduce its stimulating effect upon the hyperplastic tissue. This treatment, however, is of little benefit if the disease is due to a tumor whose activity is independent of pituitary control.

Broster and Vines have made the interesting discovery that hyperplastic adrenal cortical tissue or tumor tissue, in cases of virilism, contains large numbers of cells which have an affinity for fuchsin (fuchsinophil cells). Cells possessing this property are normally absent from the mature adrenal or present only in very small numbers. They are a characteristic feature, however, of the fetal adrenal of both sexes between the 10th and 17th weeks (in the case of the male) and between the 11th and 15th weeks (in the case of the female), but disappear thereafter. These observers suggest that virilism is due to the elaboration of a masculinizing hormone by the fuchsinophil cells, and that the female fetus normally passes through a male phase. The importance of the fuchsinophil cells in the production of hyperadrenocortical manifestations has been questioned, however, by Soffer.

Primary Aldosteronism

With the isolation of aldosterone as a highly potent mineralocorticoid, and with the development of assays for this steroid, the existence of tumors primarily secreting aldosterone has been established. The syndrome of 'primary aldosteronism' was first described by Conn in 1954, and many cases have now been detected. The major clinical manifestations of the syndrome consist of periodic severe muscular weakness, intermittent tetany and paresthesia, polyuria and polydipsia, and hypertension. The blood sodium level is raised, that of potassium lowered, there is an alkalosis. Only mineral metabolism appears to be affected. Surgical treatment is advised at present.

Clinical Tests of Adrenal Cortical Function

In mild or atypical cases of adrenocortical insufficiency the following tests may be employed for its detection.

1 *Eosinopenic response to ACTH* is one of the most sensitive tests. In normal persons, a 50 per cent reduction in circulating eosinophils results from the administration of a test dose of cortico-

trophin, whereas the response is absent or much reduced in adrenocortical insufficiency.

2 *Robinson Kepler Power test* to ingested water. Normally diuresis commences within 30 to 45 minutes after drinking water in adrenal insufficiency the excretion of the excess water is much delayed.

3 *Culter Power Wilder test*. The urinary excretion of sodium chloride during a 53 hour period of rigidly restricted salt intake accompanied by the administration of potassium. Normally less than 150 mg per 100 cc of urine is excreted in the last 4 hours of the test. The subject of adrenal insufficiency excretes a much larger quantity. This test is potentially dangerous, for unless the adrenal insufficiency is of mild or moderate degree, an adrenal crisis may be precipitated.

Other determinations are, the tendency to hypoglycemia during fasting, the sensitivity to insulin, estimation of urinary 17 KS (which are reduced in adrenal insufficiency and increased in normals by ACTH administration), and the uric acid creatinine ratio which is normally increased by cortical stimulation.

THE PARATHYROID GLANDS

DEVELOPMENT AND STRUCTURE

The parathyroid glands are the smallest endocrine organs in the body. They remained unrecognized as structures distinct from the thyroid gland (to which they are often closely applied) until Sandstrom's description in 1880. Although Sandstrom was of the view that the structures represented remnants of embryonic thyroid tissue, and named them accordingly, the glands actually arise quite independently of the thyroid as outgrowths of the endoderm of the third and fourth pharyngeal pouches. Typically, there are two pairs of glands, frequently called parathyroids III and IV to indicate the gill clefts of origin. Inasmuch as parathyroids III tend to follow the thymus during development, whereas parathyroids IV become associated with the thyroid gland, the position of the two pairs in the adult becomes reversed from that in the embryo. It is of importance that in the human, parathyroid glands may occasionally be found in the anterior, or posterior, mediastinum not associated with remnants of the thymus. Parathyroids III are constantly found in all vertebrates above the fishes, whereas parathyroids IV are absent in some species. In the human, the superior pair of parathyroids (IV) are referred to as the external, whereas the inferior pair (III) are termed the internal parathyroids. The terms 'internal' and 'external' signify the proximity of the gland to the medial, or to the lateral aspect, respectively, of the thyroid lobe. The human parathyroids are roughly oval in shape, about 6 mm in length, and weigh about 35 mg each. Pathologically, glands weighing as much as 250 grams have been reported.

The cells of the parathyroids are densely packed in masses separated by capillary blood sinuses; they sometimes form cords. Two main types of epithelial cell may be distinguished in the gland of the adult human: chief, or principal cells which contain glycogen and possess a clear cytoplasm, and oxyphil cells which have a granular cytoplasm which stains intensely with acid dyes, and lack glycogen. The principal cells are, apparently, the essential secreting cells of the gland inasmuch as they are the only ones present in the human gland up to the 10th year and indeed, are the only ones present at any age in most animals. Curiously, there is no clear cytological evidence of secretory

activity in these cells, although the physiological evidence of an endocrine function is irrefutable. The function of the oxyphil cells, which appear near puberty, is as yet unknown.

The rich blood supply of the parathyroids is derived from the superior and inferior thyroid arteries. Interference with these vessels during thyroidectomy may occasionally result in hypoparathyroidism. Branches of the recurrent and superior laryngeal nerves innervate the glands and are probably entirely vasomotor.

EARLY STUDIES AND CONCEPTS

The most prominent indication of inadequate function of the parathyroid glands is the occurrence of tetany. This symptom was long known to occur rather frequently after surgical thyroidectomy but was attributed to infection of the operation wound (Koeher), or to thyroid deficiency (Reverden). Attempts to induce tetany experimentally introduced complications, for in 1884 Schiff observed that thyroid removal in cats and dogs produced tetany and proved fatal, whereas little effect was observed in the rabbit. The difficulty was resolved by Gley in 1891, who pointed out that the inferior parathyroids lie caudal to the thyroid in the rabbit and that they were not affected by thyroidectomy. However, it was left to Vassale and Generale (1900) to differentiate between thyroid and parathyroid function by showing that removal of all the parathyroids, while leaving the thyroids intact, led to a fatal tetany. The cause of the tetany is a fall in the blood calcium level, as discovered by MacCallum and Voegtlin (1909). The same workers showed that administration of calcium salts could avert the convulsions.

For a number of years it was believed that the tetany occurring after parathyroidectomy was due to the accumulation of a toxin within the body, but this view was confounded, and the endocrine nature of the parathyroids established, when several independent workers, Han-son, Bertram, and Collip, succeeded, around 1923, in obtaining consistently potent extracts of para-

thyroid hormone. It then became possible to relate clinical observations to the effects produced experimentally by overdosage with the extract.

EFFECTS OF PARATHYROIDECTOMY—TETANY

The effects observed following experimental removal of the parathyroid glands vary in intensity according to the species studied, although comparable metabolic changes occur in all. In general, young animals are more susceptible than older ones to the effects of parathyroid deprivation, and herbivores tolerate the operation better than carnivores. The existence of necessary parathyroids offers only a partial explanation, inasmuch as tetany is induced in the rat only with difficulty following complete parathyroidectomy. The high phosphorus and low calcium content of the meat diet of carnivores probably accentuates the effects of parathyroidectomy.

In the dog, which has been studied most extensively, signs of parathyroid hormone deficiency may appear within 24 hours of operation. These include (1) a fall in serum calcium from the normal level of about 10 mg per 100 ml to 6 mg or less. The fall may be very abrupt, reaching the latter value or lower in 24 hours, or may be delayed for 48 to 72 hours or so. (2) A rise in serum inorganic phosphate from a normal level of about 5 mg per 100 ml to 9 mg or higher. (3) The urinary excretion of calcium and phosphorus is reduced, this despite an increase in the blood level of the latter mineral. (4) Fibrillary twitchings of the muscles appear, followed by tonic or clonic (jerking) muscular contractions. The jaws are clenched and the limbs are either stiffly extended or jerk violently, the head is dorsiflexed. Sometimes there are automatic swimminglike movements of the forelimbs. (5) The skeletal muscles show increased excitability to a galvanic stimulus (p. 1050) and to mechanical excitation. Cardiac muscle also displays hyperirritability. The time constant of accommodation is increased (see p. 1124). (6) The muscle phosphocreatine is reduced and its rate of resynthesis slower than normal. (7) There is rapid, noisy breathing (hyperpnea), hyperpyrexia and tachycardia, and salivation. (8) Death usually follows in the dog and is due to asphyxia through spasm of the laryngeal and thoracic muscles.

The above symptoms constitute the condition known as tetany and because the complex can be produced in other ways, Erdheim designated it as *tetania parathyreopriva*. The tetanic symp-

toms are closely related to the serum calcium level. As this falls the symptoms mild at first (perhaps merely slight stiffness of the hind limbs), become gradually more severe and when the serum calcium has fallen to between 5 and 6 mg per 100 ml, the tetanic state is usually fully developed. Chronically, the bones become denser and cataracts may develop in the eyes. As might be expected, the tetanic convulsions can be relieved or averted by injection of calcium salts.

In man, in infants and very young children tetany is usually seen in association with rickets. It may occur in the new born due to a temporary inadequate production of parathyroid hormone. In the adult, tetany may follow accidental removal of the parathyroid glands during thyroidectomy, or removal of a hyperfunctional adenoma. The symptoms are usually less intense than those seen in parathyroidectomized animals, and the condition runs a more chronic course. The serum calcium lies usually between 4 and 7 mg per 100 ml, rapid respirations and high temperature are not usually seen. The outstanding feature is the heightened neuromuscular excitability. Though jerking movements and generalized convulsions may occur in children they are unusual in adults. The hypertonic state of the muscles causes the hands and feet to be drawn into typical attitudes which are spoken of as *carpopedal spasm* (fig. 59.1). The hands are flexed at the wrists and the fingers flexed at the metacarpophalangeal but extended at the interphalangeal joints. The thumb is adducted into the palm. This position constitutes the so-called *accoucheur's hand* of tetany. The feet are extended at the ankles and the toes plantar flexed. Spasms of the eye muscles may be seen and, occasionally, spasmodic retention of urine occurs. In infantile tetany spasm of the muscles of the glottis is not uncommon, causing inspiratory stridor (*laryngismus stridulus*). When severe the laryngeal spasm causes complete closure of the glottis for a time, cyanosis results and when asphyxiation seems imminent a sharp inspiration occurs accompanied by a high pitched "crowing sound." These various forms of muscular spasm are grouped under the general term *spasmophilia*.

In association with the lack of parathyroid hormone, there is a tendency toward metastatic calcification. Cataracts frequently occur. The teeth are not affected in the adult but if the condition sets in during infancy, the roots may be hypoplastic. Enamel defects are often seen

FIG. 591 Tetany (description in text) (Upper photograph from Iurvis Stewart lower photograph from Cabot)

Latent tetany Frequently the serum calcium remains just above the critical level at which definite tetanic symptoms appear. Emotion, some undue strain upon the organism, e.g., pregnancy, lactation, or a failure in general health may however precipitate an attack of manifest tetany in a subject who has been suffering from the disease in latent form. Certain tests are employed to unmask this incipient form of the disease: (1) *Chvostek's sign*, tapping over the facial nerve in front of the ear causes twitching or spasm of the facial muscles; (2) *Trousseau's sign*, occlusion of the circulation in the arm by means of a blood pressure armlet causes the hand to assume the typical attitude (the effect is probably due to the anoxemia induced in the muscles of the hand and forearm); (3) *von Bonsdorff's phenomenon*

the facilitation of the muscular spasms caused by hyperventilation during the occlusion of the circulation to the arm; and (4) *Erb's sign*, increased excitability of the neuromuscular apparatus to a galvanic current. Stimulation of the median nerve in adults or the peroneal nerve in children produces muscular contraction with weaker currents than normal and contraction may be preferentially elicited by an anodal opening current rather than the anodal closing current as is normally the case. In mild cases of tetany, numbness and tingling of the fingers and toes may be reported.

OTHER FORMS OF TETANY

These with the chief changes in blood chemistry are shown in table 591.

INFANTILE AND IDIOPATHIC TETANY Tetany occasionally arises spontaneously in infants and may then be due to parathyroid deficiency. Spontaneous or idiopathic tetany as it is sometimes called occurs also though rarely in adults as a result of defective parathyroid function. Tetany arising in this way does not differ essentially from that following parathyroidectomy. The tetany of infants is usually however an accompaniment of rickets and so far as is known is then not due to parathyroid deficiency. During the active stage of rickets the serum calcium is little if at all depressed but during the healing stage of the disease calcium is diverted to the bones and the calcium of the serum falls. It is at this time that tetany occurs. Tetany may also be produced in rachitic rats by placing them upon an anti-rachitic diet (Hess and associates).

THE TETANIES OF OSTEOMALACIA AND SPRUE Osteomalacia is a disease of the bones of adults. Its pathogenesis is essentially the same as that of rickets. The serum calcium is often very low. Tetany is of common occurrence. Tetany occurs in *celiac rickets* and *nontropical sprue*. In the latter disease the absorption of fat and of calcium is defective and the serum calcium depressed. Tetany also sometimes occurs in tropical sprue.

TETANY ASSOCIATED WITH ALKALOSIS (GASTRIC HYPERPEPSIA, AND BICARBONATE TETANY) In pyloric obstruction dilation of the stomach or as a result of persistent vomiting from other causes the loss of chloride in the vomitus causes a change in the acid base balance toward the alkaline side. Tetany follows. Alkalosis is also the apparent cause of the tetany which results from increased pulmonary ventilation. In this case it is the excessive elimination of carbon dioxide which is the cause of the increased blood alkalinity. Alka-

TABLE 59 1*

Types of tetany

	Calcium	Bicarbonate of Blood	Chlorine	pH	Phosphorus
Infantile or idiopathic tetany	Reduced	Normal	Normal	Normal	Normal or reduced
Tetany of osteomalacia	Reduced	Normal		Normal	Normal or reduced
Tetanies of sprue and celiac rickets	Reduced	Normal			
Gastric tetany	Normal	Increased	Reduced	Increased	Increased

Phosphate tetany (Na_2HPO_4)	Reduced	Normal	Normal or increased	Normal or increased	Increased
Citrate tetany	Reduced	—	—	—	—
Tetany due to calcium and vitamin D deficiency	Reduced	—	—	—	—
Tetany due to magnesium deficiency	Normal	—	—	—	—
Guanidine tetany	Normal or slightly reduced	—	—	—	Increased

* With modifications and additions from MacCallum

losis is also evidently the cause of the tetanylike seizures which sometimes follow the administration of large quantities of sodium bicarbonate for therapeutic purposes

PHOSPHATE TETANY Phosphate tetany is produced experimentally. The intravenous injection of 0.5 gram per kilogram of either the acid or the alkaline sodium (or potassium) phosphate into animals causes a profound and rapid fall in the serum calcium. In dogs, it is only after the injection of the alkaline salts, however, that tetany occurs. This difference is probably due to the different effects of the two salts upon the acid base balance—the one tending to cause alkalosis and a reduction in the ionization of calcium, the other acidosis and a relative increase in the concentration of calcium ions (see below). The injection of a neutral mixture of the two salts or of phosphoric acid itself does not cause tetany.

CITRATE TETANY An intravenous injection of sodium citrate is a less sure way to induce tetany, but in a certain proportion of animals typical convulsions follow within 15 or 20 minutes after the injection. The serum calcium is lowered

TETANY DUE TO CALCIUM AND VITAMIN D DEFICIENCY The serum calcium of rats on a diet lacking in calcium, falls, after a period of from 3 to 7 weeks, to a low level, but tetany does not de-

velop unless the diet is also devoid of vitamin D. Even when both calcium and vitamin D are absent from the diet, tetany does not appear spontaneously, but typical convulsive seizures can be induced by stimulation with the galvanic current or by a sudden sound.

Milk fever. Hypocalcemia and tetany sometimes occur in cows after calving as a result of the loss of calcium in the milk. The condition is treated by inflating the udder with air which suppresses milk secretion and causes a rise in the serum calcium or by the intravenous injection of calcium. A similar condition is seen in sheep after lambing and is then referred to as 'lambing sickness' or 'ewe distemper'.

MAGNESIUM DEFICIENCY TETANY The general features of this type of tetany are indistinguishable from those due to calcium deficiency. It has been produced in rats, dogs, and young cattle by feeding diets deficient in magnesium. Calves reared on whole milk, which has a low magnesium content (0.01 per 100 ml), frequently show severe tetany and may die in convulsions. The blood calcium and phosphorus are within normal limits but the magnesium is reduced to little more than half the normal value. This type of tetany is not known to occur in the human subject.

PATHOGENESIS OF TETANY

MacCallum and Voegtlin discovered (1909) that the serum calcium was invariably depressed

in tetania parathyreopriva and that the condition was immediately relieved by the intravenous injection of calcium. In the years following the recognition of the connection between tetany and the parathyroids, and up to the work of Mac Callum and Voegtlin, the tetanic state was believed to be due to some endogenous toxic metabolite (e.g., guanidine) which was destroyed in some way by the parathyroids, but accumulated in the blood and tissues after parathyroidectomy.

With the general recognition of these facts the *calcium deficiency theory* of tetany came into being. The low serum calcium found in other forms of tetany, that is, produced otherwise than by parathyroid deficiency, e.g., the tetanics of rickets, osteomalacia, and sprue, also indicates that calcium deficiency is the direct cause of the neuromuscular hyperexcitability in these conditions. Depression of the serum calcium also explains the convulsions following the injection of phosphate. It is generally accepted that the determining factor in the production of tetany is the concentration of *ionized* calcium in the plasma and extracellular fluids of the body, rather than the *total calcium* concentration. For example, in nephritis with a low serum protein, the total calcium of the serum may be reduced to 3 or 4 mg per 100 ml, yet tetany does not occur presumably because the concentration of ionic calcium has not been reduced to the critical level. As shown by the experiments of Loch upon frog muscle, the sodium and potassium ions tend to increase neuromuscular excitability, the calcium and magnesium ions to depress it. The calcium concentration of the tissues themselves (muscle or brain) is not altered in tetany; the increased neuromuscular excitability would, therefore, appear to be due to an imbalance between the concentration of ionic calcium in the extracellular and intracellular fluids.

It is difficult to assess the importance of hyperphosphatemia as a factor in the production of tetany, for a reciprocal relationship exists in the blood between the concentrations of calcium and phosphorus. Phosphate retention or phosphate injection causes a fall in the calcium of the serum, a rise in the concentration of the calcium of the serum, on the other hand, tends to depress the blood inorganic phosphorus. Nevertheless, tetany can result from a reduction in the serum calcium as in infantile rickets and osteomalacia with a normal concentration of blood phosphate. Hyperphosphatemia, therefore, though undoubtedly in-

creasing the severity of the tetanic symptoms, does not appear to play the primary role in their development.

The tetany of alkalosis cannot be explained upon the basis of calcium deficiency, inasmuch as in this type the serum calcium is not significantly lowered. It is suggested, however, that the shift of the acid base balance of the blood toward the alkaline side causes a reduction in the ionic calcium fraction without altering the concentration of the total calcium of the serum. The following equation illustrates the possible relationship between the concentrations of calcium, bicarbonate, phosphate, and hydrogen ions

$$\frac{[\text{Ca}^{++}][\text{HCO}_3^-][\text{H}^+\text{PO}_4]}{[\text{H}^+]} = K$$

According to this equation, an increase in the concentration of the bicarbonate ions or of phosphate ions, or a fall in the concentration of hydrogen ions would cause a reduction in the concentration of ionized calcium without a change in the total calcium level of the serum.

Certain observations are in conformity with such an hypothesis. The beneficial effect upon tetany of the administration of an acidifying salt such as ammonium chloride, since it is not accompanied by a rise in the total calcium of the serum, and the difference, already mentioned, between the actions of the alkaline and acid phosphates may be explained upon such a basis.

The question of the neuromuscular mechanism responsible for the tetanic seizures has not received a decisive answer. D. N. Paton and his associates sectioned the cord in parathyroidectomized dogs and observed cessation of the clonic and tonic spasms, but the tremors and the fibrillary twitchings were abolished only by section of the peripheral nerves. These results indicated that the tonic and clonic spasms were supraspinal in origin whereas the finer movements were dependent upon spinal centers. West more recently concluded that the supra-spinal centers were not involved, since the characteristic tonic and clonic spasms persisted after section of the cord in the upper thoracic region. The integrity of the spinal reflex arc was, however, considered to be essential for the tonic and clonic manifestations since they were abolished after section of the dorsal roots. The fibrillary movements and the increased electrical excitability of the muscles appeared to be dependent upon a peripheral mechanism. They persisted for at least 24 hours after section of both afferent and efferent nerves. In contradiction of West's conclusions, Greenberg and his colleagues

state that in rats, tetanic movements of the hind limbs, but not of the forelimbs, are abolished by transection of the cord at the level of the seventh spinal segment. They conclude that activity of nervous centers above the spinal level is essential for the development of both the tonic and clonic seizures.

TREATMENT OF TETANY

Though the symptoms of tetany are rapidly abolished by the intravenous administration of calcium salts, the beneficial effect is of short duration. Calcium by mouth is of little value in acute tetany, but is of some value in the more chronic forms. Acidifying salts, e.g., ammonium chloride, are also of benefit. A single injection of parathyroid extract will relieve the condition in a few hours and hold it in abeyance for several days. In chronic tetany (e.g., postoperative) irradiated ergosterol in the form of dihydrotachysterol or calciferol is of great value, especially when combined with a high calcium and a low phosphorus intake. The necessity of maintaining a high calcium, low phosphorus ratio prevents the use of a milk diet because of its high phosphorus content. According to Anderson and Lyall, adjustment of the calcium and phosphorus of the diet (0.5 to 0.65 gram of phosphorus, daily) is capable alone of controlling the symptoms. Lactose or dextrin in the diet tends to reduce tetanic neuromuscular hyperexcitability, for the organic acids produced during the fermentation of these carbohydrates lower intestinal pH, and thereby increase calcium absorption.

THE ACTIONS OF PARATHYROID EXTRACT (PARATHORMONE)

The belief in the calcium regulating function of the parathyroids, which followed naturally upon the discovery that hypocalcemia was an accompaniment of parathyroid deficiency, was confirmed in 1924, when Hanson obtained an active extract of the gland. At about the same time, Collip obtained an extract from beef parathyroids which also possessed a powerful hypercalcemic effect. The intravenous or subcutaneous administration of this extract to parathyroidectomized dogs will maintain the serum calcium at the normal level. Violent tetanic symptoms are abolished within 3 or 4 hours after the injection of 10 or 20 units, and by the daily administration of considerably smaller doses than this the animal is maintained in good health indefinitely. If, after the calcium has been raised to normal, the administration of the hormone is

FIG. 59.2. Curves of serum calcium, blood phosphorus, and nonprotein nitrogen reproduced from Collip's article describing the effects of parathyroid extract. The curve representing the nonprotein nitrogen is not from the same animal as are the curves of serum calcium and blood phosphorus.

continued in frequently repeated doses (10 to 20 units twice daily, or oftener) or if given in such dosage to a normal animal, overdosage effects are produced. These are (1) *Early changes in blood chemistry*. The serum calcium rises abruptly and within from 24 to 48 hours usually reaches a concentration of from 18 to 22 mg per 100 cc (fig. 59.2). During this time the inorganic phosphorus shows a moderate fall followed by a return to normal and a small rise. There is a slight rise in the potassium and magnesium of the serum. (2) *Early symptoms*. During the rise in serum calcium there is loss of appetite, depression and weakness, polyuria, vomiting, diarrhea, and dehydration. (3) *The urinary excretion of calcium and phosphorus* is greatly increased. The increased excretion of phosphorus precedes the rise in serum calcium and the increase in urinary calcium. There is little change in the fecal excretion of these elements. (4) *Later blood changes* are a reduction in the hypercalcemia by 2 or 3 mg per 100 ml, a pronounced rise in the plasma inorganic phosphorus, a 4-fold increase in blood nonprotein nitrogen, a reduction in blood volume by 15 per cent due to plasma loss and, in consequence, concentration of the blood and a great increase in its viscosity. (5) *Later symptoms*. At the time that these blood changes are occurring urgent symptoms appear—vomiting of bloody fluid and sometimes the passage of blood stained stools, signs of renal failure, and great prostration ending in death. (6) *At autopsy* the gastrointestinal mucosa is found to be the seat of extensive hemorrhages, and the stomach and upper part of the intestinal canal contain a quantity of bloody fluid.

All the manifestations are intensified by a high

calcium diet or the administration of calcium salts

The preceding description applies chiefly to dogs. The serum calcium of herbivorous animals, rats, mice, rabbits and guinea pigs, responds much less readily to the extract and the post mortem picture so characteristic of its effects in dogs and cats is not seen. In herbivorous animals, on the other hand, repeated doses cause the deposit of calcium in the soft tissues (metastatic calcification), particularly of the arterial tree, this is infrequent in dogs. In the human subject, hypercalcemia is produced about as easily as it is in dogs. In both man and dogs tolerance to the hormone not infrequently becomes established after a certain number of doses.

Therapeutic (physiological) doses administered to a normal man, or to a subject of hypoparathyroidism, cause a moderate increase in phosphorus and calcium excretion, a fall in serum phosphorus, and a rise in serum calcium, i.e., a complete reversal of the biochemical abnormalities caused by parathyroidectomy (fig 59.3)

The excess calcium in the serum following parathormone overdosage is derived from the skeleton, there is no increase in the absorption of

FIG 59.4 Showing trabeculae of humeri of cat on (A) a high calcium diet and (B) on a low calcium diet (Redrawn from Bauer, Aub. and Albright)

calcium from the gut. Bauer, Aub, and Albright have shown that repeated doses of the extract to rabbits causes a reduction of the trabeculae of the epiphyses indicating that they serve as a store of calcium, which is rapidly mobilized by the hormone (fig 59.4). By the administration of parathormone over long periods, a condition corresponding to *ostitis fibrosa cystica* of man (see below) has been produced by Bodansky and Jaffe in guinea pigs, and by others in rats and puppies. There is a marked demineralization and resorption of bone and replacement with fibrous tissue. Continued administration of the hormone to experimental animals results in gross and microscopical changes in the parathyroid glands, they become much reduced in size and their cells appear shrunken, show hydropic degeneration and a diminution in the number of mitotic figures. Such changes indicate that the administered hormone has depressed the functional activity of the glands.

CHEMISTRY OF THE PARATHYROID HORMONE

The active principle contained in extracts of parathyroid glands (parathormone) has not been prepared in pure form. It is a water soluble protein which has still to be crystallized. The Collip preparation was obtained by boiling fresh glands for 1 hour with 5 per cent hydrochloric acid. The cooled solution was then made alkaline, to pH 8, by the addition of sodium hydroxide, followed by hydrochloric acid until a maximal isoelectric precipitation of protein containing the active principle, occurred. Subsequent workers have modified this procedure and have obtained better yields and purer preparations. The hormone is soluble in water, 80 per cent alcohol, and warm 50 per cent glycerol, and is insoluble in absolute alcohol, ether, benzene, and acetone. Its potency is lost

FIG 59.3 Showing the effects of parathormone upon the serum calcium and phosphorus, and upon the urinary excretion of these minerals in a case of hypoparathyroidism. (From Albright and Ellisworth)

upon acid hydrolysis, treatment with strong alkali, exposure to oxidizing agents, or incubation with the proteolytic enzymes pepsin and trypsin. Parathormone appears to possess no prosthetic group, it is not a glycoprotein. To be effective the hormone must be given by injection, it is inactive when given by mouth. Upon continued administration parathyroid hormone loses its effectiveness. This is generally believed to be due to the production of an antihormone, although Selye suggests the effect arises from a change in the reaction of the bones to the hormone. Clinically, an inability to respond to endogenous parathyroid hormone has been described, and is termed pseudohypoparathyroidism (Albright, Burnet, Smith, and Parson, 1942).

Assay The standard assay procedures are based upon the changes in the level of serum calcium in normal or parathyroidectomized dogs. However, with the demonstration of independent actions of parathyroid hormone in the excretion of phosphate and the mobilization of calcium, methods based on the excretion of phosphate have been devised, as well as modified serum calcium assays. None has yet achieved wide application. One USP or Hancon unit is $\frac{1}{100}$ of the amount required to raise the calcium level of the blood serum of normal healthy male dogs, weighing 10 to 12 kg, by 1 mg per 100 ml. This unit is $\frac{1}{2}$ of the Collip unit, which is also still in use.

Calcium and Phosphorus Metabolism

Before proceeding to a discussion of the mode of action of parathyroid hormone, it will be advantageous at this point to review the metabolism of calcium and phosphorus.

Calcium is an indispensable mineral, it is a constituent of all animal fluids and solid tissues and is of importance in a variety of physiological processes. Among these may be listed (1) coagulation of the blood (ch 12), (2) formation of bone (p 1062), (3) cardiac rhythmicity (ch 14), (4) maintenance of normal neuromuscular excitability (p 1052) and (5) milk production (p 1099).

THE DISTRIBUTION OF CALCIUM IN THE BODY

Calcium constitutes about 2 per cent of the weight of the adult body, and about 99 per cent of the total quantity is contained in the skeleton. The muscles contain about 8 mg per 100 grams net weight, plasma or serum from 9 to 11.5 mg per 100 ml. The red corpuscles contain only minute amounts, so that the content of whole blood is between 4.5 and 6 mg per 100 ml. The other body fluids, e.g., lymph, aqueous humor, ascitic and edema fluids, etc., contain it in some-

FIG 59.5 Showing the increase in the calcium of human fetus in later months of gestation (From Hess and Schmitz)

what lower concentration, whereas the concentration in the cerebrospinal fluid is only about 5 mg per 100 ml. Negligible amounts of calcium are deposited in the skeleton before the fifth month of intrauterine life, and nearly 70 per cent of the skeletal calcium of the new born is the result of deposition during the last 2 months of prenatal life (fig 59.5). The mother suffers a much greater loss of calcium to the suckling child. Whereas only about 20 grams of the element are lost during pregnancy, over 80 grams are secreted in the milk during a normal lactation period.

The State of the Calcium in the Blood

Practically all the calcium of blood, as just mentioned, is contained in the plasma, after clotting it is all present in the serum, and it is upon this that determinations are usually made. The clot itself contains mere traces.

The calcium of blood exists in two main forms, nondiffusible and diffusible. The nondiffusible form is bound to the serum proteins, both albumin and globulin fractions (but chiefly to the albumin fraction) in the proportion of about 0.84 mg per gram of protein. It remains in the serum when the latter is dialyzed or subjected to ultrafiltration. The nondiffusible part constitutes about 45 per cent (from 4 to 5 mg per 100 cc) of the total serum calcium. The diffusible portion amounts to 55 per cent or so (5 to 6.5 mg per 100 cc) of the total calcium, when the serum is ultrafiltered this fraction passes into the filtrate. Nearly all the diffusible calcium of the serum is in the ionized form. The previous low figures which have been given for the concentration of ionized calcium (1.5 to 2 mg per 100 cc) are, according to McLean and Hastings, erroneous. They state that only a very small amount of diffusible unionized calcium (about 0.25 mg per 100 cc) is present, it is in the form

of a citratelike compound. The ionized calcium is in the form of calcium carbonate and phosphate. The following is a summary of the calcium fractions in serum.

Serum calcium	mg per 100 cc
Nondiffusible	4.0 to 5.0
Diffusible	5.0 to 6.5
Ionized	4.75 to 6.25
Unionized	0.25

The nondiffusible calcium, as might be expected, varies with the protein concentration of the plasma. For example, in Bright's disease (with low plasma protein, and without phosphate retention) the decline in serum calcium roughly parallels the fall in plasma albumin and the hypocalcemia is due mainly to a reduction in the nondiffusible fraction. Lymph, which has a lower concentration of protein than plasma, has also a lower calcium content.

The calcium of the cerebrospinal fluid, which is practically protein free, is almost entirely in the diffusible form, and has a concentration approximately equal to that of the diffusible fraction in the plasma. The calcium concentration of the cerebrospinal fluid has, therefore, been taken as an index of the diffusible fraction of the plasma calcium upon the assumption that the former fluid is simply an ultrafiltrate. This assumption is not warranted, inasmuch as it is more probable that the cerebrospinal fluid is secreted by the choroid plexus (ch. 70). Also, the administration of parathyroid extract or the injection of calcium salts, both of which raise the diffusible calcium of the plasma, causes little increase in the calcium concentration of the cerebrospinal fluid; it is little affected by parathyroidectomy.

McLean and Hastings have devised a biological method for the determination of the ionized calcium of the body fluids based upon the sensitivity of the frog's heart to the calcium ion concentration. In this method a modified Straub cannula is passed through the aorta into the ventricle, tied into position, and then filled with the unknown fluid (serum, edema fluid, cerebrospinal fluid, etc.). The amplitude of the contraction of the heart is recorded on a moving drum, and the cannula emptied and refilled with one of a series of standard calcium chloride solutions graded in concentration by 0.1 mmole per liter. If the amplitude of contraction given by the unknown is greater than that given by the standard, then a standard of higher concentration is tried, and *vice versa*. The calcium solution giving a contraction which just matches

that given with the unknown fluid is taken as having the same concentration as the unknown.

According to McLean and Hastings, the ionization of calcium in the body is determined primarily by an equilibrium between calcium and protein which may be expressed according to the law of mass action as

$$\frac{(\text{Ca}^{++}) \times (\text{Protein}^-)}{(\text{Ca-Protein})} = K = 10^{-4.2}$$

(at 25° C and pH 7.35)

In other words, the calcium in protein-containing fluids is considered to be present as calcium proteinate which ionizes as a weak electrolyte into calcium and protein ions, with a residue of protein bound calcium—the nondiffusible calcium fraction. The above equation may be used for the calculation of the calcium ion concentration in human serum or other protein-containing fluids providing that the total calcium and protein concentrations are known.

THE ABSORPTION AND EXCRETION OF CALCIUM—CALCIUM BALANCE

Calcium is found in food as both organic and inorganic compounds, but probably it is absorbed only in the inorganic form. Absorption occurs mainly from the upper part of the small intestine. The reaction of the intestinal contents is an important condition in the absorption of this mineral, its salts, for the most part, being readily soluble in acid but insoluble in alkaline media. Sugars, especially lactose, which in their fermentation yield organic acids in the intestine, favor absorption. Fats (free from vitamin D) reduce calcium absorption on a high calcium, low phosphorus intake, owing most probably to the formation of insoluble calcium soaps, but for some reason, perhaps the production of soluble complexes with fatty acids, such fats increase the absorption of calcium on a diet with a low calcium-phosphorus ratio. Protein food tends to increase the absorption of calcium inasmuch as the latter forms soluble complexes with certain amino acids. Soluble calcium salts, such as the chloride, carbonate, lactate, and gluconate, but not the relatively insoluble phosphate, are readily and, in moderate dosage, almost completely absorbed. After the ingestion of a large dose of a soluble calcium salt, the serum calcium level rises, reaching its maximum value in about 2 hours. The normal serum concentration is reached again about 3 hours later. It is not possible to maintain the calcium level above normal for any considerable time by the administration of calcium salts.

Milk is the best dietary source of calcium, but important amounts (up to 0.2 gram daily) of available calcium may be obtained from "hard" drinking water. The calcium of many vegetables is well utilized by the rat, the calcium of carrots (and probably of certain other vegetables as well) is readily absorbed by the human intestine, being nearly as valuable as that in milk. Spinach and other plant foods containing oxalic or benzoic acid, which form relatively insoluble compounds with calcium, reduce calcium absorption. In cereals (wheat, oatmeal), owing to their content of phytic acid (inositolhexaphosphoric acid) which combines with calcium and magnesium to form an insoluble salt, much of the mineral is unavailable. The action of phytic acid in the intestine depresses the absorption of calcium in other foods as well. Whole wheat flour has a higher phytic acid content than has white flour and, therefore, is a poorer source of absorbable calcium. As mentioned elsewhere (p. 908) the phosphorus of phytic acid is also largely unavailable. These facts explain the decalcifying action of certain cereals.

Calcium is secreted into the small intestine in various digestive juices, but little is eliminated through the wall of the colon. The excretion of calcium continues upon a calcium-free diet or during a fast and, under these conditions, the body is in negative calcium balance. In man, on an ordinary mixed diet, the calcium of the feces amounts daily to from 0.4 to 0.8 gram, thus, though a considerable amount is endogenous, is mainly the unabsorbable calcium of the food.

Smaller quantities of calcium are excreted in the urine, an average of 150 mg being lost daily by this route, though there are rather wide variations. An increase or decrease in the absorption of calcium is reflected in parallel changes in the urinary excretion.

The calcium balance, that is the difference between the quantity of calcium ingested and that excreted in the urine and the feces, is positive (calcium retention) during growth, pregnancy, acromegaly or after a period of calcium starvation. Sherman and Hawley found that children from 3 to 13 years of age, upon a daily calcium intake of from 0.74 to 1.02 grams of calcium, utilized (i.e., retained) from 0.15 to 0.62 gram per day, the quantity retained was in proportion to the size of the child (0.01 gram, daily per kilogram). In adults, Breiter and his colleagues found that the utilization of the calcium of milk varied from 15.3 to 30.3 per cent. A negative calcium balance is observed in infantile rickets, celiac and renal

FIG. 59.6 Front and side views of skeletons of twin brothers (albino rats) one of which had received a diet of normal calcium content (wheat and milk) whereas the other had received a low calcium diet (wheat and meat) (From Sherman and MacLeod.)

rickets, sprue, osteomalacia, hyperparathyroidism, hyperthyroidism (ch. 57), during starvation or calcium deficiency and usually during lactation. In infantile rickets, celiac rickets and osteomalacia (p. 908), vitamin D administration reduces the negative balance, establishes calcium equilibrium, or induces a positive balance. The chief effect of the vitamin is to increase the absorption of calcium through the alimentary tract. It also augments the calcification of bone and cartilage. Vitamins A and C are also concerned in normal bone formation (ch. 53 and 54). The daily calcium requirement and the calcium content of various foods are given in chapter 55 (see also fig. 59.6).

Phosphorus Metabolism

The adult body contains about 700 grams of phosphorus of which some 80 to 85 per cent is found in the bones and teeth. The daily requirement (12 grams) is 1.5 times that of calcium. The mineral may be obtained from a wide variety of foods. Because the foods containing most phosphorus are also rich sources of calcium and protein it can be assumed that a diet containing sufficient protein and calcium also contains sufficient phosphorus. However, if an excess of calcium is present, the absorption of phosphorus may be impeded due to the formation of insoluble calcium phosphates in the intestines.

Inorganic phosphates comprise about one half of the total blood phosphate. In adults the normal blood level is 3.5 ± 0.5 mg per 100 ml. In children the level is higher by 1 to 2 mg per 100 ml because of the activities of growth hormone. The serum levels of phosphorus and calcium are closely linked, the one varying inversely with the other. The relationship is such that the product of the total calcium in milligrams per

100 ml and inorganic phosphorus in milligrams per 100 ml is approximately constant. This *solubility product* ranges between 30 and 40 in adults and 40 and 55 in growing children. It was established by Howland and Kramer in 1922 that rickets occurs in children if the product falls below 35 and that healing takes place if it rises above 40. The serum phosphorus is also said to fluctuate directly with the blood sugar.

THE FUNCTION OF PARATHYROID HORMONE

The primary concern of parathyroid hormone is the maintenance of a normal level of calcium in the blood. Following parathyroidectomy the blood calcium falls to a low level which is however maintained by residual homeostatic mechanisms. If the parathyroidectomized animal is subjected to bleeding and replacement with calcium free blood, then the blood calcium is restored to the low basal level. It is the function of parathyroid hormone to raise the blood calcium level to that prevailing normally.

The means by which parathyroid hormone is able to maintain a normal blood calcium level is not yet certain although some features are becoming clear. At one time there was considerable argument over the question whether parathyroid hormone exerted its action mainly through the kidney, or by a direct effect on bone. It now appears that the hormone acts at both sites.

Because the first change observed following the administration of parathyroid hormone is a rise in the urinary excretion of phosphate, Albright and his associates adopted the view that the hormone exerted its primary action on phosphate metabolism. Ellsworth suggested that the reabsorption of phosphate from the kidney tubules was reduced whereas in the opinion of Albright and Reifenstein the phosphate dissolved in the tissue fluids was affected in such a way as to make it more readily excreted by the kidney. The ensuing fall in serum phosphate and change in the calcium phosphate solubility product produces reabsorption of bone salt to restore the equilibrium and a rise in the level of serum calcium to maintain the solubility product produced in the face of a low serum phosphate. Since the hypercalcemia leads to a loss of calcium in the urine, there is a continued solution of bone salt.

Studies on nephrectomized animals have been prominent in experiments designed to test the above hypothesis. Thus some workers (Tweedy, Neufeld, and Collip) found that parathyroid extracts were unable to raise the blood calcium level when given to dogs, cats, or rats following removal of both kidneys, ligation of the ureters, or ligation of the renal blood vessels. If the flow of urine was

restored by opening the ureters, then the usual hypercalcemia followed injection of the hormone. Others (Ellsworth and Fletcher, Stoerck, Monahan and Freeman, and Stewart and Bowen) have since recorded a characteristic hypercalcemia following intravenous parathyroid hormone administration to nephrectomized animals. Generally when the kidneys are removed there is a steady rise in serum phosphate which, through the solubility product, will tend to reduce the serum calcium. When the parathyroids are further removed, there is a prompt fall in serum calcium, indicating that endogenous parathyroid hormone is able to keep up the serum calcium in the absence of the kidneys. The difficulties arising from the use of nephrectomized animals and the reservations which must be made in the interpretation of the findings are underlined by the work of Grollman, who found that if the blood levels of phosphate and calcium are maintained within normal limits by peritoneal dialysis, the nephrectomized dog will respond to parathyroid extract with an hypercalcemia. An extrarenal action of parathyroid hormone was thus established.

The evidence in favor of an extrarenal action of parathyroid hormone must not be taken to exclude a direct effect on the kidney, for recent work has shown that the reabsorption of phosphate is affected. Administration of parathyroid hormone depresses the tubular transfer maximum (ch. 34) of the kidney.

The production of experimental osteitis fibrosa following parathyroid hormone administration drew attention to the possibility of a direct action of the hormone on bone. Selye found in rats that correlated with the hypercalcemia and hypercalciuria there was an increase in the number of osteoclasts in bone (p. 1063). With continued treatment the osteoblasts increase in number whereas the osteoclasts are reduced, a change which accords with increased calcification of bone and a return of the serum calcium to normal. Osteoclast proliferation and resorption of bone have also been observed in nephrectomized animals following treatment with parathyroid hormone. Although nephrectomy itself elicits similar, though mild, bone changes, such changes are prevented by parathyroidectomy so that a direct action of the hormone on bone seems likely. Conclusive evidence to this effect was obtained by Barnicot and subsequently by Chang. Barnicot transplanted pieces of parietal bone together with parathyroid tissue to the cranial cavity of mice. Intense osteoclastic activity and resorption of bone was observed, perforation of the bone sometimes occurred. Calciferol and Vitamin A, also known to affect bone metabolism, had a similar effect, but as Chang showed, control grafts of cartilage, gastric mucosa, pancreas, bone marrow, thyroid, and other tissues had no effect. The histological changes in bone

following parathyroid hormone administration occur quite rapidly, McLean and Bloom observed an extensive proliferation of osteoclasts and destruction of osteoblasts 6 hours after the administration of a large dose of hormone to rats.

Although it appears quite certain that parathyroid hormone acts directly on bone, the nature of this effect remains obscure. One early suggestion was that the solvent power of the plasma for calcium is increased, and McLean and co-workers have produced evidence for the view that supersaturation of the plasma with bone salt occurs. It now seems that calcium is mobilized from the deeper areas of bone and that citric acid may be involved in the metabolic processes concerned (Talmage). The possibility that the hormone may act upon the "uncalcified" bone matrix is also receiving attention.

In summary, then, it appears that the secretion of the parathyroid gland acts directly both upon bone and the kidneys.

THE CONTROL OF PARATHYROID GLAND ACTIVITY

The secretion of parathyroid hormone is not subject to nervous control; attention must be directed instead to the concentration of calcium and phosphate ions in the plasma. There is little doubt that the secretion of hormone by the parathyroid is stimulated by a low level of calcium. Perfusion of the thyroid-parathyroid complex with decalcified blood and injection of the perfusate into normal dogs raised the serum calcium from 13 to 49 per cent within 3 hours or less. Hyperplasia of the parathyroid glands occurs in those conditions having a tendency toward a low serum calcium, such as rickets and pregnancy, and has also been produced experimentally by establishing a chronic hypocalcemia. Conversely, the elevation of the serum calcium by the intravenous infusion of calcium salts in normal man is followed by a diminished phosphate output by the kidney despite a rising blood phosphate concentration, a response associated with a low level of secretion of parathyroid hormone.

Currently, attention is also being paid to the proposal that elevation of the plasma concentration of phosphate may call forth an increased secretion of parathyroid hormone. There is evidence in favor of the suggestion, although the matter cannot be regarded as settled. However, if the point is established, then any action of ACTH and growth hormone on parathyroid function may be attributed to the changes in phosphate metabolism induced by these agents. The parathyroid glands of hypophysectomized animals have been found to be smaller than those of control animals, but as a lowered serum phosphate is also found in the hypophysectomized rabbit and rat, the changes in parathyroid size may be presumed to be associated with the altered blood levels of phosphate and perhaps of calcium. There is little evidence in favor of a pituitary parathyrotrophic factor.

No functional relationship between the thyroid, adrenals, or gonads and the parathyroids has been demonstrated.

HYPERPARATHYROIDISM

Although the terms *osteitis fibrosa generalisata*, *osteitis fibrosa cystica* or *von Recklinghausen's disease* are sometimes regarded as synonymous with hyperparathyroidism, in actuality they represent an advanced stage of the disease. The bone changes that occur include decalcification, the formation of cystlike cavities, and resorption of the bony tissue of the trabeculae and shaft which become largely replaced by fibrous tissue (fig. 597). In severe cases there may be (1) pain in the bones, (2) extreme hypotonicity of the skeletal muscles, (3) elevation of serum calcium (sometimes up to 20 mg per 100 ml or more but usually not above 15 or 16 mg) (fig. 598), (4) fall in the serum inorganic phosphate (to below 3 mg per 100 ml) and a rise in serum alkaline phosphatase, (5) increased urinary elimination of calcium and phosphate, and polyuria together with occurrence of renal cal-

FIG. 597 Showing section of humerus from a case of generalized osteitis fibrosa cystica (From Hunter and Turnbull after Hill and Lucey.)

FIG 59-8 Showing the chemistry of blood in hyperparathyroidism and the effect of removal of the parathyroid tumor (From Hunter)

culi and renal damage (this latter may take the form of peritubular calcium deposits leading to interstitial fibrosis and cystic dilation of the tubules (Anderson)), (6) metastatic calcification may be observed in the subconjunctival tissue superficial layers of the cornea, lungs, arteries, and heart, (7) spontaneous fractures, deformity of the bones of the limbs or spine, and reduced or irregular density of bone is indicated by X ray, and (8) some degree of anemia due to fibrosis of the bone marrow. However as emphasized by Reifenstein and Howard, it is possible to have four kinds of hyperparathyroidism, namely, (1) chemical hyperparathyroidism without bone and kidney disease, (2) hyperparathyroidism with kidney, but without bone disease, (3) hyperparathyroidism with bone, but without kidney involvement, and (4) classical hyperparathyroidism with both bone and kidney damage. These differential effects may possibly depend on such factors as the dietary supply of calcium and phosphorus.

Primary hyperparathyroidism is most frequently associated with the presence of an adenoma of one or more parathyroid glands. As shown by Mandl in 1926 the condition is relieved by removal of the tumor, but the operation may be followed by an episode of low serum calcium and tetany due partly to the inactivity of the residual parathyroid tissue (which had been compensatorily depressed by the overactive adenoma) and partly to an increased demand for minerals by the healing, mineralizing bones.

Secondary hyperparathyroidism generally follows procedures which tend to reduce the blood calcium level or raise the serum phosphate. It may be induced experimentally by (1) the provision of a low calcium diet (rats and rabbits), (2) lack of vitamin D (chicks), (3) daily injec-

tions of phosphate over a period of weeks, and (4) surgical reduction of renal tissue, of experimental nephritis—the former procedure producing dwarfing in rats and a condition resembling the renal rickets of children (Pappenheimer). In the human subject, hyperplasia of parathyroid tissue may occur physiologically in pregnancy and lactation, and pathologically in association with renal disease which reduces kidney function and produces a retention of phosphate.

THERAPEUTIC USES OF PARATHYROID EXTRACT

Although the administration of parathyroid hormone would seem to be the treatment of choice in tetany, its use in the clinic is limited because of the production of antihormones with frequent injection. There is also the tendency toward demineralization of bone (which may be utilized clinically in the treatment of heavy metal poisoning) to be considered. In view of this, large doses of calcium (as chloride), lactate, or gluconate are given in tetany together with a high calcium diet and dihydrotachysterol.

Attempts to move extraskeletal deposits of calcium by means of parathormone have not met with success. This is not unexpected, inasmuch as the action of the hormone in mobilizing calcium and phosphorus is confined to the skeleton and may actually induce calcification of soft tissues (see p. 1069).

THE RELATION OF VITAMIN D TO PARATHYROID FUNCTION

The actions of parathyroid hormone and of vitamin D share many points in common. This is probably due to the fact that both agents act to maintain a normal blood calcium level. In the absence of vitamin D the parathyroid glands become hyperactive. Higgins and Sheard found that the parathyroids of chicks deprived of ultraviolet light became hyperplastic but were restored to normal appearance by the administration of cod liver oil. Also the effects of overdosage of vitamin D are reduced by elimination of parathyroid function. Hess, Wentstock, and Rivkin found in monkeys that hypercalcemia is less readily induced by irradiated ergosterol after parathyroidectomy. In dogs, Taylor, Weld, Branion, and Kay found that the toxic overdosage effects of irradiated ergosterol were less severe than usual in parathyroidectomized dogs. They also showed that the overdosage effects of parathyroid hormone and irradiated ergosterol were similar in that both substances cause the same degree of hypercalcemia (fig. 59-9) and hyperphosphatemia and a rise in the nonprotein nitrogen of the blood. The symptoms during

FIG 599 Serum calcium curve of a dog illustrating the effect of a large dose of irradiated ergosterol given intravenously in divided doses over a period of 4 hours. Note the prolonged effect upon the serum calcium (From Taylor, Weld, Branion, and Kay)

life and the postmortem findings after poisoning with either material are identical and those species (herbivora) resistant to parathormone are similarly resistant to overdosage with vitamin D. It has also been shown that either parathyroid hormone or irradiated ergosterol gives rise to metastatic calcification and to bony changes analogous to osteitis fibrosa cystica. The effect of the vitamin upon the serum calcium is slower to appear than that of the hormone. The hypercalcemia of the vitamin once established, persists for some weeks (fig. 599).

Clinically, a product of irradiated ergosterol, dihydrotachysterol (AT 10), is used as a substitute for parathyroid hormone, since its effect does not diminish on repeated administration. Dihydrotachysterol is less potent in promoting the absorption of calcium from the alimentary canal than calciferol (vitamin D₂), and is also favored for that reason.

Unlike vitamin D, parathyroid hormone does not increase the absorption of calcium from the intestine.

Bone

THE COMPOSITION OF BONE

Osseous tissue freed from fatty marrow is composed of organic material (mainly protein), water, and minerals. The chief protein constituent is ossein, but there are also small quantities of osseomucoid and an albuminoid. Water constitutes about 25 per cent of the bone weight, 30 per cent organic material, and 45 per cent inorganic constituents. The minerals consist of calcium, phosphorus, and magnesium, and small

quantities of potassium, sodium, chlorine, fluorine, and iron. Citrate is present in bone, indeed, 70 per cent of the body's entire store of citrate is contained in the skeleton. The existence of a diffusible citratelike compound of calcium in serum has been mentioned. That citrate and calcium metabolism are intimately associated seems established, but the nature of the relationship is unknown. Recent work suggests that citrate may be involved in the mechanism through which parathyroid hormone releases calcium from bone (see also pp. 1054 and 1058).

Calcium makes up from 15 to 18 per cent of the weight of fresh osseous tissue and from 20 to 25 per cent of the weight of bone which has been dried and extracted with ether.

Bone calcium exists in two forms, calcium carbonate (CaCO_3) and tricalcium phosphate $\text{Ca}_3(\text{PO}_4)_2$.¹ The ash of bone amounts to about 60 per cent of its dry weight. Calcium constitutes about 36 per cent of the ash, phosphorus about 16 per cent, magnesium 0.5 per cent, and CO_2 5.5 per cent. The ratio of calcium to phosphorus is approximately 2.2:1. The ratio of residual calcium (i.e., calcium other than that present as carbonate) to residual phosphorus (phosphorus not combined with magnesium) is about 2:1. This is, approximately, the ratio of the two minerals in tricalcium phosphate. Magnesium is present mainly as $\text{Mg}_3(\text{PO}_4)_2$. The proportions of the three chief compounds in bone ash are $\text{Ca}_3(\text{PO}_4)_2$, 80 per cent, CaCO_3 , 13 per

¹ Small amounts of calcium chloride and calcium fluoride are also present.

TABLE 59 2
Calcium of bone (dog)

	Whole Bone		Bone Ash	Calcium Phosphorus Rat o
	Fresh	Dry ether extracted		
Total calcium (per cent)	18	20	36	2 2 1
Residual calcium (per cent)	—	—	31	2 1

cent, and $Mg_3(PO_4)_2$ 2 per cent. Some of the foregoing data are given in table 59 2

Rickety bone contains a lower percentage of ash and larger proportions of water and organic material. The ratio of calcium to phosphorus, however, remains unchanged, whether the rickets (experimental) develops upon a low calcium or a low phosphorus diet. The magnesium content of bone is said to be increased in rickets and in osteomalacia.

It is now generally believed that the calcium carbonate and calcium phosphata of bone are present not as separate compounds simply mixed together with smaller amounts of other mineral salts but as a complex crystalline structure.

From a comparison of the refractive indices and X-ray diffraction patterns of bone and dental enamel on the one hand and certain crystalline minerals composed mainly of calcium and phosphorus, Taylor and Sheard concluded that the inorganic solid phase of bone and of dental enamel resembled the apatite series (podolite, fluorapatite, etc.). Fluorapatite, which many considered to be nearest in chemical structure to the bone salt, has the formula $Ca_5(PO_4)_3F$. In bone, *hydroxyapatite*, $Ca_5(PO_4)_3(OH)$, in which OH replaces F or a closely similar compound, is very generally, though not unanimously, accepted as the predominant compound in bone. The bone salt is laid down in the form of minute crystals. Compounds in which sodium, magnesium, and other minerals are substituted for calcium are also found in bone.

The ratio of total calcium to phosphorus 2 2 1 (or 10 atoms of calcium to 6 of phosphorus) and that of residual calcium to residual phosphorus 2 1 (9 atoms of calcium to 6 of phosphorus) which exist in bone also support this conclusion.

Pathological calcifications, e.g., salivary calculi, arterial or pulmonary calcifications, are believed to be similar in chemical composition to bone. Hastings and his associates hold a similar view in respect to a crystalline compound related to the apatite series as being the main mineral constituent of bone.

It should be emphasized that adult bone is not simply an inert structural material but living tissue whose mineral composition fluctuates under the influence of other body functions. The trabeculae of the bone, as shown by Aub and associates, constitute a calcium store readily available when necessary for the maintenance of the calcium requirements of other tissues when the exogenous supplies are deficient. For this reason, though calcium continues to be excreted when an animal is kept even for a long period upon a calcium-free diet, no change in the serum calcium level occurs. Parathyroid extract, as mentioned elsewhere, raised the serum calcium through its action in mobilizing these calcium stores.

In birds, the extraordinary demand made upon calcium metabolism for the production of the egg shell has been provided for by the development of osseous tissue within the marrow spaces of the long bones. Weakening of the essential skeletal structure, which otherwise might result from the withdrawal of the mineral during the egg-laying season, is thus avoided. The growth of this so-called *medullary bone* is stimulated by estrogens. Normally, its growth appears to be under the control of the ovarian secretion; it is cyclical or seasonal in character and is associated with other phenomena of the mating season of birds, e.g., the appearance of serum vitellin in the circulation, an increase in plasma fat and phospholipid, and pronounced hypercalcemia.

The bones also serve a detoxicating function, elements such as lead, radium, fluorine, and arsenic being removed from circulation and deposited in the bones and teeth. Mottled enamel (chalky white patches upon the surfaces of the teeth) is attributed to an excess of fluorine in the food or drinking water, though smaller amounts of fluorine are said to be beneficial for the development of the teeth and to prevent dental caries. The mobilization of bone calcium plays a very minor role in maintaining the normal blood reaction against the ingestion or production of excess acid. Some reduction in bone calcium can be detected, however, in animals after the administration of hydrochloric acid.

BONE FORMATION

The Histology of Developing Bone

There are two types of ossification, *intramembranous* and *intracartilaginous* or *endochondral*. The bones of the cranial vault, the maxilla, and the mandible are formed through the ossification of membranes. The bones of the limbs and trunk and the base of the skull are first modeled in cartilage, which becomes transformed into bone by both

endochondral and intramembranous (i.e., perosteal) forms of ossification. Studies with radioactive isotopes have shown that calcium and phosphorus are first laid down in the epiphysis of the developing bone and are later transferred to the shaft (diaphysis) where a primary center of ossification appears and enlarging spreads toward both ends of the bone. Secondary centers appear subsequently in the epiphysis. The deposition of calcium is hastened by vitamin D. The cartilage cells just ahead of the spreading zone of calcification show active proliferation and become arranged in longitudinal rows (fig. 59.10). The transformation of the calcified cartilage into true bone is brought about in the following fashion. The cells of the deeper layers of the membrane covering the cartilage (perichondrium) give off long processes to form a meshwork of interlacing fibers. These cells are referred to as *osteoblasts*. The fibrous framework thus laid down soon becomes impregnated with calcium salts with the formation of a layer of true bone just beneath the perichondrium or periosteum as it must now be called. The subperiosteal process which is essentially the same as that whereby the cranial bones are developed from membrane is well advanced, whereas the interior of the bone still consists merely of calcified cartilage. The latter however soon becomes invaded by blood vessels from the periosteum and by large multinucleated cells (20 to 40 μ) known as *osteoclasts*. These cells which have a pronounced eroding action upon the mineralized cartilage probably through the production of an enzyme tunnel channels through it for the conveyance of the blood vessels and excavate small cavities. The excavations in which the osteoclasts lie are known as *Haversian lacunae*. Osteoblasts which have advanced into the interior of the blood vessels cause the formation of true osseous tissue in the walls of the spaces formed by the osteoclasts.

At a somewhat later date than that at which the primary ossification center appears in the shaft, a secondary or epiphyseal center appears in one or both ends of the bone. The calcification process and subsequent ossification follow the same course as that described for the diaphysis. The epiphyseal and diaphyseal areas however remain separated from one another by a layer of uncalcified cartilage, the *epiphyseal plate* until a certain age which varies between different bones.

Through the combined action of osteoclasts and osteoblasts a complete replacement of the calcified cartilage results and the structure characteristic of bone gradually evolves. The center of the shaft becomes hollowed out to form the medullary canal. The spaces which have been formed by the osteoclasts in the shaft of the bone itself become joined together and constructed into the system of *Haversian canals* which serve as conduits for the transmission of blood vessels. In the ends of the

FIG. 59.10. Developing bone, proximal phalanx of a 3-month human fetus. *kn*₁, Unchanged cartilage; *kn*₂, columns of cartilage cells; *kn*₃, zone of calcifying cartilage; *kn*₄, vestiges of walls of broken down cartilage cavities; *pk*, perichondrium (periosteal) bone (black); *pb*, perichondrium (periosteum) and * connection between periosteum and primary marrow. As yet, no endochondral bone formation. (From Maximow and Bloom after Sobotta.)

bones the spaces are much larger and irregular and becoming filled with red marrow constitute the characteristic spongy or cancellous bone of this region. The walls of these spaces appear in cross section as interlacing bars of osseous tissue and are usually referred to as trabeculae. The bone forming the walls of the Haversian canals is laid down in a series of concentric tubular lamellae. As each lamella is completed it imprisons the osteoblasts within small lacunae from which numerous fine canals are given off into these the processes of the osteoblasts penetrate. The osteoblasts in these situations lose their osteogenetic function but do not disappear. In the developed bone they are referred to simply as *osseous cells* or *osteocytes*.

A long bone grows in length at the junction of the epiphysis with the diaphysis and in thickness through the activity of the osteoblasts of the deeper layers of the periosteum. The Haversian canals and the marrow cavity are also lined with a membrane (the *endosteum*) containing osteoblasts through which increased width of the bone is also brought about.

The osteoblasts and osteoclasts are concerned not only with the development and growth of bone, but are active throughout life and are responsible, it is believed, to a large extent at any rate, for the lability of adult osseous tissue (p. 1062). Healthy bone is constantly being broken down, resorbed, and repaired. Several conditions may alter the balance one way or the other between these two processes, e.g., the relation of the calcium intake to the calcium requirement and the activities of various ductless glands—parathyroid, thyroid, pituitary, etc. Large numbers of osteoclasts are in evidence when bone resorption is taking place. Osteoclastic activity is, therefore, pronounced when remodeling of bone is occurring, as in the removal of excess callus or in the restoration to normal dimensions of the enlarged end of a bone in healing rickets, in certain bone diseases, and in wasting diseases. In old age also, the resorptive process outstrips the processes of repair, the bones become rarefied (*senile osteoporosis*) and more fragile. Ham and some other authorities deny that the osteoclasts are active agents in the removal of the bone tissue, claiming that the appearance of these cells is merely incidental or sequential to the resorption process.

When bone formation is in the ascendancy, as during the repair of a fracture, the osteoblasts show active proliferation.

Newly formed bone is stained selectively *in vivo* by madder, a red dye, or by alizarin, a derivative of it. These are, therefore, valuable agents for the investigation of the growth of bone in the living animal or of the action of parathyroid hormone and other influences upon bone metabolism. The dye which is given orally, is deposited with the mineral constituents, calcium and phosphorus.

A CONSIDERATION OF THE FACTORS UNDERLYING THE CALCIFICATION PROCESS. Several theories have been advanced in attempts to picture the processes underlying the deposition of calcium salts in the cartilaginous matrix.

1. A protein constituent of cartilage, it has been supposed, adsorbs calcium, for which it exhibits a special affinity, the calcium subsequently combines with phosphorus to form tricalcium phosphate. Wells showed, for example, that bone salts were deposited in a piece of boiled cartilage placed in the abdominal cavity.

2. The saturation of a solution with a salt such as calcium phosphate and the precipitation of the latter in solid form is determined by the product of the concentrations of the Ca^{++} and PO_4^{--} ions in the solution, i.e., upon the *ion product* ($\text{Ca}^{++} \times \text{PO}_4^{--}$), and not upon the total quantities of calcium and phosphorus present. The ion product at which the solution is just saturated is called the *solubility product*. The presence of protein in the so-

lution reduces the degree of ionization, part of the calcium, as we have seen, becoming bound to form calcium proteinate, a weak electrolyte. The body fluids are, therefore, capable of dissolving more calcium phosphate than is a protein free solution similar in its salt composition to that of plasma. The CO_2 dissolved in the body fluids also increases their ability to hold calcium salts in solution. Any reduction in the protein concentration or in the CO_2 tension in the body fluids would, therefore, be expected to favor the deposition of calcium salts.

An explanation of the calcification process upon a basis afforded by the foregoing considerations has been advanced by Howland. It is assumed that the fluids bathing the cartilage cells have, in common with other extravascular fluids, a lower protein concentration than has plasma. It is further suggested that since the cartilaginous matrix has a low metabolism, the CO_2 tension of the fluids bathing its cells is lower than that of plasma, the pH of these fluids will, therefore, tend to be higher. Such conditions, it is argued, must favor the deposition of calcium salts. A low concentration of inorganic phosphorus and of calcium in the plasma will, on the other hand, tend to retard calcification, this would be completely arrested if the ion product were below the value at which precipitation occurs. In practice, Howland and his associates have employed the product of the total calcium and inorganic phosphorus, each expressed in milligrams per 100 ml., as an index of the calcification process in infantile rickets. They state that in children with active rickets the product is practically always below 40, and when the disease is severe, below 30, whereas in normal children it is between 50 and 60 (i.e., $11 \text{ mg. of Ca} \times 5 \text{ mg. of P} = 55$). It is obvious that a fall in either inorganic phosphorus or calcium would tend to lower the $\text{Ca} \times \text{P}$ product, actually two varieties of rickets were distinguished—a *low phosphorus* and a *low calcium* type. It is now recognized, however, that these are simply different stages of the disease and that the level of the inorganic phosphorus alone is a more useful criterion by which to judge the extent of the calcification defect than the $\text{Ca} \times \text{P}$ product. For example, when rickets is progressing the inorganic phosphorus of the plasma is lowered to between 3 and 4 mg. or less per 100 ml., but the serum calcium is not far from the normal level. During the stage of healing, i.e., of active calcification, the inorganic phosphorus of the blood tends to rise and the serum calcium to fall, there might, therefore, be little change in the $\text{Ca} \times \text{P}$ product.

Another factor considered to be of importance in the calcification process is the *supersaturation* of the body fluids with calcium salts. That is, quite apart from the greater solubility of calcium salts in fluids containing protein and CO_2 , the

concentrations of calcium phosphate and calcium carbonate in the body fluids are constantly maintained above their saturation limits, owing to the extreme slowness with which final equilibrium between the solid and liquid phases is established. Precipitation of these salts from solution will continue so long as the ion product is above that of the saturation level.

Calcification, however, cannot be explained upon a physicochemical basis alone, the activity of living cells is also involved in the process. Shipley, Howland, and Kramer showed, for example, that in experiments *in vitro*, calcification was inhibited by a protoplasmic poison such as HCN. Two views have been expressed as to the nature of the vital processes concerned.

3 Watt, from a comparison of the shapes of calcium phosphate particles precipitated in certain inert colloids with those formed in bone, concluded that calcification was not a simple precipitation of calcium phosphate from solution but was due to the active secretion by the osteoblasts of bone salts derived from the calcium and phosphorus of the blood.

4 According to Robison and his colleagues, calcification is primarily dependent upon enzyme action through which the fluids in immediate relation to cartilage cells become highly supersaturated with calcium phosphate. These observers have accumulated much evidence in favor of their view. They have demonstrated the presence in bone (and also in plasma and other tissues, see below) of an enzyme capable of hydrolyzing various phosphoric esters, e.g., hexosemonophosphate, glycerophosphate, etc. This enzyme is called *phosphatase*. It is believed to be a product of the osteoblasts, the proliferating cartilage cells and the cells of the inner layer of the periosteum. According to this conception of the calcification process, the enzyme liberates inorganic phosphate from phosphoric esters and raises locally the concentration of the PO_4^{3-} ion. The product of the concentrations of the Ca^{++} and PO_4^{3-} ions then exceeds the solubility product of calcium phosphate, which is in consequence deposited in the cartilaginous matrix.

Evidence bearing upon this hypothesis is as follows.

1 It was shown by Robison that when the head of a bone from a rachitic rat was immersed in a solution of calcium hexosemonophosphate at body temperature, a deposit of calcium phosphate occurred in the zone of preparatory calcification (p 1062). This was attributed to the liberation by phosphatase of inorganic phosphate from a phosphoric ester, thus raising the product of the concentrations of PO_4^{3-} and Ca^{++} ions.

2 Shipley, Kramer, and Howland found that calcification of a rachitic bone occurred if placed in normal serum. Calcification also resulted if the bone were placed in a sterile solution of inorganic

salts containing sodium chloride, sodium bicarbonate, and magnesium sulfate, together with calcium and inorganic phosphate in the same concentrations as in normal serum. They concluded that living processes were concerned, since calcification was inhibited by HCN. They believed, however, that phosphatase could have played no part in the process for the artificial solution did not, of course, contain a phosphoric ester.

3 Robison claimed that the result of the experiment just described was dependent upon the fact that in the solution used, the concentration of the calcium phosphorus compound was near the point at which spontaneous precipitation might be expected to occur. In normal plasma, as already mentioned, calcium and phosphorus remain in solution at these concentrations because it contains protein which depresses the ionization of calcium, the ion product upon which precipitation depends is, therefore, considerably lower. Robison and Soames showed that calcium phosphate precipitates after a few days from a solution such as that employed by Shipley and associates if simply allowed to stand. It was found indeed by the latter workers that the addition of protein to the extent of 1 or 2 per cent inhibited the calcification of the immersed bone. Robison and Soames showed later that though calcification of rachitic bone will occur when immersed in a solution containing calcium and phosphorus if the concentrations are sufficiently high, i.e., $\text{Ca} \times \text{P}$ product over 40 (4 mg of phosphorus and 10 mg of calcium per 100 cc.), calcification will not occur if the product is lower than this unless a phosphoric ester is added. Quite small amounts of the ester (glycerophosphate) were sufficient to cause calcification.

4 Phosphatase is present in bone in large amounts when and where active calcification is taking place (see below), which strongly suggests that it plays an essential role in the calcification process.

5 Certain facts have been cited as opposed to the phosphatase hypothesis: (a) in rickets the phosphatase activity of bone and plasma is increased rather than the reverse, and in the blood of rachitic rats the percentage of phosphoric esters hydrolyzable by phosphatase is not below normal, (b) normal plasma contains only very small quantities of phosphoric esters, which seem inadequate to supply the inorganic phosphate necessary for the calcification process, and (c) certain tissues which do not calcify normally are rich in phosphatase whereas other tissues, such as the arteries which are frequently the site of pathological calcification, do not contain the enzyme.

Robison did not contend, however, that the phosphatase mechanism is the only one concerned in the calcification process for, as mentioned above, calcification will occur in the absence of a phosphoric ester provided the concentrations of

calcium and inorganic phosphate are sufficiently high. He and his colleagues found that when bone slices were treated with KCN or with certain fat solvents (alcohol chloroform or acetone) before placing them in the supersaturated solution, calcification did not occur in the absence of glycerophosphate. These substances however exerted little or no inhibitory effect if glycerophosphate were present i.e. the phosphatase mechanism was not paralyzed and calcification proceeded. Formalin on the contrary prevented calcification whether a phosphoric ester was present or not. These results in Robison's view point to two distinct mechanisms governing the calcification process: (1) The phosphatase mechanism poisoned by formalin which produces in the fluids bathing the cartilage cells a state of supersaturation in respect to bone salt. (2) A mechanism poisoned by several agents especially cyanide which is responsible for the deposition of bone salts from a supersaturated solution whether this is the result of phosphatase action or is brought to the cartilage matrix from another source. The nature of the second mechanism is unknown. It may be due. Robison suggests to a slight increase in the pH of the matrix fluid brought about by some membrane equilibrium. Since this mechanism is inhibited or paralyzed by cyanide it is evidently dependent also upon the activity of living cells.

At the present time a satisfactory description of the processes underlying the calcification of bone cannot be provided. Among the factors contributing to the prevailing uncertainty two are prominent:

1. There is no agreement concerning the precise structure of bone salt or of the identity of the mineral deposited during calcification. Although it is accepted that the material is of the general nature of an apatite—a complex of tricalcium phosphate and calcium hydroxide—there is also the presence of carbonate and its variable composition in different areas to be accounted for. Perhaps the bone salt may be precipitated in one form and then remodeled to another.

2. The function of alkaline phosphatase remains obscure. Although there is little doubt that the enzyme is concerned in some way with calcification, the view that the phosphatase may be concerned with the production and maturation of the bone matrix prior to calcification rather than with the deposition of bone salt is now thought possible. In this connection it is of interest that ossifying areas of cartilage display a particular affinity for calcium and phosphate even after boiling (Waldman).

Additional suggestions are that the enzyme might be concerned with the formation of a phosphate ester acting as a template for the catalytic

crystallization of bone salt, or that it keeps the surface of bone crystals free of ester phosphate thus permitting continued crystal growth.

THE DISTRIBUTION AND PROPERTIES OF 'ALKALINE' PHOSPHATASE Phosphatase² is present in greatest amount in ossifying cartilage, in smaller amount in formed bone, but is absent from resting epiphyseal cartilage and from nonossifying cartilage in other situations. It was shown by Robison to be absent from the patella before the appearance of the ossification center in this bone, but present thereafter. The teeth of young animals contain it in relatively large amounts. It is present in milk³ and also in the floral parts of plants.

The optimum pH for phosphatase activity is around 9.0. Magnesium ions greatly increase the activity of the enzyme whereas calcium ions are mildly inhibitory. Phosphatase activity has been demonstrated in a number of tissues (see table 59.3). The alkaline phosphatase in plasma, kidney and intestine are not necessarily identical with that found in bone inasmuch as the bone and kidney phosphatase but not intestinal phosphatase are inhibited by bile acids. Bone is apparently the main if not the sole source of plasma phosphatase since this is not appreciably reduced after the removal of various organs (intestine, kidney, spleen, pancreas, etc.). Phosphatase is excreted by the liver—a marked rise in plasma phosphatase therefore occurs in obstructive jaundice and in jaundice due to liver damage but not in the purely hemolytic type (ch. 39).

The pathological calcification of arteries such as the aorta which Kay states does not contain the enzyme cannot be satisfactorily explained upon the phosphatase hypothesis of Robison. The phosphatase in bone and the other solid tissues mentioned is reduced by the administration of irradiated ergosterol in amounts which cause the withdrawal of calcium from the bones and calcification of the tissues whereas small doses cause an increase. On the other hand it has been shown by Kay that the plasma phosphatase is increased often markedly in diseases involving extensive changes in bone structure (see table 59.4). Bone and certain other tissues e.g. kidney, serum and semen but especially the human prostate contain

² Phosphatase activity is expressed as the number of milligrams of inorganic phosphorus liberated per gram of tissue from sodium β -glycerophosphate after 48 hours hydrolysis at the optimum pH and at a temperature of 38°C.

³ Kay and Graham have introduced a test by which one may determine whether a given sample of milk has been properly pasteurized. The test is based upon the fact that the temperature used in the pasteurization process destroys the activity of the enzyme.

TABLE 59.3*

an "acid" phosphatase. Its optimum pH is between 4 and 5.4. Its concentration in the serum is increased in prostatic cancer with metastases.

DEFECTS OF OSSIFICATION AND PATHOLOGICAL CALCIFICATIONS

Diseases of Bone

Several of these have already been considered in other parts of the text—*infantile rickets*, on pages 447, 453, and 454, *osteomalacia* on page 908, and *osteitis fibrosa cystica* on page 1059.

The hardness, strength, and rigidity of healthy bone depend upon the proportions of the organic and inorganic constituents incorporated into its structure, much as the properties of a plaster bandage depend upon the impregnation of the cotton mesh with plaster of Paris. The mineral and fibrous components are of equal importance, each reinforces the other. The cotton bandage has a certain tensile strength but lacks rigidity, a cast of plaster of Paris alone has maximum rigidity, but is brittle and readily broken or crushed. In most bone diseases the normal proportions between these two components are altered. In rickets and osteomalacia, for example, the bone salts are reduced in relation to the organic material. In these diseases, as also in *osteitis fibrosa cystica*, the bones are in consequence softer and more yielding than the normal. In certain other bone conditions the proportion of mineral to organic material is increased. The bone as a result is brittle and easily fractured. In other instances again there may be little change in the proportion of these two materials but the mass of the bone is increased or diminished with corresponding variations in strength.

Osteitis deformans (Paget's disease) is a disease of the skeleton involving mainly the bones of the skull, pelvis, limbs, and spine. The cranium is enlarged and its wall greatly thickened, the long bones of the limbs are massive and curved, the back is bowed (kyphosis) and its movements restricted. The organic matter of the bones is increased and the calcium content decreased, but the total amount of phosphorus is not far from normal. A pronounced degree of arteriosclerosis is frequently a feature. There is good evidence that the overgrowth of osseous tissue is secondary to a primary bone destruction. Metabolic studies in this disease have yielded little information though there is said to be a retention of calcium and phosphorus, the blood alkaline phosphatase level is high.

Fragilitas ossium (*osteogenesis imperfecta*) is a congenital disease characterized by thinness and

extreme fragility of the skeleton, especially of the long bones and ribs. The cranium shows defective calcification. Fractures result from the most trivial injuries or may occur without any apparent cause. Union and healing of the fractures occur, however, as readily as in a normal bone. The bones have a low calcium content, the cortex is very thin, and the medullary cavity dilated.

Achondroplasia is a congenital disease in which endochondral ossification (p. 1062) of the limb bones, especially the humeri and femora, is defective. Periosteal ossification is active. The long bones are, therefore, much shorter and thicker than normal, strong, and dense. A characteristic type of dwarf results, short arms and legs with a trunk and head of almost normal dimensions. The bones of the base of the skull fuse prematurely and the development of certain facial bones is abnormal. Achondroplastic dwarfs develop, as a result of these abnormalities, a distinctive facies, depressed nasal bridge (pug nose), a broad forehead and prominent lower jaw.

Marble or chalky bone (*Albers-Schönberg's disease*) In this condition the density of the bone is greatly increased, the cancellous tissue is filled with a chalky material and the medullary canal may be almost obliterated by the concentric thickening of the shaft. The excessive calcification, however, renders the bones soft and brittle. Calcification of soft tissues (arteries, lungs, tendons) is often a feature. The disease is exceedingly rare.

The cause or causes of the foregoing osseous abnormalities is unknown. The possibility of some endocrine disorder of course comes to mind but there is little or no evidence of such.

Renal rickets, *renal osteitis fibrosa cystica*, or *generalisata*. This is a condition commencing most usually in childhood and associated with chronic nephritis, rarefaction of the skeleton, dwarfism, low serum calcium, and, sometimes, calcium deposits in the soft tissues, especially in the kidneys, there are also acidosis and phosphate retention. The parathyroids show hyperplasia. We have seen that a rise in serum phosphate causes a reciprocal reduction in serum calcium and it is usually held that the hypocalcemia seen in this disease is due to the retention of phosphate resulting from the renal insufficiency. The hypocalcemia so produced causes, it is presumed, a drain of calcium from the bones. Increased excretion of phosphate into the intestine as a result of the diminished excretion by the kidney, with consequent depression of calcium absorption is possibly a contributory factor in the production of the low serum calcium. Albright and his colleagues suggest that renal osteitis fibrosa cystica or generalisata is a more appropriate name for this disease than renal rickets inasmuch as the histological changes in the bones are indistinguishable from primary hyperparathyroidism (p. 1060). This brings up the question as to

whether the demineralization of the skeleton is due to the hyperparathyroidism induced as a compensatory reaction to the low serum calcium. In the opinion of Albright and his associates, the withdrawal of calcium from the skeleton is not directly due to the parathyroid hyperplasia, i.e., to the parathyroid hormone itself, but to the acidosis which results from the failure of the diseased renal tubules to produce ammonia. Calcium is used as a base for the neutralization of acid, the tendency toward a fall in serum calcium is met by the withdrawal of calcium from the bones. Parathyroid hyperplasia occurs as a compensatory reaction to the hypocalcemia. The effect upon the bones was found to respond to measures which reduce the acidosis.

Calcification of Soft Tissues

Dystrophic calcification is the term applied to the deposition of calcium salts in dead, dying, or chronically inflamed tissues and in areas of fatty or hyaline degeneration. Thus areas of necrosis, infarcts, scar tissue, caseous tuberculous areas, and degenerated nerve cells tend to undergo calcification. Calcification also occurs in the infarcts of the placenta which appear in the later half of pregnancy. Many of the examples of pathological calcifications to be described are simply special examples of dystrophic calcification. The factors determining the deposition of calcium salts in devitalized tissues are obscure. It has been suggested that since the CO_2 production in such tissue is minimal or entirely absent they will have a more alkaline reaction, this, of course, would tend to cause the deposition of calcium salts.

Calcinosis is the name given to conditions in which (1) calcified areas are scattered throughout the skin and subcutaneous tissues (*calcinosis circumscripta*) or (2) a more generalized calcification of skin interstitial tissues, tendons, fascia, or muscles occurs (*calcinosis universalis*). When the calcification process involves predominantly the interstitial tissues of the muscles the condition is usually referred to as *myositis ossificans*. In calcinosis the calcium and phosphorus levels of the blood are normal. Metabolic studies have in some instances revealed a retention of calcium. In the region of the calcified areas true bone formation may occur. Calcinosis of the superficial tissues is in many cases associated with scleroderma (a condition characterized by induration of the skin due to an increase in the intercellular collagenous tissue). The cause of calcinosis is obscure; the calcification process may be secondary to degenerative changes in the tissues themselves. There is no evidence that it is dependent upon an abnormality of parathyroid function, though Selye has reported a con-

dition in rats resembling scleroderma following the administration of parathyroid extract.

ARTERIAL CALCIFICATION *Arteriosclerosis* is seen in two main forms: (1) the *atherosclerosis* (athere = crushed grain, porridge) of Marchand, (2) the *medial sclerosis* of Monckeberg.

METASTATIC CALCIFICATION This term connotes a transference of calcium from the skeleton to the soft tissues. It occurs in animals treated with excessive doses of parathyroid extract or irradiated ergosterol. Though the calcium deposits may be found in any of the soft tissues, the arteries, kidneys, and lungs are especially susceptible to calcification. The fundus of the stomach is also a common site. It will be noted that the three last mentioned organs eliminate acid, and it has been suggested that since this will leave the cells more alkaline in reaction a condition favorable to calcium deposition is created. Metastatic calcification also occurs occasionally clinically. It has been reported in hyperparathyroidism (p. 1060), renal rickets, and in certain bone diseases, e.g., multiple myelomata. It is very natural to assume that in conditions of disturbed calcium metabolism and destructive disease of bone the calcium deposits are simply the result of the excess calcium in the circulation. It is quite possible, however, that in some instances at any rate, it is secondary to tissue injury and may therefore be in reality, a type of dystrophic calcification induced by a toxic agent. Parathyroid extract and irradiated ergosterol, for example, besides their effects upon calcium metabolism have a definitely toxic action. Furthermore, metastatic calcification is in some instances associated with hypocalcemia.

It is a fact of great interest that the calcium deposits in the arteries and in other soft tissues in the various types of pathological calcification have the same composition as the main mineral compounds of bone. Evidence obtained by both chemical and physical methods support this conclusion. In certain instances actual bone formation occurs, even to the extent of producing red marrow tissue. Areas of ossification have been observed in the aorta and in the neighborhood of calcium deposits in the necrotic kidney of the rabbit. Also, as shown by Huggins, if a section of the mucosa of the bladder be transplanted into the subcutaneous tissues it becomes the site of bone formation.

Renal calculi (*nephrolithiasis*, *urolithiasis*) kidney and bladder stones composed largely of calcium phosphate have been produced in experi-

mental animals (rats) by the administration of irradiated ergosterol or parathyroid extract in excess. They are apparently the result of the excretion in the urine of large amounts of calcium liberated from the bones.

Renal or vesical calculi are also associated with various bone diseases of a destructive nature, they are quite frequent in hyperparathyroidism. Renal calculi may be composed of calcium oxalate (in acid urine), or of calcium carbonate or phosphate (in alkaline urine), or of urates, uric acid or cystine. There is an undoubted relationship between the urinary excretion of citrate and the production of calcium stones. Citrate excretion is reduced in those suffering from renal calcium deposits even though the intake of citrate is greatly increased. In normal persons, the urinary excretion of citrate runs parallel with the calcium excretion and varies with the calcium of the diet. It is suggested that citrate in some way reduces the tendency toward the precipitation of calcium. Nephrolithiasis is particularly prevalent in the tropics and the possibility has been suggested that hypervitaminosis D, due to overirradiation with ultraviolet light and, possibly, deficiency of vitamin A are causative factors. The production of renal calculi in animals by hypervitaminosis D, as mentioned above, occurs only, however, when doses are employed which cause bone resorption and an increased concentration of calcium in the urine. Such results have, therefore, little bearing upon the question of the production of urinary calculi in the human subject. Also, though there is some evidence that avitaminosis A is conducive to the development of urinary calculi in animals (the cornification of the epithelium of the urinary tract being, apparently, a predisposing factor), there is little warrant for applying the results of animal experiments to the question of urinary lithiasis in man.

Albright's syndrome (polyostotic fibrous dysplasia, osteitis fibrosa disseminata) This is a rare disease with bizarre manifestations, consisting of bone cysts, fractures, patches of brown pigmentation in the skin, outward bowing of the femur, and, in female children only, precocious puberty. The bony changes resemble those of osteitis fibrosa cystica but are more localized, they, as well as the cutaneous pigmentation, often show a segmental distribution, suggesting a neurological or developmental origin. There is no evidence of parathyroid overactivity or of a fault in any other endocrine.

THE ENDOCRINE ORGANS OF SEX

The Genetic Basis of Sex

The sex glands—testes and ovaries—are known also as the *gonads* and are the *primary organs of sex*. They furnish the male or female sex cells (spermatozoa or ova) and the hormones upon which the *ultimate* maleness or femaleness of the individual depend. Associated with the sex glands are organs which are essential for procreation but whose activities are governed by the secretions of the sex glands. These are the *accessory sex organs* and include the external genitalia as well as the uterus, fallopian tubes and vagina in the female and the seminal vesicles and prostate glands of the male. Certain sexual characteristics, the *secondary sex characters*, make their appearance at the time of sexual maturity (puberty). They include the occurrence of hair on the pubis of the human male or female, the deepening of the voice in men, the development of the mammary glands in women and the psychic manifestations in both sexes. In certain other forms the secondary sex characters differ even more noticeably, (e.g., the development of the antlers of stags, the distinctive plumage of birds, the comb and wattles of the cockerel).

The genetic sex of an animal is determined at the time of conjugation of the *gametes* (spermatozoon and ovum) and depends upon which one of two types of chromosome is contained in the sperm cell. The cells of the human body contain 23 pairs of chromosomes. During gametogenesis the pairs are split so that each gamete contains a single representative of each of the 23 pairs of chromosomes, in other words 23 chromosomes instead of 46. This is the process of *meiosis*. The partners in one pair of chromosomes of the male, the sex chromosomes, are dissimilar, one X, is larger than the other, Y, and during meiosis these are separated so that one male gamete will contain an X chromosome and the other a Y. In the female two X chromosomes are in combination as the sex chromosomes, so that on meiotic division to form ova each ovum comes to possess one X chromosome. It will be seen that the chromosomes determining sex are carried by the gametes produced by the male. If an ovum is fertilized by a sperm bearing an X chromosome then the combination XX will be produced and result in the development of a female. On the other hand, if the fertilizing sperm bears a Y chromosome, then the XY com-

bination produces a male. It is perhaps worth noting that in birds the heterogametic sex (XY) is female, whereas the sex possessing two X chromosomes (XX) is male.

Besides carrying the genes concerned with sex determination the sex chromosomes may also contain the genes controlling certain diseases and defects. Hemophilia, color blindness and fishskin disease (ichthyosis) are examples of such abnormalities. Hemophilia and color blindness are transmitted from grandfather to grandson, through the intermediary of a normal carrier female and are conveyed on the X chromosome, whereas ichthyosis passes from father to son via the Y chromosome. If a man afflicted with hemophilia marries a normal woman the disease is not transmitted to his sons (XY), for the X chromosome received from the mother does not carry the defect and neither does the Y chromosome received from the father. The daughters, however, have received an abnormal factor in the X chromosome from the father as well as a normal one from the mother but remain free of the disease since the abnormal character is recessive and is suppressed by the dominant normal character. Should the daughters marry and a Y-sperm fertilize an ovum then a male (XY) zygote results and the child will show the disease for one of the abnormal X chromosomes of the mother has paired with the Y of the father. The Y chromosome does not offset the effect of the abnormal X chromosome. It should be remembered that since the mother possesses two X chromosomes a normal and an abnormal one, it is an even chance which one the child will receive. A classic series of cases of the disease may be found among the descendants of Queen Victoria who was a carrier. Eleven hemophiliacs are to be found in the three succeeding generations.

Sex chromatin. Since every cell of a male individual differs from that of a female, in that it possesses a dissimilar sex chromosome, it might be postulated that suitably refined cytological techniques would prove capable of distinguishing between male and female cells. Such is so. In 1919 Burr and Bertram reported the discovery of a sexual dimorphism in the neurone of the cat, since then their findings have been extended to a

FIG 60-1 Nuclei of cells in epididymal smears of a chromosomal female (left) and chromosomal male (right). Note the sex chromatin indicated by arrows in the female. (From Grumbach and Barr.)

variety of tissues and a variety of species, including man. The difference between male and female cells lies in a special mass of chromatin, known as the *sex chromatin*, which is characteristic of the female. In man, skin biopsy preparations smears from the oral mucous membrane, and blood films yield satisfactory preparations for study. The sex chromatin is typically a plano-convex mass, about 1 micron in diameter lying close to or in contact with the nuclear membrane (fig 60-1). It stains readily with basic dyes and is Feulgen positive, indicating the presence of deoxyribose nucleic acid. The sex chromatin appears to be a chromosomal derivative since, like the chromosomes, it is consistently Feulgen positive, whereas the nucleolus (with which the sex chromatin might be associated) is Feulgen negative. There is no evidence that the sex hormones influence the chromatin. Typical sexual dimorphism has been found in the nuclei of individuals of all ages, from the early embryo to senility. It is likely, although not proven, that the sex chromatin of female cells represents certain regions of the two X-chromosomes that adhere together. The importance of the discovery of sex chromatin apart from its theoretical significance lies in the diagnosis of the genetic sex of individuals with sexual anomalies, such as in cases of pseudohermaphroditism, gonadal agenesis, etc. These will be examined further below.

Sex ratio. If spermatozoa carrying X chromosomes and spermatozoa carrying Y chromosomes are produced in equal numbers in the testis and if each has an equal chance of fertilizing an ovum, then equal numbers of male and female individuals should be conceived. In actual fact, in the human, more male embryos than female develop; the *primary sex ratio* is greater than one. Precise

figures are difficult to obtain for man, but in the pig, Parkes concluded that the ratio must be about 160/100; in cattle, it is about 130/100. Between conception and delivery, there is an appreciable mortality which preferentially affects the male, so that the proportion at birth, the *secondary sex ratio*, is lower, being in the pig about 100/100. In Britain, the human secondary sex ratio is about 106/100. Through childhood and in adult life, the male mortality exceeds that of the female, so that numerical equality of the sexes is reached during adolescence and thereafter, the females outnumber the males. At around 50 years or so, there are twice as many women as men. The cause of the primary sex ratio is uncertain. It has been suggested that the spermatozoa bearing the smaller Y chromosomes are more active than those carrying the larger X chromosome, so that more male spermatozoa than female reach the ovum. Alternatively, the environment of the genital tract could favor one kind of spermatozoon—attempts to control the primary sex ratio have been made on this basis.

The Hormonal Factors in Development of the Genital System

Although the sex of an individual has been seen to be determined genetically, a variety of factors may intervene to modify embryonic sexual development. The gonads are derived from mesodermal primordia arising in the genital ridges along the dorsal surface of the coelomic cavity. Essentially, they are bipotential organs which can become testes or ovaries. The testicular and ovarian components are antagonistic, and the balance normally becomes tipped so that the resultant gonad conforms to the genetic sex of the individual. Experimentally, in lower forms such as amphibians and birds, treatment with sex hormones can reverse gonadal development, so that a presumptive testis becomes an ovary and vice versa. In mammals, gonadal reversal has not been achieved experimentally, but evidence in favor of a hormonal

effect on gonadal development has long been derived from study of the bovine *freemartin*. Here a sterile female calf (a freemartin) is born as a twin with a normal male. The sexual abnormalities of the freemartin include a small undeveloped uterus and an enlarged clitoris. The gonads are intraabdominal and resemble testes to a variable extent. It is well established that the freemartin is a genetic female (this has recently been confirmed by sex chromatin studies) and that the condition is caused by a hormone that reaches the female embryo from the male twin through vascular anastomoses between the partially fused placentas (Keller and Tandler, Lillie). In the unusual case when fusion of the chorion did not occur, and the female embryo remained free from masculinization by the male, the female twin remained normal. Modification of the development of the accessory sex structures is more easily achieved. Following castration of the male rabbit fetus the male tubular system (Wolffian ducts) regresses whereas the coexistent female (Müllerian) system persists and differentiates into a female reproductive tract together with female external genitalia (Jost). Removal of the fetal ovary, on the other hand, does not interfere with the differentiation of a female genital tract. Testosterone given to castrated males or to females stimulates the development of the masculine characters but does not inhibit the uterine horns or tubes. There is thus good evidence for the existence of a hormone secreted by the testis at a very early stage of development which results in the repression of the female primordialia. The early observation of Bown and Ancel that the interstitial cells (p. 1101) of the testis are well developed at this time supports this view, but the identity of the embryonic testicular hormone is unknown.

The facts summarized above are of importance in the study of a variety of sexual abnormalities. These include true and pseudohermaphroditism and gonadal dysgenesis. In cases of *true hermaphroditism* the individual possesses both ovarian and testicular tissue. There is generally some degree of ambisexual development of the genital tract but this, and the development of the secondary sexual characteristics, is highly variable. The chromosomal sex may be male or female. Two variations of *pseudohermaphroditism* exist: the male and the female type. In the male type the individual has testes only but exhibits development of the female genital duct system to a variable degree. The patients may appear male or female, but are genetically male. Female pseudohermaphrodites possess only ovaries and show variable masculine genital development. The sex chromatin is female. A variety of causes underlie these defects but, in the female, congenital viriliz-

ing adrenal hyperplasia is the most common. In typical cases of *gonadal dysgenesis* the internal and external genital structures are female but remain infantile, and there is little development of the secondary sexual characteristics. Congenital anomalies may be present including webbed neck, lymphedema of the extremities, coarctation of the aorta, and various skeletal deformities. Following the description by H. H. Turner of a series of cases in 1938 the condition gained the name of *Turner's syndrome*. Patients with this syndrome do not possess gonads as such but in the position of the ovary there is a narrow ridge of fibrous connective tissue. On the basis of experimental studies on the effect of gonadectomy in rabbit and mouse fetus Jost and Wilkins independently predicted in 1950 that some patients with gonadal dysgenesis should be genetically male. This prediction was proved correct when study of the sex chromatin revealed that more than 80 per cent of cases had male nuclei. The factors underlying this condition are obscure.

The Effect of Fxision of the Gonads— Castration—Spaying

Removal of the gonads of a young animal prevents the development of the accessory sex organs and the secondary sex characters fail to appear. The effects of castration upon the secondary characters are evident even in such simple forms as the earthworm and hermit crab. Castration of the male frog prevents the appearance of the sexual changes which normally occur during the mating season. The thumb-pad and fore-limb muscles do not hypertrophy, the clasping reflex cannot be elicited and the animal does not emit its characteristic croak. The sexual development of birds and mammals is profoundly affected by castration. The castrated cockerel (capon), for example, has a greater proportion of body fat than does the normal bird, whereas the comb, wattles and spurs, and the sex instincts, do not develop. Development of the spurs and plumage, however, is not prevented. Corresponding effects of gonadectomy are seen in the young turkey cock and in the young of other avian species. Removal of the ovaries (spaying) causes the development of spurs, a comb resembling that of a cock, and male plumage. The spayed duck assumed the plumage of the drake.¹

¹ Male plumage is considered to be the basic or neutral type. Its development is suppressed by the female sex hormone when the female type of plumage appears. Hence the male plumage appears after ovariectomy and persists after testicular removal.

The effects of castration upon young cattle, horses and stags are well known. Castration of young bulls causes an increase in the size of the skeleton and a greater deposition of fat. The mature development of the accessory organs is prevented. The antlers of young stags do not develop after castration. Castration of boys before puberty retards ossification of the epiphyses of the long bones with consequent enlargement of the stature due to disproportionate lengthening of the lower limbs. There is also adiposity, with a tendency toward a feminine distribution of the fat. The larynx is not prominent, as in the mature male, and the voice remains high-pitched. Hair fails to grow upon the face and body, but is unusually plentiful on the head. The penis remains infantile and sexual feeling is suppressed. Such a state is called *eunuchism*. Ovariectomy in women is followed by changes characteristic of the menopause (p. 1080), namely, amenorrhea, atrophy of the secondary sex organs and obesity. If performed before puberty the characteristic feminine attributes do not appear, the girl tends to become somewhat mannish in type whereas the accessory organs fail to develop fully and menstruation does not occur.

Sexual desire in higher animals and in the human subject is not necessarily entirely dependent upon the gonads, particularly in the male. Ovariectomized adult female chimpanzees show few signs of desire for intercourse but ovariectomized women may show as much erotic behavior after the operation as was exhibited previously. Castration of male primates often produces no diminution in the capacity to mate or (in man) to achieve sexual climax during coitus (Ford and Beach). In lower mammals, such as the cat, removal of the ovaries abolishes sexual behavior. It may be recalled that, following removal of the gonads, androgens produced by the adrenal gland may be responsible for some of the sexual responses observed.

Transplantation or grafting experiments. If the excised gonad (testis or ovary) is transplanted to another situation in the body and survives the otherwise inevitable endocrine effects of castration are prevented. This fact first demonstrated by Berthold in the cock in 1849 proves conclusively that the gonad furnishes an internal secretion. The studies of homotransplants show that feminization of the caapon, or masculinization of the ovariectomized hen, can be induced by transplantation of the gonad of the opposite sex.

The Ovaries

Development of the ovaries. The ovaries as well as the testes, arise from the celomic epithelium covering the inner aspect of the Wolffian body. The epithelial cells of this region assume a columnar form and proliferate to form several layers which constitute the *germinal epithelium* whereas the mesenchymal stroma underlying the germinal epithelium becomes thickened to form the *genital ridge*. By means of a localized multiplication of cells in the germinal epithelium fingerlike processes arise which penetrate into the mesenchymal stroma. These processes are known as the *primary sex cords* and contain both germinal and supporting tissue. Up to this point there is no difference in the differentiation of an ovary or testis. If the gonad is destined to become an ovary then the germinal epithelium remains thickened and proliferates a set of *secondary sex cords* or *cortical cords* which form the definitive cortex of the adult ovary. The primary sex cords become the adult medulla. In the process of testis formation the germinal epithelium becomes reduced in thickness and the primary sex cords progress to become the seminiferous tubules.

Structure of the ovary. The adult ovary is a flattened oval structure (about 3-4 cm. long) with one of its edges the hilus attached via the mesovarium to the broad ligament. It consists of a dense stroma of connective tissue which carries blood vessels and in which are embedded the oocytes and *Graafian follicles* in all stages of development. The stroma also contains smooth muscle fibers and small numbers of large polyhedral epithelial cells—the *interstitial cells*. The surface of the ovary is covered with a layer of epithelial cells, the germinal epithelium, which is continuous with the epithelium of the general peritoneum.

The Graafian follicles. It is possible that the germinal epithelium covering the ovary retains its embryonic character and proclivities after birth—until the end of the reproductive period (to about the 45th year in women). The question of postnatal formation of ova has been the subject of much debate. The general opinion is that the ovary continues to form sex cells after birth although at a diminishing rate. A *primordial follicle* is formed by invagination of a cord of cells from the germinal epithelium. An island of cells becomes separated, one of the group develops into a *primitive ovum* whereas the rest form a surrounding layer of *granulosa cells*. At this time the primordial follicle is about 45 microns in diameter and becomes displaced towards the deeper regions of the cortex. It appears that the orderly arrangement of cells in the development of primordial follicles is governed by the ovum itself, for when the ova are destroyed by X-ray treatment the germinal epithelium forms cords and clumps instead of follicles.

FIG 60 2 Successive stages in the development of the ovum and Graafian follicle (diagrammatic) EP germinal epithelium covering the surface of the ovary C a cord of cells growing from the germinal epithelium into the ovarian substance G primordial ovum encircled by a single layer of (granulosa) cells In 4 the membrana granulosa and the cumulus oophorus are shown but the follicle has not yet reached full development F ovarian stroma

The infantile ovary contains some 400 000 primordial follicles, but subsequent development requires the participation of pituitary activity which becomes manifest at puberty. As follicles develop two more layers of cells are produced from the ovarian stroma. The inner layer—the *theca interna*—is thought to be formed by some influence exerted upon the stroma cells by the granulosa cells. This layer is vascular and more cellular than the outer layer—the *theca externa*—which is fibrous in character. At the same time that these changes are occurring the granulosa cells multiply to form a cell mass several layers deep now known as the *membrana granulosa* in which two concentric zones can be distinguished. These become separated by the accumulation of fluid (liquor folliculi) and a cavity or *antrum* is formed. It is at this time that the follicle may be called a Graafian follicle. The cells of the inner zone of membrana granulosa surround the ovum and these are piled in pyramidal fashion in contrast with part of the wall of the follicle. This mass protruding into the antrum of the follicle is the *cumulus oophorus*, or *discus proligerus*.

The growth of the follicle and the changes just described represent follicular maturation or ripening and during this process the follicle extends outwards so that when mature the follicular wall

projects from the surface of the ovary. A mature follicle may have a diameter of up to 10 mm and contains an ovum some 100 to 150 microns across bounded by a clear membrane the *zona pellucida*. Full maturity of the ovum is heralded by the extrusion of the first polar body and following this the follicular wall ruptures and the ovum together with some discus proligerus cells forming the *corona radiata* is discharged. It passes along the Fallopian tube to the uterus.

After discharge of the ovum the cavity of the ruptured Graafian follicle may become filled with a clot of blood. The small body formed in this way is sometimes spoken of as the *corpus hemorrhagicum*. The clot is soon replaced by a mass of cells containing a yellow lipid material (luteal cells). These are derived from the proliferation of the epithelial cells of the membrana granulosa (*granulosa lutein cells*) and of the theca interna (*theca lutein cells*). The follicle with its content of luteal cells constitutes the *corpus luteum* (fig 60 3). The circumference of the follicle by this time has become more vascular and capillaries penetrate into the yellow cell mass. The transformed follicle may now be looked upon as a temporary organ of internal secretion. If fertilization of the ovum does not occur, the life of the corpus luteum is short. In the human it persists for about 10 days and then regresses. Its vessels become obliterated the luteal cells disintegrate and are replaced by fibrous tissue nothing then remains of the follicle but a pale scar—the *corpus albicans*. On the other hand if fertilization of the ovum occurs the corpus luteum continues to grow and in women attains a diameter of three quarters of an inch or more by the middle of pregnancy. It then commences to

FIG 60 3 Section of corpus luteum showing luteal tissue under high magnification (From Parkes *The Internal Secretions of the Ovary* by permission of Longmans Green & Co.)

FIG 60.4 Showing uterus (a) in anestrus, (b) one month after ovariectomy (c) in estrus (After d'Amour and Blood)

shrink and is finally absorbed by the seventh month.

Of the vast number of ova and primordial follicles in the ovary only a few ever reach the Graafian follicle stage. In women, not more than one or two ova are as a rule discharged each month, or a total of 400 or so during the entire reproductive period. The remaining follicles develop to some extent and then undergo degenerative changes to become atretic follicles. Each of the latter is finally replaced by fibrous tissue derived from the theca and only a small scar, a *corpus fibrosum*, remains.

The factors which determine the rupture of the ripe follicle are not definitely known but clearly involve the effects of the rhythmic secretions of the pituitary gland. The accumulation of fluid and the consequent increase in intrafollicular pressure is probably a factor in some animals, or the contraction of the smooth muscle fibers of the stroma may play a part. In most species, including man, the follicle ruptures "spontaneously," but in the rabbit, cat and ferret ovulation occurs only after copulation.

The Sexual Life of Females

Three sexual periods of different lengths occur in female mammals.

1 A single long period occupying the greater part of the animal's life. It commences at *puberty*, at which time the first ovulation occurs. The accessory organs of reproduction mature, sex desire is aroused and the secondary sex characters appear. It ends with atrophic changes in the ovary and accessory organs. In women the termination of this period is called the *menopause* (p. 1080).

2 A period which recurs once or oftener each

year, known as the *mating, sexual, or breeding season*. In most species it is only during this time, or during a part of it, that the female will receive the male.² The duration of the mating season and the number of times it occurs annually vary in different species. In the dog, for instance, it is generally said that two such periods of about six weeks' duration occur each year (spring and autumn), whereas in certain other species they occur more frequently, and in others again only once, and may be of long or short duration. In the human, reproduction is not confined to any one part of the year, although a study of birth statistics shows that fertility is greatest at certain periods (April to June). It has been suggested that in primitive man a mating season corresponding to this time of year did exist.

3 *The estrus cycles*. These are periods of sexual activity in animals which occur once or oftener in each breeding season. The first cycle commences at puberty. Animals such as the bitch, in which a single estrus cycle extends throughout the breeding season, are called *monestrous*. *Polyestrous* animals, on the other hand, are those such as the domestic cat, the mare, cow, sow, rat and mouse, in which two or more cycles, separated by short periods of sexual quiescence, occur in succession during the breeding season. In a monestrous animal the following phases of the estrus cycle are distinguished: (a) *Proestrus*, or period of "coming on heat." There is usually swelling and congestion of the external genitalia together with growth and increased vascularity of the uterus (fig. 60.4).

² The corresponding period which occurs in the males of some species is known as the *rutting season*. In many species however, the male is capable of copulation at any time.

There is, as a rule, some enlargement of the mammary glands and, in the dog and mare, bleeding from the vagina. During this stage of the cycle the Graafian follicles are undergoing maturation preparatory to rupture. (b) *Estrus*,* or "period of desire." The female receives the male and ovulation occurs. The term "heat" is commonly applied to the combined period, proestrus and estrus. (c) *Pseudopregnancy* or *pregnancy*. During this phase there occurs pronounced proliferation and secretory activity of the uterine glands, hypertrophy of the mucosa and a great increase of the uterine blood supply. It will be seen presently that these phenomena are dependent upon the formation of a corpus luteum. The growth of the mammary glands is stimulated. The uterine changes are looked upon as anticipating the arrival of and providing nourishment for, a fertilized ovum. (d) *Anestrus* is the period of sexual quiescence between the mating seasons. In the cycle of those animals in which pseudopregnancy does not occur, the short period following estrus and during which the phenomena of estrus subside, is called *metestrus*. The monestrous cycle may be illustrated as follows:

In polyestrous animals the short intervals of quiescence separating the estrous cycles are called *diestrous* periods. The term *anestrus*, as in the case of monestrous species, refers to the longer periods of rest between the mating seasons.

Although the onset of estrus in some species is quite obvious in others such as the rodents, it is difficult to detect by the ordinary means. Stockard and Papanicolaou discovered that the vaginal mucosa of the guinea pig underwent certain changes (cornification of the epithelium) coinciding with estrus. Similar changes occur in the vagina of the rat and mouse as well as in the human vagina (fig. 605). By the examination of a smear of the vaginal secretions the stages of the estrus cycle can be readily followed in these animals.

* *Estrus* L. = *gad fly* with figurative meaning of frenzy or intense desire.

Leukocytes which are present in smears taken during the diestrus or anestrus period are absent from the vaginal secretions during proestrus and estrus but large squamous (cornified) cells with small pyknotic nuclei, appear. The intact vaginal epithelium becomes stratified squamous in character.

The menstrual cycle and sexual life in the human. The sexual cycle of primates is termed a *menstrual cycle*. This differs from that of lower forms in so far as the period of desire is not localized to any one phase of the cycle (such as estrus), and that external bleeding occurs roughly midway between two ovulations rather than at the time of ovulation. Therefore in equating the typical 28-day menstrual cycle of the human with the *estrous cycle of an animal such as the bitch*, it may be said that the first 14 days of the menstrual cycle (day 1 being the first day of the flow) are represented by the phases of diestrus and proestrus during which follicular ripening occurs whereas the last 14 days of the menstrual cycle correspond to the phases of metestrus and pseudopregnancy associated with the development of corpora lutea. The ovarian and uterine changes which occur in the menstrual cycle, and the hormonal factors regulating the cycle, afford evidence in support of this relationship and are described further below (p. 1089). It may also be mentioned that slight bleeding does rarely occur in the human at about the time of ovulation, that is midway between the menstrual periods proper.

The sexual life of the human female usually commences between the 12th and 15th years, when the first menstruation or *menarche* occurs. This period of sexual awakening which is seen in animals and man of both sexes is referred to as *puberty*, with the periods before and after being called *pre-* and *postpubertal* respectively. Some year or more before the appearance of the overt signs of puberty in girls gonadal hormone can be detected in the urine in amounts which are found to vary cyclically. At this time the ovaries show increased growth. The growth of the uterus is accelerated, the breasts enlarge and, in both girls and boys, hair appears upon the pubis and in the axillae. Deepening of the voice, enlargement of the genitalia (penis and testes) and growth of hair on the face are characteristic features of this period in boys. In both sexes, somatic growth is accelerated. The first menstrual cycles are frequently irregular and may be prolonged, with intervals of amenorrhea. During the next two or three years a menstrual rhythm becomes established but during this phase fertility has not

FIG 60-5 The vaginal epithelium and smear at various stages of the estrus cycle of the rat. A estrus B proestrus C estrus D metestrus E ovariectomized (From Turner)

reached the adult level and the girl passes through a period of *adolescent sterility*.

The length of the menstrual cycle has been measured on numerous occasions with variable results. Most commonly the cycle lasts 26 to 29 days with a mean close to 28 days. However only 10 to 15 per cent of the cycles examined are of this duration and a normal range may be said to be 24 to 35 days. Studies on individual women

show that two consecutive cycles may differ in length by several days; this could be due to the operation of psychic factor.

Ovulation occurs usually but not invariably about the middle of the intermenstrual period that is some 13 to 17 days after the first day of the last menstruation. Evidence in favor of this timing has been derived from the recovery of ova and early embryos from the tubes of women with

known menstrual histories, from pregnancies following a single artificial insemination on a known day of the cycle, from the results of coitus at known times, from the occurrence of midmenstrual bleeding, which is associated with ovulation, and from the study of vaginal changes, hormone excretion, and variations in basal temperature.

For a variety of reasons it is sometimes of importance to establish the day of ovulation in an individual. A number of approaches have been made to this problem. In 1935 Burr, Hill and Allen discovered that ovulation in the rabbit was accompanied by a sharp rise in *electrical potential* across the pelvis just before rupture of the follicle, and this observation was confirmed in the human. However, subsequent work indicated that the effect was an indirect one only remotely due to ovarian influences, and unsuitable for the detection of ovulation. The *blood levels of hormones* and their excretion in the urine has been studied. Briefly, the maximum concentration of estrogen (p 1031) in blood and urine occurs at about the time of ovulation, whereas a metabolic product of progesterone (p 1031), pregnanediol, is demonstrable in the urine a day or so after ovulation. There is also an increase in the concentration of gonadotrophin (p 974) in the urine at about the time of ovulation. Studies of the *cervical mucus* have revealed cyclic changes in the character and composition of this secretion. It becomes less viscous and more plentiful about the time of ovulation, whereas on drying the mucus a characteristic crystallization pattern appears. By far the most convenient index of ovulation is the change in *basal temperature* that occurs about this time. The body temperature, recorded daily during the menstrual cycle, shows an abrupt fall at about the time of ovulation (13 to 17th day). It then rises sharply and is maintained at a level about 0.8° F above that seen during the first half of the cycle until the commencement of the menstrual flow.

Information as to the time of ovulation in women has a practical value in contraception. The so-called "safe period" during which conception presumably cannot occur, has been placed in those parts of the cycle before and after ovulation. However, the time of ovulation varies considerably in different women and may occur several days before or after the 15th day of the cycle. The "safe period," therefore, cannot be predicted in any individual case without preliminary study although the least likely time for

conception to occur is within the last eight days or so of the cycle, that is, eight days before menstruation.

Factors Concerned in the Fertilization of the Ovum

The ovum, if unfertilized, degenerates within a few hours after its discharge from the ovary, probably in the Fallopian tube. For this reason, and because only one ovum is discharged each cycle, the period during which fertilization can occur is very short, probably not longer than 6 or 7 hours. Yet the period during which coitus may lead to conception is relatively long, for the spermatozoa may retain their capacity to fertilize the ovum for some 48 hours or so, although this varies from species to species. In the rabbit the fertilizing capacity of sperm in the female tract may be retained for 32 hours, whereas in the mouse the corresponding period is only 6 hours. In the guinea pig this period is 22 hours, in the rat 14 hours, and perhaps remarkably, in the mare 5 to 6 days. The sperm shows motility for some time after it has lost its ability to fertilize. The former property is therefore not a reliable index of the latter.

As mentioned in the preceding section, if the sperm do not penetrate the ovum within a few hours after ovulation, they cannot do so at all. Fertilization is effected in the Fallopian (uterine) tube and here also the earlier stages in the maturation of the ovum take place. When discharged, the ovum is surrounded by the *cumulus oophorus*. It has been thought that this covering could not be penetrated by the sperm, and must first be destroyed by the enzyme *hyaluronidase* contained in the sperm of most mammalian species; however, there has been a misconception in this regard for the mammalian spermatozoan can reach the ovum through an intact cumulus. It is possible, however, that the enzyme aids the sperm in some other way in its approach and penetration of the ovum. A hyaluronidase inhibitor, such as tri-gentisic acid (rehibin) added to rabbit semen before insemination was found by Parkes to prevent fertilization—an effect not due merely to a nonspecific spermicidal action.

The menopause. Between the ages of 42 and 52 (average 47 years) the menstrual cycles become irregular and finally cease. This time is known as the *menopause* or *climacteric*. As menstruation ends retrogressive changes gradually set in in the accessory organs of reproduction, e.g., atrophy of the uterus, shortening and narrowing of the

vagina with loss of its epithelium and replacement by fibrous tissue, and shrinkage of the mammary glands. These results are due to atrophic changes in the ovary—disappearance of the Graafian follicles together with a general fibrosis and shrinkage of the organ. Similar changes in the uterus and vagina follow the removal of the ovaries in earlier life, and constitute an *artificial menopause*. Psychic disturbances quite often occur during this “change of life” and occasionally may progress to melancholia and hysteria. Vasomotor and other autonomic disturbances, hot flushes, sweating, etc., are very common features of the climacteric. The effect of the natural menopause upon the sex libido varies in different subjects. In married women it shows little alteration as a rule. It would seem that the menopause occurs through a failure on the part of the ovary to secrete estrogen (p. 1054).

The Ovarian Hormones

In addition to its gametogenic function the ovary produces hormones which regulate the reproductive processes. These are (1) the *estrogenic*, or follicular hormone, *estradiol*, (2) the hormone of the corpus luteum, *progesterone*, and (3) *relaxin*. The exact status of the latter hormone is doubtful since under certain conditions it can be formed by other parts of the reproductive tract. It has been isolated from the corpus luteum of the pig. The estrogenic hormone exerts its effect primarily during the first part of the estrus cycle, whereas the corpus luteum hormone is concerned particularly with the latter part, with pseudopregnancy and pregnancy.

THE ESTROGENIC HORMONE

During the first twenty years of this century the evidence derived from ovariectomy and transplantation experiments had made it clear that the ovaries furnished an internal secretion which was responsible for the sexual development of the female. However the use of whole ovaries, and the use of rather uncertain biological indicators, confused the results available until the work of Allen and Doisy in 1923. These workers aspirated the liquor folliculi from sows' ovaries and found that it was capable of inducing estrus in immature animals. The success of these workers was due to a large extent to the use of a precise method for the determination of estrus, namely the vaginal smear technique described above. Other investigators had mostly studied the effects of their extracts upon the uterus. With a sensitive test

available the next step was to isolate the active constituent of follicular fluid. It was soon found that the material was extractable by fat solvents and could be concentrated, but another twelve years passed before the hormone was characterized. Meanwhile other estrogens had been isolated from the urine of pregnant women, pregnant mares, human placentas, and, surprisingly, the urine of stallions, and in 1929 Doisy, Veler and Thayer, and Butenandt independently announced the crystallization of an estrogen in pure form from the urine of pregnant women. It was believed at this time that there was only one estrogen and the workers concerned were generous in bestowing names upon it. Unfortunately, this led to confusion, particularly when the existence of other estrogens came to light, therefore many of the early names have been discarded and a formal nomenclature is now used.

The Origin and Distribution of Estrogen

The elements of the ovary responsible for the production of the follicular hormone are not definitely known. Its presence in high concentration in liquor folliculi, and the fact that follicular maturation coincides with the onset of estrus, point to the follicular cells (probably the theca interna) as being the chief source. Yet these cells cannot be solely responsible, for Parkes showed that estrus continues at regular intervals after the follicles have been completely destroyed by X-rays, moreover the hormone can be extracted from the stroma alone. The interstitial cells in the latter situation may be a source of the hormone. One of the most remarkable features of estrogen is its very wide distribution in animal tissues. It or a similarly acting estrogen is found in the blood and urine of both pregnant and nonpregnant females, in the urine of adult males, and in the testes, with the testes and urine of stallions being among the richest known sources (Zondek). It is present in very high concentration in the urine of pregnant women after the first 2 or 3 months. In the later months around 300,000 or more international units (see below) are excreted daily. It is also obtainable in large amounts from the urines of pregnant mares and monkeys. The human placenta contains large quantities of estrogen which are believed to be manufactured by this organ, for women ovariectomized during the later months of pregnancy continue to excrete large amounts of the hormone in the urine. An estrogen is present in the corpus luteum, in the fetal membranes and amniotic fluid, and in the adrenal

cortex, it has been demonstrated in a human chorionic vesicle containing an embryo 12.5 mm in length

Chemistry and Terminology

There are three well established natural estrogens. These are *estradiol*, *estrone* and *estriol*. Two others, *epiestriol* and *hydroxysterone* have recently been isolated from human pregnancy urine. Of these *estradiol* is now generally believed to be the true estrogenic hormone, i.e., the estrogen formed in, and secreted by the ovary. Doisy and coworkers, and Butenandt were able to isolate *estrone* from the urine in 1929, whereas *estradiol* was obtained by MacCorquodale, Thayer and Doisy in 1935—after the use of 2 tons of ovaries as starting material. *Estriol* was first isolated in 1930 from human pregnancy urine independently by Doisy and associates and by Marrian. *Estrone* was named *theelin* by Doisy and modifications of this name were subsequently applied to the compounds later discovered.

The estrogens possess a basic steroid nucleus like the hormones of the adrenal cortex. They differ

in that ring A is benzenoid or aromatic in character so that the phenolic hydroxyl group attached to carbon 3 has weakly acidic properties. This feature implies a solubility in alkaline solution and has been utilized in the separation of the hormones. In addition the estrogens possess an oxygen, or an hydroxyl group linked to carbon 17, and thus possess the capacity to exhibit stereoisomerism.

Estradiol (dihydrotheelin, dihydroxyestrin) *Estradiol* was first obtained in the laboratory by reduction of the ketone group in *estrone* to an hydroxyl group, and was only later isolated from ovarian tissue. Two stereoisomers of *estradiol* are possible: *estradiol-17 α* , and *estradiol-17 β* , depending on the relative position of the hydroxyl group. There has been confusion over the relative biological activity of the two isomers but it is now established that the active one is *estradiol-17 β* , or the *cis* form. The replacement of the hydroxyl group in the 3 position with benzoic acid gives a product possessing more prolonged physiological action than the original compound due to a slowed rate of inactivation. This compound *estradiol benzoate*, is known commercially by various names. *Estradiol dipropionate* and *ethinyl estradiol* exert an even more prolonged effect.

Estrone This was the first estrogen to be crystallized and was given a variety of names. These include *theelin* (Doisy), *estrin* (Parkes and Belerby), *folliculin* and *estrone*. It has been isolated from human pregnancy urine, human male urine, human placental tissue, bovine adrenal glands and the bile of pregnant cows. It differs from *estradiol* in possessing an oxygen atom instead of an hydroxyl group at carbon 17.

Estriol (*theolol*, Doisy, trihydroxyestrin) has been obtained from human pregnancy urine, and from human placental tissue. Despite the reported isolation of this hormone from the placenta of the chimpanzee and from the female pussy willow, the hormone is believed to be characteristic of the human species. Since *estriol* contains three hydroxyl groups it is more soluble in water than the other estrogens.

The Metabolism of Estrogens

Like the adrenal cortical hormones the estrogens appear to be synthesized in the body from cholesterol. A fall in the ovarian cholesterol has been observed to occur following stimulation with pituitary gonad-stimulating hormones. Certainly cholesterol can be used as a starting material in the laboratory synthesis. Starting with ergosterol, *estrone* was synthesized in 1936 by

Ketohydroxyestrin
(Theelin or estrone)

Trihydroxyestrin
(Theolol or estriol)

Dihydroxyestrin or estradiol

Benzoate of estradiol

Marker and his associates, others have synthesized estradiol from cholesterol

The estrogens seem to be converted one to the other in the body according to this relationship
 estradiol $\rightleftharpoons$ estrone $\rightarrow$ estriol

Administration of estradiol or estrone results in an increased excretion of estriol, whereas administration of estriol does not increase the output of the other two hormones. Radioactive estrone and estradiol are converted to radioactive estriol. Estriol may be the main estrogen in human plasma.

There is little doubt that estrogens are inactivated by the liver. Incubation of estradiol and estrone with liver slices caused loss of activity, use of a heart-lung liver preparation has revealed loss of estrogen in the perfusing fluid, whereas the activity was returned when perfusing a heart-lung preparation. Liver damage, such as follows the administration of carbon tetrachloride, is associated with an increased effect of estrogens, as well as a greater urinary excretion of these materials. In rats if pellets of estrogen are implanted into the spleen so that the estrogen drains directly into the portal system no estrogen activity is detected. If the spleen is transplanted elsewhere in the body, or adhesions of the spleen to the stomach or body wall form, allowing escape of estrogens from the portal circulation then full estrogenic activity appears. Clinical observations fully support the above experimental findings. Increased estrogen excretion often occurs in association with liver disease. Gynecomastia, loss of chest and axillary hair, testicular atrophy and loss of libido have all been described in men with cirrhosis of the liver, although the significance of these findings has recently been questioned. The inactivation of estrogens also appears to be impaired in cases of malnutrition and inanition, it has been argued that a deficiency of vitamin B₂ is also of importance in this respect. Normally, estrogens are rapidly destroyed in the body.

Estrogens are excreted in the urine in the form of water-soluble conjugates, little is eliminated through the feces. They are combined mainly with glucuronic acid, as well as with sulfuric acid, and in this form are physiologically inert. Upon hydrolysis with acid, or enzymically with glucuronidase or phenol sulfatase, the conjugates are split and estrogenic activity reappears.

Synthetic estrogens Estrogenic materials are not restricted to animal sources. Estrogens can be obtained from petroleum, peat and lignite rape seeds and pussy willow. Estrogen has been demonstrated in the mud at the bottom of the Dead Sea. It is not necessary for such substances to possess

a similar chemical structure to that of the natural compounds. Thus Dodds and his associates found active estrogens among the derivatives of diphenylethane and diphenylethylene and one of them, *stilbestrol* (4,4'-dihydroxy- α - β -diethylstilbene) introduced in 1938 has been of great clinical value for many years. It is as active as the natural estrogens but unlike the estrogens it retains its potency when given by mouth. The success of stilbestrol greatly stimulated work in this field and now a wide range of synthetic estrogens is available for clinical use. Two other synthetic compounds widely used clinically are *dihydroethylstilbestrol*, or *hexestrol*, and *dienestrol*.

On the basis of estrogen withdrawal bleeding (p. 1084) dienestrol possessed 90 per cent of the potency of stilbestrol and hexestrol possessed about 10 per cent. This finding reveals an order of potency quite different from that observed in animals.

The reasons underlying the estrogenic effect of the synthetic compounds are not well understood. One structural relationship between stilbestrol and estradiol was pointed out by Dodds and is shown below, but when the structures are com-

pared three dimensionally there is not the same degree of similarity

The Physiology of Estrogen

For descriptive purposes the actions of estradiol, estrone and estrin are identical, for these compounds differ only in relative potency. When used without qualification 'estrogen' implies any or all of these materials and may include stilbestrol.

The main effects of estrogen are as follows

- 1 It induces estrus in immature animals, or in normal adult animals during anestrus, there result in consequence hypertrophy of the uterus (fig. 60 6), and development of a proliferative type of endometrium, vaginal changes (cornification), growth of the mammary glands (p 1095), and rhythmical contraction of the muscle of the uterus and Fallopian tubes, as well as the psychic phenomena associated with estrus. Prolonged treatment with estrogen causes pronounced hyperplasia of the endometrium which may come to resemble the clinical condition known as 'Swiss cheese' endometrium.

- 2 It prevents the otherwise inevitable atrophy of the accessory reproductive organs in ovariectomized animals.

- 3 It is responsible for the development of the secondary sex characters which in some species are such prominent features of the mature female.

FIG 60 6 Effect of injection of follicular extract into 8 week old rabbits. Animals were litter sisters. No 807 received 2 mg. of extract. No 805 was not injected and was killed at the same time as No 807 for control. No 808 received 1 mg. of extract daily for 4 days and No 809 received 1 mg. daily for 8 days. No 808, uninjected control was killed on the same day as No 809. (After Doisy, Ralls, Allen and Johnston.)

- 4 It prevents nidation of the fertilized ovum or induces abortion in early pregnancy.

- 5 Estrogen is largely responsible for the enormous growth of the uterus during pregnancy. When pregnancy is confined to one horn of the rabbit's uterus, that horn alone increases in size. It is thought, therefore, that estrogen produced by the placenta may act locally on the uterine tissue rather than through the general circulation.

- 6 Estrogen exerts a direct effect upon the ovary. Since estrogen stimulates mitosis the hormone present in the liquor folliculi itself promotes the growth of the follicle. The administration of large doses of estrogen has been found to prevent ovarian atrophy in immature hypophysectomized rats. It has also been suggested that on ovulation the follicular fluid comes into contact with the germinal epithelium of the ovary and promotes a burst of mitoses which produces a new crop of oogonia ready for a future cycle.

- 7 With more moderate dosage estrogen induces ovarian atrophy, as well as testicular atrophy in the male, by suppressing the release of the pituitary gonad stimulating principles.

- 8 If, after menstruation has been abolished in monkeys by ovariectomy, a series of injections of estrogen is given and then stopped abruptly, menstruation occurs a few days later. During the treatment of these ovariectomized monkeys phenomena appear analogous to those seen during the estrus period of lower animals, i.e., endometrial changes, reddening and swelling of the external genitalia, and the production of a vaginal smear showing cornified cells and lacking leukocytes. The induction of uterine bleeding by the above "estrogen withdrawal" has been utilized in the human, for artificial menstrual cycles can be produced in this way in women suffering from amenorrhea.

- 9 Estrogen appears to be concerned in the production and maintenance of corpora lutea. In rats the administration of estrogen leads to the formation of many corpora lutea, and in rabbits estrogen will maintain the corpora lutea in the ovaries of the hypophysectomized pseudopregnant animal.

- 10 A synergic action between the follicular hormone and the oxytocic hormone of the posterior pituitary (ch 56) has been demonstrated. After estrogen is administered to a mouse toward the end of pregnancy, a dose of oxytocin (which is ordinarily ineffective) causes a powerful uterine contraction (fig 60 7).

- 11 This ovarian hormone induces water reten-

tion, an increase in blood volume and of the water content of the muscles. Ovariectomy results in a loss of water and a diminished volume of blood which is restored to normal by estrogen administration.

12 Estrogen presumably acts upon the nasal mucous membrane (see p. 1092).

13 In the male, estrogen in physiological dosage, or derived endogenously (testicular estrogen) may act synergistically with androgen in the development of the secondary sex characters. Protracted treatment with estrogen causes hypertrophy of the fibromuscular tissues of the prostate, but has little or no effect upon the glandular elements. Growth of the male mammary glands may be stimulated. In young males other feminizing effects are produced.

14 Estrogen causes hypertrophy of the adrenal cortex, apparently by stimulating the output of ACTH.

15 Prolonged treatment with estrogen raises the blood calcium, particularly in pigeons and fowls.

16 Estrogen exerts a variety of additional effects throughout the body, e.g., on the skeleton. These actions are best discussed elsewhere in relation to the end-organ concerned.

Assay and Standardization of Estrogens

It has been the practice to assay the activity of estrogenic preparations upon ovariectomized rats or mice, with a unit being defined as the minimal quantity of the material required to induce estrus in 50 per cent of a group of test animals as shown by the vaginal smear. This is basically the technique of Allen and Doisy, but can be made quite sensitive by applying the estrogen directly to the vagina of the test animal. Alternatively, the increase of uterine weight produced by estrogen in ovariectomized or intact immature rats or mice has been used as an index of activity. Although there may be a linear relationship between the logarithm of the dose of estrogen and the increase in uterine weight, the dose response curves of the separate estrogens differ one from the other so that it becomes difficult to assay mixtures of estrogens, such as occur in the urine. Further, the use of such methods is complicated by the finding that results vary with the mode and frequency of administration of the hormone, as well as by the presence in urine of materials which may augment the action of estrogen.

Initially, in work on the assay of estrogens, a rat or mouse unit on the lines outlined above was used, but there were wide discrepancies between the results of different laboratories and in 1932 the Commission on Biological Standardization of

FIG. 60.7 Action of estrin in sensitizing an isolated uterus to pitocin. P.E., pituitary extract (After Bourne and Burn.)

the League of Nations defined an international unit. This was expressed in terms of estrone and was the activity exhibited by 0.1 μ g. of the standard preparation. Later, with the use of esters of estrogen, an additional standard was set up and one international unit was constituted by the activity of 0.1 μ g. of estradiol 17 β monobenzoate.

Currently, most attention is being given to the development of chemical procedures for the assay of estrogen. These are essentially colorimetric or fluorimetric, in which the color or fluorescence is developed after a somewhat complex extraction and purification sequence. In the colorimetric method, when a pink color, which can be measured, is developed, the estrogens are heated with phenol and sulfuric acid, diluted with water and reheated. This is the Kober reaction first described in 1931 and altered in detail since. The fluorimetric method is more sensitive but less specific than the colorimetric; it depends on the fact that an intense yellowish green fluorescence develops when an estrogen is heated with sulfuric or phosphoric acid.

Estrogens and Cancer

Since estrogens powerfully stimulate the growth of the uterus, vagina and mammary gland, it is not surprising that with continued administration benign proliferation may develop into malignant growth. As long ago as 1916, before the isolation of estrogens, Leo Loeb noted that spontaneous mammary cancer occurred in mice and was confined to the female, whereas in 1932 Lacasagne succeeded in producing mammary cancer in the male mouse by the prolonged administration of estrogen. However, there are important species differences in the occurrence of mammary cancer. For instance, dogs and rabbits never develop breast cancer following administration of estrogen, neither does the rhesus monkey. But such a carcinoma can develop in dogs and rabbits following pregnancy toxemia which may damage the liver and interfere with the inactivation of estrogen. Rats never develop mammary cancer.

spontaneously, but will do so when subjected to treatment with estrogen. In women carcinoma of the breast is quite common but according to Bishop there is surprisingly little evidence that cancers develop with the administration of estrogen, particularly when the enormous number of women given estrogen at one time or other is taken into account.

From the present point of view there are two kinds of cancer, those that are *hormone dependent* and those that are *hormone independent* (Huggins and Scott). As the classification implies the hormone dependent carcinoma requires a particular hormone or hormone complex for its development. Denial of this need frequently inhibits the growth and promotes regression. In the male, cancer of the prostate gland (p. 1108) provides an instance of this class of tumor which is dependent upon androgen for its continued growth. Removal of endogenous androgen by orchidectomy generally produces a remission although in some cases the adrenals may provide an alternative supply of androgen. *Hormone independent* tumors are not subject to control by any endocrine secretion and develop in such tissues as the skin, stomach and lung. However, a hormone dependent tumor can become independent of a particular hormone and so become autonomous. It should be pointed out that in a number of cases an optimal endocrine environment may be necessary for tumor growth. Thus it appears that following hypophysectomy certain chemical carcinogens failed to induce cancers of the liver whereas they continue to do so in other parts of the body. The full carcinogenic effect is restored by ACTH or growth hormone administration.

The mode of action of carcinogens remains obscure. Interest was aroused when it was found that the *reservative agents* so and for which induced cancer when painted on the skin were benzanthrane compounds possessing a structure akin to that of the steroid hormones. This finding greatly stimulated studies with estrogens but the nature of mechanism underlying the process is uncertain, although it appears to involve the genetic material of the cell.

THE LUTAL HORMONE

The suspicion that the corpus luteum might be a gland of internal secretion which functions during gestation has long been held. Indeed, Corner relates that when Gustav Born lay dying in 1900 he imparted this idea to Ludwig Fraenkel for subsequent experimental test. Three years later (1903) Fraenkel reported that destruction of the corpora lutea in the ovaries of the rabbit was not compatible with the continuance of pregnancy,

whereas Anel and Boun (1910) found that the cycle of growth and regression of the corpus luteum was closely linked with a series of (progestational) changes which take place in the uterus. Also about this time Loeb discovered (1909) that stimulation of the uterine mucosa of the non-pregnant guinea pig by means of a glass bead or a silk thread, or merely by scratching the endometrium with a needle during the development of the corpora lutea resulted in the growth of a small mass of decidual tissue (*deciduoma*) at the point of stimulation. This *Loeb reaction* could not be obtained after the corpora lutea had been excised or during a phase of the estrus cycle when they were absent. Even transplanted uterine tissue responded to stimulation if the ovary contained corpora lutea. Other observers have since obtained corresponding results in the rat, rabbit and dog. Thus it appears that the contact of the fertilized ovum with the endometrium is the natural stimulus which in the presence of a corpus luteum causes the formation of decidual tissue.

Corner first showed that the corpus luteum was necessary for the survival and implantation of the rabbit embryo and, in collaboration with W. M. Allen, he obtained a crude extract which was active in maintaining pregnancy in ovariectomized rabbits. Within five years (1934) the active constituent of the extract was obtained in chemically pure form by several groups of workers, and had been synthesized from stigmasterol by Butenandt and his associates. The hormone is now known as *progesterone* with Corner's original name *progestin* being used as a general term for any substance possessing similar actions.

Corpora lutea are not restricted to the mammals nor are they invariably associated with viviparity since they have been described in viviparous and ovoviviparous selachians, teleosts and reptiles and in mammals they first appear in the viviparous Monotremata. However, any hormone produced is not necessarily progesterone.

Progesterone

Progesterone has the structure shown below. It occurs in two crystalline forms, the α and β , but these are about equal in physiological activity. Comparison with the estrogens (p. 1082) and the adrenal cortical hormones (p. 1039) shows that it is more closely allied to the adrenal hormones and that it belongs to the carbon 21 or pregnane group of steroids. This relationship is underlined by the fact that progesterone can be

transformed *in vitro* to corticosterone and 17 hydroxy corticosterone

Progesterone can be isolated from ox adrenal tissue and administration of ACTH to ovariectomized women has been found to increase the urinary output of pregnenediol, a metabolic product of progesterone. It would appear that progesterone is formed from cholesterol since Bloch found that when isotopically labelled cholesterol was given to a pregnant woman, the pregnenediol in the urine contained the isotope. A decline in ovarian cholesterol has been demonstrated to follow stimulation with gonadotrophin.

Progesterone is produced by luteal tissue, by the adrenal cortex and by the placenta. During pregnancy in women the corpus luteum gradually ceases production of progesterone, and the placenta takes over this function. For this reason gestation can continue after ovariectomy if the latter operation is carried out after 4 or 5 months. A similar situation exists in the monkey, cat and guinea pig, but in the rabbit, rat, goat and cow, abortion occurs if the corpora lutea are destroyed at any time during pregnancy.

Progesterone is rapidly metabolized *in vivo* and normally cannot be detected in the urine. There appears instead the reduced form, pregnenediol, as a glucuronide. Sodium pregnenediol glucuronide is water soluble. Measurement of this steroid in the urine provides a useful index of the rate of production of progesterone. However, caution is necessary in the interpretation of results since, according to Loraue, less than 20 per cent of a dose of administered progesterone may be ex-

creted in the urine as pregnenediol. Also a rise in urinary pregnenediol has been reported to follow the administration of desoxycorticosterone and, in certain cases of adrenocortical hyperplasia or tumor, the pregnenediol output may be increased so that the possible participation of adrenal steroids should be borne in mind. It seems fairly clear that the liver is involved in the metabolism of progesterone, and its conversion to pregnenediol glucuronide. This has been shown by studies (with isotopically labelled progesterone) of patients with liver disease, by studies of the constituents of human bile, and by a comparison of the effects of progesterone in normal and partially hepatectomized rabbits. Pregnenediol is physiologically inert and is readily converted to progesterone in the laboratory. It was isolated from the urine of pregnancy in 1929 by Marrian and in 1930 by Butenandt, before the characterization of progesterone.

THE PHYSIOLOGY OF PROGESTERONE This hormone produced by the corpus luteum possesses a spectrum of activity which includes (1) effects on the uterus, (2) the maintenance of pregnancy, (3) participation in the control of the growth of the mammary gland and (4) suppression of estrus and ovulation. These actions will now be examined.

Effects on the uterus. It was previously shown, as described above, that progesterone treatment develops the endometrium. In the rabbit this is marked by a typical arborization of the glands which is identical to that appearing during pregnancy or pseudopregnancy. Corresponding changes have been observed in other species during treatment with progesterone, and under these conditions deciduomas (p. 1086) are readily induced. In the immature rabbit treatment with progesterone fails to produce the endometrial changes outlined above, nor is the treatment effective in adult rabbits which have been ovariectomized for some time. However, administration of estrogen for several days before the progesterone treatment results in the appearance of progesterone changes. It is clear that the uterus must be "primed" with estrogen before it can respond to progesterone. This effect is not confined to the rabbit, it is also well marked in the monkey, where progesterone has little effect in the ovariectomized animal. When preceded by estrogen, progesterone will produce a typical premenstrual endometrium in 7 to 10 days. Two other aspects of this process must be emphasized. First, it is possible for progesterone to produce

proliferative changes in the uterus by itself, but enormous doses must be given, and second, estrogen also antagonizes some effects of progesterone. This latter effect appears when the ratio of estrogen to progesterone, optimal for uterine development, is altered in favor of estrogen. Under these circumstances the action of progesterone is inhibited. Conversely, progesterone will block the action of estrogen, the coloration and edema of the sexual skin of a spayed monkey, developed by treatment with estrogen, is lost following a single injection of progesterone. It will be seen that, depending upon the relative amounts of these hormones, estrogen and progesterone can interact to produce a variety of effects. This is of importance in a number of reproductive processes.

The deciduoma reaction (which can be elicited under the influence of progesterone) has been described previously. This can be inhibited by treatment with estrogen.

In addition to the effects on the mucosa of the uterus, progesterone also exerts an action on the muscle. In the castrate rabbit the uterus is flaccid and quiescent and does not display any motility, although when estrogenized, regular rhythmic contractions appear. These are also seen in the estrous rabbit, rat or sow, however, administration of progesterone abolishes such activity. The oxytocic hormone of the posterior pituitary (ch 56) is probably implicated in the uterine response to estrogen, for it has been shown that the activity of the uterus of the estrus animal is greatly increased by the oxytocic hormone. Following treatment with progesterone, oxytocin can no longer produce this effect upon the uterus which is then said to be "desensitized." Such phenomena would seem to be of value in the normal individual since a motile estrous uterus would aid the transport of sperm toward the ova, and the movement of ova along the tubes. In agreement with this concept oxytocin has been found to be released at coitus (p 987). Further, once the uterus contains blastocysts, the uterine contractions, which would be detrimental to their implantation and survival, are blocked by progesterone. Toward the end of pregnancy uterine reactivity to oxytocin reappears, possibly due to the increasing amounts of circulating estrogen, and discharge of the fetuses is facilitated.

Maintenance of pregnancy This function of progesterone has previously been noted (p 1086). In ovariectomized rabbits about 1 mg. of progesterone daily will compensate for the absence of corpora lutea and maintain pregnancy, although

in the later stages up to 5 mg. may be necessary. In the rhesus monkey the corpus luteum may be removed as early as the 25th day without disturbing pregnancy, whereas in women gestation can continue following ovariectomy after the first weeks. In the latter species the placenta becomes responsible for the production of progesterone. Administration of progesterone toward the end of pregnancy in rabbits prolongs the gestation period and results in the delivery of larger young.

Suppression of estrus and ovulation The estrous cycle or menstrual cycle does not continue during pregnancy, ovarian follicles do not mature and ovulation does not occur. This change is brought about by progesterone, which interrupts the normal sexual cycles in nonpregnant individuals. If the corpora lutea are removed during a pseudopregnancy then estrus and ovulation quickly follow, whereas if the corpora lutea are extirpated from the guinea pig ovary early in the estrous cycle then the next ovulation occurs sooner than usual (Loeb). Elimination of the corpora lutea of the cow's ovary by manipulation through the rectum hastens the onset of the next estrous period. The ovulation which normally follows copulation in the rabbit is blocked by the administration of progesterone. Such effects are brought about by the inhibition of the secretion of gonadotrophin from the pituitary (p 971). During pregnancy or pseudopregnancy the superficial layer of cells in the vagina lose their squamous and cornified character and become rounded and filled with a mucus like substance. This change occurs under the influence of progesterone, acting in cooperation with estrogen.

Growth of the mammary glands The part played by progesterone in the development and function of the mammary glands will be discussed on page 1095.

ASSAY AND STANDARDIZATION OF PROGESTERONE The international standard of progesterone is defined as the progestational activity of 1 mg. of the international standard crystalline preparation. The test animal is an adult female rabbit which has been mated and then castrated or an immature female rabbit which has been primed for 5 days previously with estrogen. These preparations are relatively insensitive and do not permit the detection of progesterone in blood. Hooker and Forbes (1947) used intrauterine injection of the hormone in ovariectomized mice and examined the endometrium histologically. This procedure will measure 'progestogenic activity' in the blood of pregnant women but is not very specific. Recently Zander and Simmer (1954) have developed

a chemical method, using ultraviolet spectroscopy, which will measure the progesterone concentration in blood

Since pregnanediol is regarded as a metabolic product of progesterone and is present in relatively large amounts in the urine, assay of this steroid has been used as an index of progesterone production. The first method, described by Venning in 1937, involved extraction of the urine with butanol, precipitation with acetone, and weighing the precipitate. During the past 10 years a variety of procedures have been developed which generally involve chromatography, and colorimetry. The technique of Klopfer, Michie and Brown (1955) is sensitive enough to measure the pregnanediol derived from the adrenals of men.

RELAXIN

One of the many adaptive processes occurring in pregnancy is the relaxation of the ligaments of the symphysis pubis which takes place in a variety of species. This "pubic relaxation" occurs in women, monkeys, guinea pigs, mice, dogs, cows and ewes, among others. In 1926 Hisan discovered that the blood serum of the pregnant rabbit contains a substance which produced this effect in nonpregnant guinea pigs. It was called *relaxin* and has now been detected in the serum of women, mares, sows, dogs and cats. Relaxin differs from other ovarian hormones in that it appears to be peptide or polypeptide in nature, is readily soluble in water, and is destroyed by proteolytic enzymes. It has been extracted from the corpora lutea of sows, whole ovaries, blood serum, urine and placenta. The relaxin content of the sow ovary begins to increase early in pregnancy and reaches its highest concentration by the time the fetuses are from 12 to 15 cm. long.

For a time the existence of relaxin was questioned, for it was claimed by some workers that pubic relaxation could be induced by estrogen or progesterone or a combination of the two. Abramowitz and his associates found, however, that an extract prepared from sows' ovaries, when given in a dosage far below that necessary for an estrogenic or progestational effect, caused relaxation of the pubic ligaments. It would seem that relaxin is formed in the uterus under the influence of estrogen and progesterone as removal of this organ greatly reduces the action of these steroids on the pelvis, whereas the potency of relaxin is retained. Even in the intact guinea pig relaxin acts much faster (within 12 hours) than progesterone or estrogen. Further, histological studies have shown that estrogen relaxes the pubic symphysis by promoting resorption of the bone, and a

proliferation of loose fibrous connective tissue whereas relaxin produces a dissolution and splitting of the collagenous fibers into thin threads. The changes following progesterone treatment are similar to those induced by relaxin.

THE HORMONAL CONTROL OF THE MENSTRUAL CYCLE

Although essentially similar to the estrous cycle of lower animals, the menstrual cycle of primates possesses several features which must be examined. The hormonal basis of the process has also to be discussed.

Uterine Changes in the Menstrual Cycle

The occurrence of uterine bleeding marks the end of a menstrual cycle, although it is customary to describe the period of hemorrhage as days 1 to 4, i.e., the first stage of the cycle. The remainder of the cycle is usually divided into two stages—the stage of repair and proliferation (days 5 to 14) and the days of secretion (days 15 to 28). However, since ovulation and any corpora lutea formed thereby exert a regulating influence on the succeeding menstrual flow, it is more logical to describe the cycle as commencing with the stage of repair and proliferation.

The stage of repair and proliferation—follicular phase. During the 10 days or so after the end of the menstrual flow the epithelium of the endometrium which was shed at that time is restored by rapid outgrowths from the mouths of the glands. The epithelial lining then hypertrophies and the glands show proliferative changes. The uterus enlarges as a result of the growth of its stroma and as it becomes more vascular the arteries which supply the inner third of the endometrium—the spiral arteries—become coiled. In the ovary, the Graafian follicle has been undergoing maturation and ovulation occurs at the end of the proliferative stage. The proliferative changes in the uterus occur under the influence of estrogen.

The premenstrual or secretory stage—luteal phase. This stage, following the follicular phase, lasts for 13 or 14 days. The uterine mucosa shows marked hypertrophy and is highly vascular, its glands become elongated and assume a coiled or corkscrew form. The glandular secretion becomes greatly increased and more mucoid in character and toward the end of the premenstrual stage the endometrium resembles the decidua of early pregnancy, with the appearance of typical decidual cells in the uterine stroma. During this phase the

spiral arteries continue to lengthen disproportionately to the growth of the endometrium. Some time before menstruation there is a reduction in the blood supply to the endometrium which shrinks and compresses the spiral arteries. The blood is then further slowed until there is a state of stasis. Finally the spiral arteries constrict and ischemia of the endometrium occurs. The stage is set for menstruation.

The uterine changes occurring in the luteal phase are produced by progesterone secreted by the corpus luteum, and to this extent the stage corresponds to that of pseudopregnancy observed in some lower species. If fertilization of the ovum does not occur the corpus luteum does not persist, its influence upon the endometrium wanes and this change is marked by shrinkage of the endometrium. At the end of the premenstrual stage swelling of the mammary glands may be noted and mild psychic disturbances (irritability, nervousness, depression, etc.) may appear.

The destructive stage or stage of menstrual flow lasts for about 4 days. After a period of ischemia of the endometrium individual spiral arteries relax and hemorrhage occurs through rupture of the wall of an arteriole or capillary. The blood may escape through the epithelium or may collect in the underlying tissues to form a hematoma which eventually discharges into the lumen of the uterus. Hemorrhage ceases locally through vasoconstriction of the spiral arteries, but constriction and relaxation of these vessels does not occur synchronously throughout the uterus so that some bleeding continues. During the process fragments of the epithelium become desquamated and blood vessels may be observed to project freely into the lumen. Gradually the vessels close permanently and an intact circulation becomes reestablished through the basal arteries. This heralds the end of menstruation and the commencement of a new follicular phase.

The blood discharged during menstruation differs from normal blood in that it does not clot. This is apparently due to its passage through the endometrium, for blood that escapes during arterial hemorrhage clots rapidly.

Markee has followed the process of menstruation microscopically in pieces of endometrium transplanted into the anterior chamber of the eye of monkeys. Bleeding occurred from the transplanted tissue during menstruation, but preceded the appearance of blood in the vagina by about 3 hours. His observations emphasize the essentially endocrine nature of the uterine changes occurring during the menstrual cycle. In the human

subject patches or tumors of endometrial tissue are sometimes found in extrauterine situations, e.g., surface of the broad ligament or ovary, in the omentum, pelvic peritoneum or subcutaneous tissue of the vulva or perineum, or in the tissue in the neighborhood of a laparotomy scar. The ectopic tissue bleeds during menstruation. The condition is not uncommon and is known as *endometriosis*.

Effects of Estrogen—Progesterone Interactions on the Menstrual Cycle

It is evident that estrogen-progesterone interactions underly many of the changes observed during the menstrual cycle. However, although the changes seen are well accounted for on this basis, the precise mode of action of the ovarian hormones merits further examination.

It is not necessary for a luteal phase to precede menstruation. This is shown by the fact that in monkeys, as well as in women, ovariectomy during the follicular phase is followed in a few days by a premature menstrual period. Such postoperative bleeding can be postponed by administration of estrogen. Markee showed that an intraocular transplant of endometrium menstruated when a crystal of estrone inserted into that eye was removed, and also that while the crystal was present, the graft in that eye did not bleed at a time when the uterus did so. Also, in monkeys and young women, menstrual cycles can occur without ovulation and the formation of luteal tissue. In these cases cyclic changes in the blood level of estrogen alone presumably are responsible for the flow. Evidence for this view is the finding that ovariectomized monkeys, subjected to a course of estrogen treatment, menstruate soon after the withdrawal of the hormone. This is the estrogen withdrawal effect alluded to earlier (p. 1084). Bleeding may also follow if the dose of estrogen is suddenly reduced although continued at a low level.

Cessation of progesterone administration results in similar effects to estrogen withdrawal. If a short series of progesterone injections is superimposed upon a long course of treatment with estrogen in an ovariectomized monkey, then menstruation ensues shortly after the withdrawal of the progesterone. Alternatively progesterone will prevent estrogen withdrawal bleeding when given immediately following the estrogen. On stopping the progesterone then a progesterone-withdrawal menstrual period ensues. Menstruation follows the end of progesterone treatment in a recently ovariectomized monkey not given es-

rogen Progesterone delays menstruation when given during the normal menstrual cycle

It would seem from the observations above that menstruation follows a reduction in the hormonal stimulus applied to the uterus—whether progestational or estrogenic. In the usual menstrual cycle bleeding normally follows a decline in the circulating level of progesterone (fig 608) for the urinary excretion of pregnanediol begins to fall a few days before the onset of menstruation. With regard to estrogen the recent observations of Brown (1955) on the excretion of the hormone during the menstrual cycle give the following picture. The excretion of estrogens increases steadily up to about the 13th day when an *ovulation peak* is reached. It then suddenly falls, remains low for several days, and thereafter slowly increases to reach a *luteal maximum* at about the 21st day. Finally, immediately prior to the onset of menstruation the excretion of estrogen falls once more.

So far the menstrual cycle has been discussed as if it were a process lying entirely under the sway of the ovary. This is not so, for the participation of the gonadotrophic hormones of the pituitary gland in regulating the cyclic activity of the ovary has been neglected. These are discussed on page 971, so that here the interactions may be tentatively summarized.

The estrogen content of the blood rises when the ovary is stimulated by the follicle-stimulating hormone of the pituitary, and when the concentration of this ovarian hormone reaches a certain level it, in turn, acts to suppress the output of follicle-stimulating hormone and excite the release of luteinizing hormone. The concentration of estrogen upon which the proliferative stage of menstruation depends is thus reduced. Next the hypophysis releases its luteinizing principle which stimulates the development of the corpus luteum but as the concentration of progesterone in the blood rises the production of the luteinizing principle is in turn suppressed, with the result that the integrity of the luteal tissue cannot be maintained. With the fall in the concentration of estrogen and progesterone menstrual bleeding occurs and the secretion of follicle stimulating hormone is then resumed—with commencement of another cycle.

Menstrual Irregularities

The nonoccurrence of the menstrual periods in postpubertal life is called *amenorrhea*, except during pregnancy, when suppression of the menses is a physiological phenomenon, the failure of the

FIG 608 Upper diagram estrous cycle lower diagram menstrual cycle (After Corner)

menstrual cycles at any time between puberty and the menopause is abnormal. Amenorrhea may be either *primary* or *secondary*. In the former instance the menses have never occurred in the latter they appeared but were subsequently suppressed. Primary amenorrhea is in many instances associated with arrested development of the reproductive organs. Scanty menstruation is termed *oligomenorrhea*, whereas *menorrhagia* is excessive bleeding. *Metrorrhagia* is the loss of blood from the uterus in the intermenstrual periods. A large proportion of these menstrual irregularities, when unaccompanied by some gross disease (e.g., tumor in the uterus) have an endocrine basis.

Amenorrhea is frequently the result of ovarian hypofunction. *Dysmenorrhea* painful menstruation, is the result of irregular and spasmodic contractions of the uterine muscle which may in many cases have an hormonal origin. In the past, excessive bleeding in the absence of some obvious uterine disease has been put down to inflammation of the uterine mucosa (endometritis). Before the physiological changes in the endometrium were correlated with the stages of the ovarian cycle (p 1089) the normal premenstrual characters of the uterine mucosa were considered to be pathological evidence of endometritis!

With the knowledge currently available it is clear that disorders of the menstrual cycle, such as amenorrhea, can result from a variety of causes which will operate through the ovaries or through the pituitary. The operation of psychological or neurological factors which act on the pituitary gland through the hypothalamus must not be neglected in this regard. It is well known that gross diseases of the anterior pituitary gland

such as acromegaly, Simmonds' disease, and dystrophia adiposogenitalis are associated with menstrual irregularities which usually appear as oligomenorrhea or amenorrhea. Amenorrhea also occurs as an accompaniment of hyperthyroidism and as a symptom of several general diseases, notably anemia, tuberculosis and malnutrition.

The treatment of menstrual disorders depends, of course, upon the nature of the factors precipitating the condition.

The nasogenital relationship. A number of observations suggest a physiological relationship between the sex processes and the nose. In the first place the mucosa covering the nasal conchae has a cavernous structure suggestive of the erectile tissue of the penis and clitoris, and olfactory stimuli and psychic aspects of sex are very closely associated. Nasal coagestion, often associated with epistaxis, occurs regularly in many women at the time of the menses, and in both sexes it is not unusual for nasal bleeding to occur at puberty. Sometimes the nasal hemorrhage in girls or women has seemed to replace menstruation which was coincidentally suppressed, and for this reason was termed erroneously "menstrual menstruation." Swelling and reddening of the nasal mucosa is a common finding in women during pregnancy and in monkeys during the menstrual cycles. Stimulation of the interior of nose has been reported to alter the periodicity of estrous cycles in rats, whereas excision of the conchae in young animals is said to result in hypoplasia of the sex organs. On the other hand, degenerative changes in the nasal mucosa have been observed as a sequence to castration, which could be reversed by estrogen injections.

The Endocrine Functions of the Placenta

The human placenta has been found to contain (a) estrogens, (b) progesterone, and (c) a gonadotrophin, it is now clear that it acts as an endocrine gland.

Estrogen. Following ovariectomy in pregnant women large amounts of estrogen continue to be excreted in the urine. This observation clearly points to the existence of an ancillary source of estrogen. The fact that the output of estrogen falls abruptly at parturition, and that this hormone can be extracted from the placenta, indicates that it is produced in this organ. Although placental tissue grown *in vitro* does not appear to produce estrogen, Stewart has demonstrated estrogenic stimulation of the uterus of ovariectomized rabbits with intraocular implants of full term human placenta.

Estrone, estradiol and estriol have all been iso-

lated from placental tissue, and are probably produced by the syncytial trophoblast. Of these estriol is the most important from the quantitative point of view. During pregnancy the placenta takes over much of the function of the ovary in the human. During gestation the output of estrogen in the urine rises fairly sharply in the first trimester and then remains more constant. At term the 24-hour excretion of the various estrogens is approximately as follows: estriol, 30 mg.; estrone, 2.0 mg.; estradiol, 0.75 mg. whereas 2 mg. of hydroxyestrone and 0.75 mg. of epiestriol are also eliminated. Such large amounts of estrogen are not excreted in the free form but are conjugated with glucuronic acid (p. 1083). Toward the end of pregnancy it has been found that the proportion of combined to free estrogen, normally of the order of 99:1, falls as more free estrogen appears in the urine, and this has been taken to indicate a change in the metabolism of estrogen at this time. However, a fairly recent study by Clayton and Marrian indicates that the presence of unconjugated estrogen is due to the action of β -glucuronidase in the urine with consequent hydrolysis of the glucuronides. At delivery, with expulsion of the placenta, the urinary output of estrogen falls sharply to the levels found in nonpregnant individuals.

Progesterone. The production of progesterone by the placenta is implied in the finding that pregnancy continues in certain species following ovariectomy (p. 1088). In other species such as the rat, "pregnancy" will continue in the ovariectomized animal provided that the number of fetuses is reduced to a minimum. If the fetuses alone are removed, the placenta will survive and be delivered at term, meanwhile all the signs of pregnancy will continue.

The excretory product of progesterone, pregnanediol, was first obtained from human pregnancy urine in 1929. According to Venning the amount of pregnanediol excreted during pregnancy steadily increases from about 5 or 10 mg. daily to around 80 mg. per 24 hours at term. Following delivery the pregnanediol in the urine falls sharply to reach nonpregnant levels in a few days. Recent applications of more specific assays for pregnanediol indicate that the peak output may not be as great as that noted above.

Gonadotrophin. The existence of a gonadotrophic principle in the blood and urine of pregnant women was established in 1927 by Ascheim and Zondek, but it was left to later workers to show that the principle was derived from the pla-

centa. Since the hormone concerned has been shown to possess actions similar to those of the pituitary hormones it has been termed "anterior-pituitary-like" (APL), or "pregnancy prolactin." However, as it is now known to be produced by the chorionic villi, the name "*human chorionic gonadotrophin*" (HCG), or simply "*chorionic gonadotrophin*" (CG) has been adopted and is in general use.

The hormonal secretions of the pituitary are required during pregnancy in the rabbit and dog, whereas in other species, monkey, mouse, guinea pig and rat, pregnancy is interrupted only if pituitary ablation is performed early. Thus, in conjunction with the evidence that in the rat the ovaries are essential for the maintenance of pregnancy, implies that the placenta produces a gonadotrophic (lutetrophic) hormone.

In the human, chorionic gonadotrophin appears in the urine very shortly after conception, in a fortnight or so, and the amount rapidly increases to reach a peak about 50 to 70 days after the last menstrual period. Thereafter there is an equally rapid fall until the 112th day when a low level is reached which is maintained until the end of gestation. In the chimpanzee and monkey chorionic gonadotrophin is excreted for only a short time during pregnancy.

It is clear that chorionic gonadotrophin is produced by the Langhans' cells of the fetal chorion. In addition to the extraction of the hormone from the human placenta, fragments of this tissue implanted into the eyes of rabbits have been found to liberate gonadotrophin. Chorionic gonadotrophin is also produced by tissue cultures of the placenta. Further, gonadotrophin is detectable in the urine in all conditions in which normal or abnormal chorionic tissue is present, and disappears with its complete removal. In cases in which the placenta is retained after expulsion of the fetus, gonadotrophin excretion continues. Chorionepitheliomas of the uterus, or of the testis, are also characterized by the excretion of chorionic gonadotrophin in the urine, as is hydatidiform mole (a cystic degenerative disease of chorionic tissue).

In its actions chorionic gonadotrophin differs from any of the pituitary hormones. When immature female rats are treated with chorionic gonadotrophin prepared from human placenta, placental implants, or extracts of human pregnancy urine, follicular maturation, estrus and the formation of corpora lutea result, the luteinizing action is the predominant effect. LH is ineffective in immature animals. The failure of the pituitary

principle is believed to be due to the absence of FSH whose synergistic action is required by both HCG and LH. The placental hormone appears to stimulate the release of FSH from the hypophysis of the rat, whereas the pituitary hormone does not. Human chorionic gonadotrophin causes enlargement of the ovaries, but to a lesser degree than the pituitary principle, and hypertrophy of the interstitial (Leydig) cells of the testes. In the latter case the output of male sex hormone is increased and the growth of the accessory sex organs is stimulated. This action may be of value in the treatment of undescended testes and eunuchoidism. Chorionic gonadotrophin will also maintain the integrity of the seminiferous tubules in hypophysectomized animals but will not prevent ovarian atrophy after hypophysectomy, for here the synergistic action of FSH is required.

In summary, it would seem that the function of chorionic gonadotrophin is to supplement the action of the pituitary in maintaining the corpus luteum during pregnancy, and from this point of view the hormone is lutetrophic in effect. Support for this concept may be obtained from the finding that the life of the corpus luteum in women can be prolonged by chorionic gonadotrophin.

A wide variety of techniques has been used in the assay of *human chorionic gonadotrophin*. Those performed on the rat include the increase in ovarian weight, the production of ovarian hyperemia, the increase in uterine weight, changes in the vaginal smear and increase in the weight of the accessory reproductive organs of the male. The production of ovulation in the rabbit and toad, as well as spermatiation in the male toad are also used. For comparative purposes the international unit represents the activity contained in 0.1 mg. of the international standard preparation.

Pregnancy Tests

Quite apart from strictly quantitative or assay purposes a number of the tests noted above are of value in the diagnosis of pregnancy. Since chorionic gonadotrophin appears in the urine some 2 or 3 weeks after conception, detection of the hormone permits an early diagnosis of the presence or absence of pregnancy. Such tests are also of importance in cases of suspected chorionepithelioma and hydatidiform mole.

The more important pregnancy tests are

1. *The Aschheim Zondek test*. This was the first procedure devised and depends on the changes induced by HCG in the ovaries of immature mice.

Two milliliters of urine are given over 2 days and the ovaries examined on the 5th day. The presence of hemorrhagic follicles and luteinized follicles indicates that the urine contains chorionic gonadotrophin.

2. *The Kupperman test* In order to save time the immature rat may be used. Here 2 ml. of urine are injected subcutaneously into each of three immature females, which are killed 6 hours later. If the urine contains HCG a marked hyperemia of the ovaries is observed. Alternatively the response may be read after 2 hours following intra-peritoneal administration of the hormone.

3. *The Friedman test* depends on the production of ovulation in the rabbit following the intravenous injection of 10 to 15 ml. of urine. The ovaries are examined 24 to 48 hours later.

4. *The Hogben test* utilizes the South African clawed toad, *Xenopus laevis*. A mature female is isolated and a concentrate, prepared from 20 to 30 ml. of urine, is instilled into the dorsal lymph sac. If the urine contains HCG ovulation follows between 6 and 12 hours later.

5. *The Galli Mainini test* employs the male amphibian and is the most recently developed method. It depends upon the expulsion of spermatozoa and the result can usually be read within 2 hours. A variety of species may be used, including *Bufo arenarum* (which was the first tested), *Rana pipiens*, *Bufo bufo*, *Bufo marinus* and *Xenopus laevis*.

Finally, it is perhaps worth recalling that as Aschheim has pointed out, tests for pregnancy are not a modern innovation. In an Egyptian papyrus some 3000 or 4000 years old it is directed that should a woman wish to know whether she is pregnant she should place some earth and barley in a vessel and add a little of her urine each day. Should the barley grow she is pregnant. It has since been found that estrogen, which is present in quite high concentration in the urine after the first month or two of pregnancy, is a stimulant to plant growth.

Pregnant mare serum gonadotrophin The existence of a gonadotrophin in the serum of the pregnant mare was discovered in 1930 by Cole and Hart. This hormone appears about the time of implantation of the blastocyst and its concentration in the blood reaches a peak at about the 80th day, although, unlike HCG, only very small amounts appear in the urine. It seems fairly clear that pregnant mare serum gonadotrophin (PMS) is produced by specialized structures in the mucosa of the uterus—the endometrial cups—and the production of PMS may be correlated with the appearance of a number of accessory corpora lutea in the ovary.

In hypophysectomized rats, PMS causes a marked increase in ovarian weight, in follicular growth, and, with large doses, in luteinization.

The interstitial cells in the testes of the male are markedly stimulated.

The hormone is seldom used clinically in view of its limited effect on the human gonad and the ease with which antigenic reactions are stimulated.

The Structure and Development of the Mammary Glands and the Secretion of Milk

The Structure of the Mammary Glands

The secretory tissue of the mammary glands consists of elongated slender sacs or ducts—the *alveolar ducts*—whose walls show numerous pouches—the *alveoli*. The walls of the alveoli are composed of a basement membrane, a layer of myoepithelial cells and an inner layer of columnar epithelium. The epithelial cells are the secreting elements.

The gland is composed of some 15 to 25 lobes marked off by connective tissue septa containing much fat and derived from the mantle of adipose tissue which envelops it. A lobe is subdivided into lobules which are variable in size, shape and number. Each lobule gives rise to a narrow duct which is the continuation of an alveolar duct but whose wall is quite devoid of alveoli. By the successive junctions of these lobular ducts a single *lactiferous duct* is formed which serves an entire lobe; it is lined by stratified epithelium. The lactiferous ducts converge toward the nipple, become dilated beneath the areola and then constrict again. Near the base of the nipple they turn abruptly to run vertically toward the skin surface. Each opens separately at the apex of the nipple by a minute mouth called the *galactopore*. In the nonlactating gland few alveoli, if any, are to be found and the gland consists of ducts, connective tissue and fat. Preparatory to lactation the glandular tissue shows active growth, leading to the development of the lobular alveolar system which completely transforms the histological appearance.

The nipple and an area of the skin (the *areola*) surrounding it are darkly pigmented. The pigmentation deepens in the early months of pregnancy, a sign recognized from the earliest times, and only partially fades after gestation. As in other cutaneous pigmented areas the color is due mainly to the accumulation of granules of pigment in the squamous epithelial cells of the skin, but the actual production of pigment is a function of cells called *melanoblasts* lying just below the epithelial layers. These are the cells which give the "dopa" reaction (p. 1043), but they themselves may contain little pigment. The function of this pigment is unknown but its increase during pregnancy appears to be causally related to the functional activity of the underlying gland, an influence being

conveyed from the active tissues to the melanoblasts through the rich sympathetic innervation (Cathcart and associates). There is possibly also a hormonal factor carried to the melanoblasts in the general blood stream.

The nipple contains smooth muscle which is arranged circularly as well as vertically. The vertical fibers are in close relation to the lactiferous ducts. The stiffening and erection of the nipple which results from mild stimulation is caused by the contraction of these strands of muscle. The nipple is one of the most richly innervated structures in the body. Nerve fibers both medullated (somatic) and nonmedullated (sympathetic) are found in profusion in and beneath the skin, and especially in relation to the openings of the lactiferous ducts. In the dermis, nerve fibers form a loose open network without encapsulation, or enter end organs of various forms. Pacinian and Meissner's corpuscles commonly found in other cutaneous and subcutaneous areas are absent, and Krause's end organs are scarce. The sensations aroused from the nipple and areola are, apparently like those of the glans penis, of the diffuse protopathic or thalamic type. Light touch with cotton wool or von Frey's hairs is not appreciated.

The Roles of the Ovaries and Anterior Pituitary in Mammary Development

There are three phases in the development and activity of the mammary glands. These are seen as (a) the period up to and including puberty, (b) the phase during which the action of the corpus luteum is prominent, that is during pregnancy and pseudopregnancy, and (c) the final secretory phase of lactation when milk is secreted and discharged.

The building of the framework upon which the mechanism of lactation is to be hung, begins before puberty, for it has been shown that growth of the mammary glands of the rat becomes faster than that of the body as a whole at about the 22nd day (Cowie). At this time it would appear that estrogen is largely responsible for the growth changes seen. It is generally true that estrogen is responsible for the growth of the mammary duct system whereas progesterone, acting synergistically with estrogen, promotes full alveolar development. But the above is a generalization and in the mouse, rat and monkey progesterone alone, in sufficiently high dosage, will cause alveolar development in spayed animals lacking estrogen. Further, it is possible to group various species according to the effect estrogen has on the undeveloped mammary gland. In some species, the dog and probably the ferret, estrogen alone causes

little or no mammary development, whereas in the next group, which includes the mouse, rat, rabbit and cat, estrogen in physiological dosage evokes primarily and mainly duct growth. In the third group, which includes the monkey, guinea pig, cow and goat, estrogen produces extensive growth of the alveolar system—lobular alveolar development—as well as of the ducts.

Surprisingly little is known about the relative roles of estrogen and progesterone in the development of the human mammary gland. Mammary development has been produced clinically by the topical administration of estrogen. A number of workers have described cyclic changes in the tissues of the breast during the menstrual cycle, with growth occurring in the luteal phase and regression after menstruation. However such reports have been contested. Physiologically, the enlargement of the mammary glands seen during pregnancy is due to the growth of the corpus luteum which superimposes the alveolar developing action of progesterone upon the basically ductal action of estrogen.

It has long been thought that an intact anterior pituitary gland is essential for the stimulating actions of the ovarian hormones on the mammary gland. In hypophysectomized rats, mice or guinea pigs, estrogen exerts little or no effect upon duct development unless anterior pituitary replacement therapy is initiated. The nature of the pituitary principle necessary for the response to estrogen and progesterone has provided a controversial topic over many years. Turner and his associates produced evidence for the view that the pituitary produced two mammatogenic principles, distinct from any known hormone. *Mammogen I* was thought to stimulate the duct system and to be liberated under the influence of estrogen, and *Mammogen II*, was believed to produce the growth of the lobular alveolar system and to be secreted under the influence of progesterone. Thus the ovarian hormones acted, not directly on the mammary gland, but through the hypophysis. However, the theory has failed to find general favor. It has recently proved possible to obtain full mammary development, typical of late pregnancy, in the hypophysectomized rat by giving estrogen, progesterone and the anterior pituitary hormones, prolactin, growth hormone and adrenocorticotrophin (Lj ons). Further, Ahren and Jacobsohn have shown that if insulin is supplied to the hypophysectomized immature female rat (together with estrogen and progesterone), then mammary growth and differentiation

will follow. This observation underlines the importance of general metabolic activities in mammary development.

The direct action of prolactin in promoting mammary growth (as distinct from its lactogenic effect described below) was shown by Lyons who induced localized hyperplasia of the glandular epithelium by injections of prolactin into the mammary ducts of rabbits previously treated with ovarian hormones.

Prolactin

The existence of a lactogenic hormone in the pituitary has already been mentioned, and is discussed elsewhere, in chapter 56. However, certain points are of interest here. The first evidence of the existence of such a hormone was provided by Stricker and Grueter in 1928 who found that crude anterior pituitary extracts induced lactation in ovariectomized, pseudopregnant rabbits. The material would also restore lactation in rabbits which had ceased lactating 10 to 15 days previously, and was later found to act similarly in bitches. In 1930 Corner showed that injections of anterior lobe extract caused enlargement of the mammary glands and lactation in ovariectomized virgin rabbits. Many workers quickly confirmed that anterior pituitary extracts were able to initiate lactation in the adequately developed glands of a wide variety of species. Within a few years it was established that the extracts contained a separate hormone which had pronounced lactogenic effects (Riddle and Bates), and was called *prolactin*, *galactin*, or *mammotropin*.

The Role of the Placenta in Mammary Growth

The work of Lyons on the hypophysectomized rat showed that mammary development could be obtained after replacing prolactin administration by placental extracts. This finding is in accord with the results of rather different work performed some 20 years ago. It was then found that removal of the ovaries and fetuses from rats together with hypophysectomy causes mammary regression if the placentas are also removed, but mammary growth continues if the placentas are left. It appears then that the placenta can substitute for the ovaries as well as the pituitary. The production of estrogen and progesterone by the placenta should be recalled in this connection (see also p. 1092).

The Initiation of Lactation

Although lactation is generally held to start at end of pregnancy, the secretion of milk sets

in long before this, at about the fifth month. Nevertheless the initiation of a copious lactation is a striking consequence of delivery.

The factors underlying this event have excited comment for many years, and a variety of explanations have been put forward. Thus it was supposed that lactation resulted as a natural consequence of the end of pregnancy and mammary development, so that when the growth stimulus was removed, secretion began. Support for this view came from experiments in which, for example, lactation followed the end of a course of estrogen injections in the guinea pig. With the discovery of prolactin, attention was directed to the pituitary gland as well as to the endocrine activities of the placenta, and Nelson in 1936 put forward a new concept. This was that during pregnancy the ovarian hormones induced proliferative changes in the mammary glands and in addition, and particularly during the latter half, inhibited the actual secretion of milk. The restraining influence was visualized as acting (a) by suppressing the secretion or release of the pituitary lactogenic hormone, and (b) by a direct inhibitory effect on the mammary glands. Thus the high ovarian hormone levels during pregnancy would promote glandular development, whereas the sharp fall in concentration at parturition would permit lactation to begin. It is known that lactation is inhibited in most animals by estrogen, or by measures which stimulate estrogen liberation and is also promptly suppressed by human chorionic gonadotropin (HCG) which stimulates the production of luteal tissue. Collip and his colleagues reported that if the luteinized ovaries induced in virgin rats by the administration of HCG were removed, then the hypertrophied raammæ secreted profusely. Removal of the pituitary, however, together with the ovaries prevented this result. When lactating cows become pregnant, milk production declines progressively during gestation but rises abruptly after calving. In guinea pigs, removal of the ovaries and embryos, although leaving the placentas intact, does not induce lactation, but lactation occurs following expulsion of the placentas. Observations of the above nature lend strong support to the view of Nelson. Evans also explained the milk secretion which occasionally occurs in the child shortly after birth ("witches milk") on this basis, for the fetus is exposed to ovarian hormones and the elimination of these after birth might result in the liberation of prolactin from the pituitary of the infant.

The theory as described above, with an em

phases on the inhibitory action of estrogen, has limitations. Thus the amounts of estrogen required to suppress established lactation probably are greater than those produced during pregnancy, and the typical signs of high estrogen levels (cornified vagina, estrous behavior) are not seen during pregnancy. Further, low doses of estrogen actually stimulate mammary secretion in some forms (goat and cow). It was to account for difficulties of this nature that Meites and Turner in 1942 drew attention to the possible role of progesterone. These workers suggested that during pregnancy progesterone inhibited a stimulating effect of estrogen on the secretion of prolactin, but at the time of parturition estrogen became dominant and was able to evoke a quick rise in the output of prolactin and so initiate lactation. In support of this view it was found that in rats and guinea pigs the prolactin content of the hypophysis began to rise a few days before the birth of the young, and that the urinary excretion of prolactin after parturition was from 8 to 16 times greater than that during pregnancy. Estrogen was found to increase the content of prolactin in the hypophysis, so that the low prolactin content during pregnancy was attributed to the relatively high progesterin content of the blood, and its antagonistic effect on the action of estrogen. It was found that estrogen and progesterone given in appropriate proportion had no effect on the prolactin content of the pituitary.

In turn, the view of Meites and Turner has been subjected to criticism, notably by Folley, who was not convinced that increases in pituitary prolactin content (assumed to reflect pituitary secretion rate by Meites and Turner) were accompanied by an increased secretion of prolactin into the blood, and objected to the key position assigned to prolactin in the initiation of lactation. He suggested, as a modification of the Nelson theory, that low levels of circulating estrogen stimulate the secretion of anterior pituitary hormones concerned in lactogenesis, whereas high levels inhibit such secretion. At about the time of parturition the level of circulating estrogen, previously above the threshold for pituitary inhibition, falls and in passing through the range between the two thresholds will cause functional activation of the anterior pituitary with respect to the production of lactogenic hormones and so initiate full lactation.

More recently it has been found (Meites and Sgouris) that estrogen and progesterone exert an antagonistic effect toward prolactin at the mammary gland level. Thus the ability of a moderate

dose of prolactin to initiate milk secretion in ovariectomized rabbits with well developed glands could be effectively inhibited if optimal mammary growth promoting doses of estrone and progesterone were given at the same time. In the absence of either or both steroids prolactin elicited a good lactational response. Variation of the amounts of gonadal or hypophyseal hormones given showed that the occurrence of mammary growth (or of lactation) depended on the balance achieved. In the light of this work it is clear that to focus attention solely upon the hypophysis at the onset of lactation is to neglect other important factors. Although retaining his "double threshold" theory, Folley now believes that "lactogenic" doses of estrogen may be deprived of their lactogenic action by suitable doses of progesterone, and that the combination of the two hormones may act as a potent inhibitor of lactation during pregnancy. At parturition the fall in the ratio of progesterone to estrogen would remove the inhibition, and the positive "lactogenic" effect of estrogen would act unopposed.

An entirely different viewpoint is that of Petersen, who does not concern himself with estrogen-progesterone-prolactin interrelationships. It is now clear that milk production, i.e., the formation of milk and its secretion into the alveoli, begins some time before parturition. The question, therefore, is not a matter of secretion after childbirth, but of the discharge or ejection of milk from the gland. As pointed out by Petersen, the low water content of the first milk secreted, the *colostrum*, strongly suggests a retained secretion which tends by distention of the alveoli to depress secretory activity, but with the emptying of the alveoli the inhibitory effect of distention is removed and a continuous profuse secretion is maintained by the lactogenic hormone.

The Maintenance of Lactation

With parturition the operation of a number of as yet imperfectly understood factors results in lactation, a process which is maintained in many farms for months.

Neural factors. The mechanism underlying the continuance of lactation is not clear, although it is certain that the pituitary is involved since lactation is arrested abruptly by hypophysectomy. It is common knowledge that weaning is followed by rapid involution of the mammary gland and cessation of milk production. This might be due to the retention of milk within the gland, with consequent deleterious effects on its secretory activity, or to loss of a stimulus to

lactation—the stimulus of suckling. The latter alternative is more likely, for there are numerous cases in which suckling has been shown to induce lactation in male individuals of various species (bull, goat, wether, man). Lactation has often been induced in this way in virgin girls, as well as experimentally in the rat. Selye and his coworkers showed that suckling tended to delay the involution of the mammary glands in rats in which the galactophores were tied (to prevent the egress of milk) and suggested that the suckling stimulus caused a nervous reflex release of lactogenic hormone from the pituitary which maintained lactation. In lactating mice deprived of their litters the mammary involution which normally occurs may be retarded by painting the nipples with an irritant such as turpentine. The prolactin content of the hypophysis of lactating rats has been observed to fall over a 30 minute nursing period. In nonpuerperal women lactation may follow extensive operations involving the thoracic wall, probably through irritation of the intercostal nerves. Such observations indicate that nervous factors play an important part in the maintenance of lactation. The operation of psychic factors in women is not to be neglected, their operation is well seen in relation to milk ejection (see below).

Hormonal factors. The precise nature of the hormonal systems activated by neural stimuli has not been elucidated. It is presumed that the stimulus is transmitted to the hypothalamus and from there to the hypophysis by the portal vessels. But the nature of the response of the anterior pituitary gland is not certain. With the availability of purified pituitary hormones the maintenance of lactation in hypophysectomized rats has been attempted. Cowie found that, using growth hormone, prolactin and ACTH singly and in combination, the best result was given by prolactin plus ACTH. Oxytocin was also given to make certain that the litters obtained any milk produced. Lyons in rather similar work found that prolactin and hydrocortisone together were able to raise the milk production to about half of normal.

When pure pituitary hormones are given to lactating animals, and the effect on the milk output is studied, it is found that growth hormone augments the secretion of milk (*galactopoiesis*) to the greatest extent. This effect can be observed, not only toward the end of lactation, when the milk yield is declining, but also at the height of milk secretion. It is further significant that upon cessation of treatment the milk yield does not fall below the expected level—the action of

growth hormone is thus not due to mobilization of reserves. Prolactin exerts very little galactopoietic activity although its continued secretion is probably necessary for the maintenance of lactation. Injection of ACTH in cows has been found to temporarily depress the milk yield although it is evident from work involving adrenal ectomy and replacement therapy that the adrenal corticoids are essential for the maintenance of lactation. In adrenalectomized rats cortisone and desoxycorticosterone acetate (DCA) together provided the best maintenance of lactation (Cowie), whereas later work showed that chlorohydrocortisone gave virtually complete maintenance. The effects of thyroidectomy on lactation, although depressive, do not appear to be particularly striking. It was found more than 60 years ago that thyroid feeding increased the milk yield of women and cows. This has been confirmed, and similar responses demonstrated in the rat. Pituitary thyrotrophic hormone is also active in this regard. Besides increasing the weight of milk produced, L-thyroxine increases the percentage of fat and nonfatty solids in the milk, whereas the concentration of alkaline phosphatase drops markedly. Recent work has shown that triiodothyronine (ch. 57) is about twice as active as L-thyroxine. Unlike thyroxine, triiodothyronine is not effective when given orally to cows. Dried thyroid and L-thyroxine have been used with benefit in the treatment of human hypogalactia, but can not be regarded as a panacea.

Milk Ejection

The production of milk by the maternal mammary gland forms only one step in the process of lactation. For lactation to be successful the milk must be transferred to the young. It is not possible to empty a mammary gland passively by compression or by suction, since the milk is retained in the small ducts and alveoli. Physiologically, emptying of the gland is achieved by the operation of a neurohormonal reflex referred to as the milk ejection reflex. It consists of an afferent nervous pathway, which begins with the sensory end organs in the nipple and areola, passes up the spinal cord to the hypothalamus and to the posterior lobe of the hypophysis through the supra-optico-hypophyseal tract. That is the neural part of the reflex. In the posterior pituitary the neurohypophyseal hormone, oxytocin, is discharged into the blood stream whence it is carried to cause the contraction of myoepithelial cells embracing the alveoli. There is little doubt that this is the reflex activated by milking in cattle which

results in "let-down," or by sucking in women, which results in the "draught." The reflex is highly susceptible to conditioning, and is easily inhibited by fright or, in women, by embarrassment. Experimentally, milk ejection can be produced by electrical stimulation of the supraopticohypophyseal tract, and blocked by lesions of this nerve pathway. In the latter case milk ejection may be restored by injection of oxytocin.

It follows from the above that interference with the process of milk ejection will stop or prevent lactation just as surely as disturbance of the formation of milk. Neglect of this consideration has in the past led to much confusion in both experimental and clinical investigations.

The fact that both oxytocic hormone and lactogenic hormone are secreted in response to the same physiological stimuli has led several investigators to suggest that oxytocin released from the neurohypophysis acts on the anterior pituitary to cause the release of lactogenic hormone. In support of this concept it has been found that the administration of oxytocin to rats whose litters had been removed retarded mammary involution. This effect was not apparent in the hypophysectomized animal. However, it must also be pointed out that lactogenic hormone appears to be released from the hypophysis isolated from neural influences by transplantation away from the sella turcica.

The Composition of Milk, the Origins and Secretion of Its Constituents

With the onset of lactation, the epithelial cells lining the alveoli become loaded with fine droplets of fat which soon coalesce to form large globules in the part of the cell lying next to the alveolar lumen. The fat, with other constituents of the milk, may then be discharged into the alveolus as droplets, or the inner part of the cell is pinched off as it were from the larger portion and is freed into the lumen. The latter represents the process of apocrine secretion.

Colostrum. At the end of pregnancy and the beginning of lactation the secretion contained in the mammary gland is unlike normal milk. It is known as *colostrum*. Colostrum contains numerous globules and cell fragments, together with *colostrum bodies*, which are large ameboid cells. Colostrum contains little fat, but a larger amount of antibodies than are present in milk proper. It is presumed that *colostrum formation occurs* when there is an unbalance between the secretion of milk and its removal. Thus it is found at the end of pregnancy and at the end of lactation.

Milk. Milk consists essentially of an emulsion of fat globules in a colloidal solution of protein, together with crystalloids in true solution. It contains two substances not found elsewhere in the body, casein and lactose, the combination of glycerides forming milk fat is peculiar to it.

The composition of human milk is compared with that of cow's milk in Table 60 1. The quantity of protein in cow's milk is more than double that in human milk, the difference is largely confined to the casein content. The sugar and fat content of cow's milk is lower than that of the human. Calcium is the mineral present in largest amount. Both human milk and cow's milk vary greatly in composition and in quality due to the operation of many factors, psychic, dietary, hormonal, period of lactation, time of day (greater volume during night), etc. The daily output increases up to a maximum of from 1000 to 3000 ml at about the 25th week after childbirth and then gradually declines. Human milk of good quality contains all the elements essential for building body tissue, and adequate amounts of vitamins A (as well as carotene), the B complex and C. Vitamins B₁ and D are in low concentration and may be present in inadequate amounts. Raising the protein in the diet tends to increase the total milk yield and a high fat diet increases the yield, as well as the fat content, of the milk. Carbohydrates, if in high proportion in the diet, reduce both the yield and the quality of the milk.

The milk protein. The proteins of milk consist largely of casein, lactalbumin and lactoglobulin. Since the phosphoprotein, casein, occurs in no place other than the mammary gland it is clear that it must be synthesized there. The details of the synthesis have not yet been worked out. According to Folley, milk protein may be synthesized entirely from the amino acids of the circulating blood, or partly from these and partly from degradation of plasma protein in the mammary gland. Alternatively the milk proteins might arise from plasma proteins by rearrangement of peptide chains, or partly in this manner and partly from blood amino acids. From measurement of

TABLE 60 1

	Total protein	Casein	Lactalbumin	Lactoglobulin	Lactose	Fat	Ash	Water
	%	%	%	%	%	%	%	%
Cow's milk	3.63	0.0	5.0	0.85	3.50	7.87	2	
Human milk	1.51	1.0	4	—	6.84	0.02	2.87	5

the arteriovenous difference of blood amino acids in the lactating udder, it is clear that some amino acids are utilized by the mammary gland. However, it has been claimed that the uptake is sufficient to account for only about half of the casein in milk. For this reason attention has been directed to the plasma proteins and it was thought that a glycoprotein present in small amounts in blood represented the precursor. Quite recent work with udder perfusion methods and with labelled amino acids indicates that casein is indeed synthesized from plasma amino acids, and that a similar conclusion may well be reached in the case of lactoglobulin.

Milk fat. Milk fat differs in composition from the neutral fat of the blood in that it contains a relatively high proportion of short chain fatty acids of the series C_4 to C_{12} . The fatty acids, e.g., butyric, caproic, caprylic, lauric, and myristic, constitute about 30 per cent of the total fat of milk. The fat of milk therefore cannot be simply neutral fat transferred from the circulation to the gland and there concentrated. Of the long chain fatty acids, oleic (35 per cent) and palmitic (30 per cent) are present in greatest quantity. Stearic acid constitutes only about 2 per cent. Much of our knowledge of the synthesis of milk fat is derived from work on the ruminant, where it is probable that most of the fatty acids up to, and including, palmitic acid are formed in the udder from small molecules, mainly acetate and possibly β hydroxybutyrate. In other species, e.g., the rat and rabbit, considerable quantities of glucose may be used in addition for fat synthesis.

Lactose. Like the other constituents of milk just discussed, lactose is found only in the mammary gland. This disaccharide, galactose glucose, must therefore be formed in that organ. Lactose could be produced from small molecules taken up from the blood, like lactic acid and pyruvate, or from the blood glucose. Most evidence favors glucose as a precursor. Thus perfusion of a bovine udder with blood containing labelled glucose, followed by extraction and hydrolysis of the lactose resulted in isolation of labelled glucose and galactose. This result implies that galactose is derived from glucose and is supported by experiments in which slices of mammary tissue, incubated with glucose, formed lactose. It has also proved possible to synthesize lactose from glucose in homogenates of mammary gland tissue. It is perhaps worth noting here that procedures which lower the blood sugar tend to decrease the concentration of lactose in milk whereas hyperglycemic procedures have the reverse effect.

The Testes

THE STRUCTURE OF THE TESTES

The testes are ovoid glands suspended in the scrotum by the spermatic cords. Each is surrounded by a firm, thick capsule—the *tunica albuginea*, which is in turn enclosed by a double layer of peritoneum. The layers of the *tunica vaginalis communis* slide freely upon one another, enabling the testis to move easily within its scrotal sac.

The substance of the testis consists of a mass of coiled tubules, the *convoluted seminiferous tubules*, bound together by a stroma of connective tissue. Each seminiferous tubule is a rather closely coiled tube between 35 and 70 cm. long and from 150 to 300 microns in diameter. They are held in wedge shaped compartments or *lobules* by incomplete connective tissue septa. Through the gaps in the septa they are joined to one another by short tubular connections. The combined length of the convoluted tubules of man has been estimated at over 300 yards. At the apices of the lobules the seminiferous tubules join the first elements of the excretory duct system. These are narrow straight tubules—the *tubuli recti*—which in turn empty into a system of irregular cavernous spaces, the *rete testis* in the hilum or mediastinum in the posterior part of the testis. At the upper part of the *rete testis* some dozen or more ducts, the *ductuli efferentes*, arise, passing to the upper part or *caput* of the epididymis, these ducts become confluent to form the *ductus epididymis*. This latter is a long greatly tortuous tube which forms the body and tail of the epididymis. At the lower extremity of the epididymis the ductus ends abruptly upon itself to be continued as the *vas* or *ductus deferens*. The *vas deferens* on each side, after a devious course, is joined by the duct of the corresponding seminal vesicle, and terminates as an *ejaculatory duct* which opens into the urethra.

The convoluted tubules are lined by several layers of cells, the *spermatogenic cells* which produce the spermatozoa. Among the spermatogenic or sex cells are a small number of *cells of Sertoli*—long cells attached perpendicularly to the basement membrane. The spermatogenic cells undergo well defined changes in the course of transformation into spermatozoa. In the mature testis these can be distinguished, for the primitive stages lie close to the basement membrane and develop on passage toward the lumen of the tubule. Initially the germ cells are large round cells at the periphery of the tubule and are called *spermatogonia*. They alone are present in the immature testis. *Spermatogonia* multiply mitotically, giving rise to *primary spermatocytes*. These are larger than the *spermatogonia*. Each divides into two smaller *secondary spermatocytes*, and each of these in turn divides to produce two *spermatids*. The latter

transformation involves a reduction or *meiotic division* of the nucleus, so that each spermatid contains only half the normal number of chromosomes in its nucleus. The spermatids which are found near the lumen of the tubule are transformed directly, i.e., without division, into the free spermatozoa (see figure 60-9). About half the number of spermatids or spermatozoa contain a Y chromosome and half an X chromosome.

Sertoli cells The Sertoli or sustentacular cells occur fairly regularly at intervals around the tubules. The nucleus of a Sertoli cell is large, but division has not been seen under normal conditions. In the human testis, the Sertoli cell contains a spindle-shaped crystalloid near the nucleus. The Sertoli cells are believed to perform a nutritive and supporting function toward the developing spermatozoa; the spermatids are found to be attached to them. Unlike the spermatogenic cells, the cells of Sertoli are highly resistant toward a variety of noxious factors. To judge from the findings in cases of Sertoli cell tumors of the testis, the sustentacular cells may secrete estrogen.

The interstitial cells The tubules of the testis lie in a stroma of connective tissue, and in this connective tissue are found clumps of irregularly polyhedral cells—the *interstitial cells of Leydig*. The Leydig cells appear to be differentiated from fibroblasts, and contain many granules of lipid material and pigment. In the fetus and newborn the Leydig cells are remarkably prominent due to stimulation by chorionic gonadotrophin. After birth they atrophy but become conspicuous once more at puberty. The Leydig cells are known to secrete androgen.

The accessory sex glands Linked in functional association with the testis are a number of glands which produce secretions which, with the sperm of the testis, together make up the *semen*. They are functionally dependent upon the endocrine secretion of the testis, for they display atrophy in its absence. The most important are the *seminal vesicles*, *prostate gland*, and the *bulbo-urethral or Cowper's glands*.

The *seminal vesicles* are paired organs lying dorsal to the bladder, their ducts join the vas deferens. They are absent in many mammals (e.g., the whale and dog) and so are not considered essential in reproduction. On the other hand they are greatly developed in boars, hedgehogs, rats and guinea pigs, and their secretion increases the volume of the ejaculate in these species. They do not act as reservoirs for the spermatozoa. The secretion of the seminal vesicles is a yellowish

FIG 60-9 Spermatogenesis a spermatogonium b primary spermatocytes c spermatozoa d spermatids, e cells of Sertoli

viscous fluid which is marked by its content of fructose. The level of fructose is closely associated with the blood titer of male sex hormone, and falls sharply in its absence (as after castration). The fructose appears to be derived from blood glucose since it is increased in diabetic rabbits or in humans, and falls after the administration of insulin.

The semen The fluid ejaculated from the male genital tract is known as *semen*. It contains about 60,000,000 spermatozoa per cu. ml., although the normal limits range from 23,000,000 to 225,000,000. In the assessment of fertility from a sample of semen the motility and viability are often regarded as more important than the sperm count. The average volume of an ejaculate is about 3 ml and immediately after expulsion the semen coagulates, to liquefy again in a few minutes. The spermatozoa in the seminiferous tubules are non-motile and appear to be carried along the ductus efferentia by the cilia of the cells lining these channels. They are stored in the epididymis. Ejaculation of the semen during coitus is brought about by contractions of the deferentia and the ejaculatory ducts.

THE PHYSIOLOGY OF THE TESTIS

The function of the testis is two-fold, namely, the production of germ cells, *spermatogenesis*, and the elaboration of the male sex hormone, its *endocrine function*.

The Gametogenic Function of the Testis

In man the production of spermatozoa in the testes is carried on continuously in the adult

life, with the formation of an astronomical number of germ cells. In some other species the production of sperm occurs seasonally, at a time when conception of young will lead to their delivery at an auspicious time of the year. The sheep, deer, ferret and many classes of birds display this condition, sheep, for example, breed in autumn and the young are delivered in spring. During the remainder of the year, outside the breeding season, little sign of germinal activity is seen in the testis. Experimentally, however, spermatogenesis may be promoted by administration of pituitary gonadotrophic hormones.⁴

The testis like the ovary, is functionally dependent on the pituitary gland. The removal of the hypophysis is followed by arrest of spermatogenesis and testicular atrophy, these changes can be reversed by implantation of pituitary tissue or suitable extracts of anterior pituitary glands. Upon hypophysectomy the testes soften and lose weight. Differentiation of the gametes does not proceed beyond early spermatocyte formation and thus spermatids and spermatozoa disappear from the organ. The Leydig cells become inactive and androgen production ceases, with consequent atrophy of the accessory sexual organs and accessory sex characters. Implantation of pituitary tissue or injection of gonadotrophic extracts of the pituitary speedily results in the onset of spermatogenesis in the immature individual whether mouse or man. The effect is sometimes seen clinically in cases where pituitary overactivity advances puberty in boys. It is believed that the follicle stimulating hormone (FSH) of the hypophysis is mainly concerned with spermatogenesis, as injection of purified FSH into hypophysectomized male rats prevents atrophy of the seminiferous tubules and will restore gametogenic activity. Similar effects have been reported in studies employing purified FSH in man. The luteinizing hormone (LH) of the pituitary also exerts an effect on spermatogenesis. Here it is believed, mainly from studies on rats, that the action is initially on the Leydig cells to promote androgen secretion, which in turn stimulates sperm formation. It has been found that androgen (testosterone) will support gametogenesis in the hypophysectomized male rat but it should be borne in mind that in normal individ-

uals large doses of testosterone suppress spermatogenesis and, via its suppressive action of the secretion of pituitary gonadotrophin, causes testicular atrophy.

In man and many other mammals, but not in the sloth, whale or elephant, the testes are contained extraabdominally in the scrotum. In many of these the testes descend into the scrotum at puberty and remain there permanently, in others again the testes occupy a scrotal position only during the breeding season. It is now evident that the scrotum exerts a thermo regulating function (Moore). This has been established in a variety of studies. In the developmental anomaly known as *cryptorchidism* the testis fails to descend into the scrotum and spermatogenesis does not occur in the undescended organ. This condition can be reproduced experimentally by returning the testes of the normal adult animal from the scrotum to the abdomen, degeneration of the seminiferous tubules will follow in a few days. Upon replacement of the testis in the scrotum there is a restoration of normal testicular appearance and function provided that the stay in the abdomen has not been too long. It is possible to produce this effect in the ram by enclosing the testis in a bag of heat insulating material which raises the temperature of the testis by a few degrees. Such an observation ensures that the result of moving the testis to the abdomen was not an artifact due to operative procedures. Measurement of the temperature of the scrotum has shown that it is several degrees lower than that of the abdomen. It has also been found that exposure for 15 minutes or so to a temperature of 6° C above the normal body temperature leads within some 10 days to degeneration of the sperm producing cells. The human testis may suffer in febrile illnesses, as a result of the high temperature, but as a rule the loss of function is only temporary. The requirement for a lower temperature than that prevailing in the rest of the body explains why testicular transplantation has seldom been associated with continuing spermatogenesis, unless a cool location (such as the anterior chamber of the eye) is chosen. Normally it appears that the descent of the testis is dependent upon the secretion of androgen, although in cases of *cryptorchidism* gonadotrophin is used to produce descent in order to avoid the depressive effects on the pituitary of androgen alone.

⁴ Spermatogenesis can also be advanced in seasonally breeding species by modifying the external environment such as by altering the period of illumination during the day. This latter effect is mediated by the nervous system which brings about an increase in the secretion of pituitary hormones.

Ligation of the vas deferens has been stated by some (e.g., Stenath) to cause degeneration of the spermatogenic cells, and further, to increase the

production of sex hormone. These claims have been conclusively disproved. Vasoligation has been advocated as a means of increasing the output of male hormone and so causing rejuvenation, but it is based on error. It exerts no lasting effect upon either the sperm producing cells or upon those of internal secretion. Ligation or resection of a portion of the vas deferens results in sterility by preventing the egress of the male germ cells but does not interfere with the sexual drive of the male.

The spermatogenic function of the testis is affected adversely by several conditions such as exposure to X rays or radioactivity, alcoholism, vitamin E and B₁ deficiency and (in some species) close confinement. Following irradiation of the testes there is a marked destruction of spermatogonia whereas the Sertoli and Leydig cells survive. This effect would seem to be due to the operation of the principle that the most actively dividing cells are those most adversely affected by ionizing radiations. The effect of vitamin B deficiency may be exerted through the pituitary, whereas lack of vitamin E would seem to act directly. Testicular function is depressed in cases of simple starvation.

The Endocrine Function of the Testis

The effects of castration have long been known. Aristotle described the changes following castration in the bird more than 2000 years ago and before that testicular tissue was used as a treatment for impotence in India. More recently John Hunter showed that the normal function of the prostate and seminal vesicles was maintained only in the presence of the testes and Berthold in 1849 demonstrated that the testes discharged some material into the blood stream essential for the growth of the cock's comb. Among the first to attempt the preparation of an active material was the noted physiologist Brown Séquard (1889) who administered testicular extracts to himself and thought that he acquired an increase of vigor and a greater capacity for work after the treatment. This concept was later revived by Voronoff in France and Steinach in Germany who believed that senescence was related to testicular atrophy and consequent reduction or loss of male hormone. However this idea has been discredited and it is only necessary to point out that although in the female ovarian function ceases at the menopause (p. 1080) senile changes are not prominent at this time. Eunuchs did not show premature senility and in any case the sexual functions in the male often continue well into senility.

The effects of castration have been discussed at the beginning of this chapter (p. 1074) and it

will be recalled that in the male the accessory sexual organs are developed and maintained under the influence of androgen as are certain characters including the pattern of pubic and facial hair and the pitch of the voice. In lower mammals other features can be studied such as the presence of horns in the stag, the cape of long hair in the male baboon and the male odor of the billy goat. These male features may be maintained in the castrated animal by the transplantation of testicular tissue or androgen therapy.

When the testes are transplanted from the scrotum to a situation elsewhere in the body germinal activity ceases (p. 1102) but the endocrine function continues. A similar finding is made following destruction of the germinal elements with X rays and it then becomes evident that germinal cells are not concerned with the production of androgen. This function is exercised by the Leydig cells. Apart from the evidence which denies this function to other testicular constituents it has been found that in rats with vitamin B deficiency there is a loss of androgenic activity and the interstitial cells are atrophic but normal production of sperm continues. Injections of pitch dissolved in olive oil have been found to cause atrophy of the interstitial cells and involution of the accessory sexual organs although the tubular epithelium appeared unaffected. In man tumors of the interstitial tissue of the testis produce excessive quantities of androgen and in boys cause a premature appearance of masculine characteristics.

An active androgen containing extract of testis was obtained by Pézard in 1911 who produced comb growth in capons with a saline extract. McGee in 1927 obtained an active lipid extract of bull's testes but it was not until 1935 that the pure hormone *testosterone* was separated in crystalline form by Laqueur and his colleagues. Meanwhile more success had been achieved with extracts of human urine for between 1931 and 1934 two androgenic substances had been isolated. These were androsterone and dehydroandrosterone and were found to differ from the hormone in testicular extracts in being less potent and more stable to alkali.

THE ANDROGENS. In recent years the efforts of the biochemists in isolating steroids from organs such as the adrenal cortex, ovary and testis have resulted in the identification of a wide variety of androgens.

Of the steroids isolated from the testis *testosterone* is the most important and is regarded as

true male hormone. It has been synthesized from cholesterol. When the testis is perfused, or incubated, with isotopically labelled acetate and gonadotrophic hormone, labelled testosterone appears, together with another androgen, Δ^4 androst-3,17-dione. A further constituent of the testis is pregnenolone (Δ^5 pregnen-3 β -ol-20-one) which, although lacking androgenic activity, maintains testicular weight and spermatogenesis in the hypophysectomized rat.

Testosterone

Androsterone

Dehydroandrosterone

The urine provides a ready source of androgens. Here the first androgen isolated, androsterone, is also the principal androgen, and it is about one-tenth as potent as testosterone. It has been synthesized from cholesterol by Ruzicka and coworkers. Two isomers of androsterone exist and are found in urine. Epiandrosterone is about five times less active than androsterone, whereas the other isomer etiocholan-3 α -ol-17-one is almost inactive. It has been shown that the principal metabolites of testosterone in urine are androsterone and its isomers. The testicular androgen Δ^4 androst-3,17-dione is also found in urine. A further androgen, dehydroepiandrosterone, with an activity of the order of that of epiandrosterone, also occurs in urine.

At least five androgens have been isolated from the adrenal gland. These are 17 α hydroxyprogesterone, adrenosterone, Δ^4 androstene-3,17-dione,

androstane 3 β ,11 β diol 17-one and 11 β hydroxy Δ^4 androstene-3,17-dione.

Most of the androgens found in the urine possess a ketone group attached to carbon 17, and are thus 17 ketosteroids. On the other hand, certain urinary 17 ketosteroids which possess a ketone group at this site lack androgenic activity. Etiocholan 3 α -ol-17-one and dehydroepiandrosterone are examples of such compounds. This is in part due to the fact that the adrenal makes a major contribution to the output of 17 ketosteroids. Therefore measurement of these compounds by chemical methods (Zimmerman reaction) does not necessarily coincide with the amounts as measured by biological assay of androgenic activity. However a reasonable correlation exists between the results of the two methods.

Only very small amounts of androgens or 17 ketosteroids are found in the urine of children. At puberty the output increases and it reaches a maximum in men of about 25 years of age when the excretion is 12 to 17 mg. of 17 ketosteroids daily. In women the daily excretion is 7 to 12 mg. per day, much of which comes from the adrenal and which does not exert any androgenic effect physiologically. Androgen has been extracted from ovarian tissue and the production of androgens by the ovaries has been demonstrated experimentally. Clinically, virilism (p. 1044) has been found in association with several kinds of ovarian tumors (arrhenoblastoma, 'Leydig cell tumor', 'theca cell tumor', 'adrenal like' tumor). These tumors thus seem to produce androgens, although it should be borne in mind that progesterone in large doses is androgenic and will maintain spermatogenesis and the accessory sexual organs in the castrate.

In general the actions of androgen may be summarized as follows:

- 1 They promote the growth of many tissues. Besides that of the accessory sex organs such as the seminal vesicles and prostate glands, there is a general increase in body mass with growth of muscle, kidneys and bone. This action is marked by an increased blood supply to the various organs, which obviously follows application of androgen in the cock's comb.

- 2 Perhaps as part of the growth promoting action, androgens are remarkably anabolic and cause nitrogen retention. This response is of clinical value and compounds allied to testosterone are being studied in the hope of finding one with high anabolic activity but little androgenic potency.

- 3 They act directly upon the nervous system to shape the sexual behavior of the individual. This is clearly shown by the effects of castration.

on masculine sexual behavior and the return to normal with androgen treatment perhaps before effects on the sex accessories are observed. In the intact female androgens may result in a b sexual pattern of behavior. In women moderate doses of androgen appear to heighten but not alter the sexual interests.

The actions of androgens Androgens exert an effect upon the genital system from the earliest period of life. When frog larvae (or tadpoles) are treated with testosterone genetic females are transformed into apparently normal males which will produce normal spermatozoa. In the mammalian fetus such as that of the rat the injection of androgens markedly stimulates the Wolffian (male) structures both in the male and female without promoting the disappearance of the Müllerian system. This effect can also be observed

when large amounts of male sex hormone are given to the pregnant cat or mouse. Here also alongside the development of the Wolffian system in the female the Müllerian ducts persist.

The effects of androgen in the fowl have been long studied. In the castrated cock or capon androgens restore the size of the comb and wattles and enlarge those of the female (figure 60 10). The ability to crow is regained and male sexual behavior becomes manifest. Continued administration of androgen to hens enables them to assume dominance over other members of the flock and so assume a higher rank in the social scale or peck order.

Castration atrophy of the accessory male organs (seminal vesicles prostate gland Cowper's glands scrotum and penis) is prevented by testosterone or other androgens (figure 60 11). The

FIG. 60 10 Showing the effect of testis hormone (from urine) upon the comb growth of capons. The birds in the upper photograph received daily injections over a period of 15 days. Lower photograph untreated controls. (After Link, Harrow and Lejwa.)

FIG. 60 11 Effect of castration and testis hormone on epithelium of seminal vesicles. (Moore, Hughes and Gallagher.) 1 cells from normal animal showing secretion granules. 2 cells from 90-day castrate. 3 cells from 20-day castrate treated with male hormone.

epithelium of the seminal vesicles is restored to its normal condition and the level of fructose in the gland is raised. Involution of the prostate gland is prevented and there is stimulation of the secretion of the gland with elevation of the concentration of acid phosphatase.

The effect of androgens upon the testis seems to be largely dependent upon the amount given. With a moderate dose there is testicular atrophy together with arrest of spermatogenesis and atrophy of the Leydig cells. The pituitary is involved in this response, for when gonadotrophic hormone is given with the androgen there is no atrophy. High doses of androgen stimulate the seminiferous tubules and will partially prevent the results of hypophysectomy, but the Leydig cells still undergo degeneration, for they are solely under the control of the hypophysis. Androgens do not exhibit the seminiferous tubule maintenance to the same degree. The most potent in this regard is 17 methyl Δ^4 androstene 3 β ,17 β diol (methylsdrostenediol) whereas testosterone is much less effective.

In the female small doses of testosterone modify the secretion of gonadotrophin by the pituitary in favor of FSH so that mainly follicular activity is observed in the ovaries. When testicular tissue is implanted into an intact prepubertal female rat, the animal displays constant estrus on reaching sexual maturity (Pfeffer). The effect of male hormone would seem to be exerted at an hypothalamic level since transplantation of the pituitary of a male rat under the median eminence of an hypophysectomized female permits the restoration of normal estrous cycles. In large doses androgens inhibit the gonadotrophic function of the hypophysis and so produce ovarian atrophy. Testosterone exhibits progesterone-like effects in the female, as seen by the changes induced in the endometrium of the uterus. However, deciduomas cannot be produced or pregnancy maintained.

Regulation of Testicular Function

There is much evidence to show that the testis and pituitary interact with one another. Besides the striking effect of hypophysectomy upon the testis (p. 961) it is well known that removal of the testes results in enlargement of the hypophysis and the appearance of characteristic signet ring cells or *castration cells*. This change is prevented by the administration of androgen. Further, assay of the gonadotrophic hormone in the urine after castration shows that the excretion of gonadotrophic hormone is increased but can be reduced

by the administration of sex hormones. This phenomenon is observed clinically in cases of primary testicular deficiency in which the gonad is defective. Here too the output of pituitary hormone can be limited by administration of testosterone.

However, a variety of observations indicate that the normal regulation of testicular function is not a simple matter of a depressive action of testosterone on the pituitary. For example, in cases of primary testicular failure more testosterone is required to inhibit the secretion of gonadotrophin than to restore the secondary sex characters. Mottram and Cramer in 1923 found that although radium treatment caused atrophy of the tubular epithelium of the rat testis without apparently harming the interstitial cells, castration cells nevertheless appeared in the hypophysis. This observation indicated that the tubular epithelium might produce a hormone which inhibited the pituitary, and search for it began. Although an aqueous extract which caused disappearance of castration cells in the hypophysis without stimulating the accessory sex organs was prepared and was called 'inhibin' this work has not been confirmed. Albright and his colleagues direct attention to a close analogy between testis, pituitary and ovary-pituitary function. In their view an 'X hormone' produced by the Sertoli cells of the testis takes the place of the estrogen secreted by the analogous granulosa cells of the ovary. The identity of the postulated 'X hormone' is not established although it is likely that the Sertoli cells produce estrogen (p. 1044). Estrogen will inhibit the secretion of gonadotrophin in the male in smaller dosage than testosterone. Nelson and his coworkers find little to favor in the inhibitory concept. Although they agree that the testis produces estrogen (but locate its origin in the Leydig cells) they put forward the hypothesis that the germinal cells inactivate pituitary gonadotrophin during spermatogenesis and so keep down the level of hormone in the blood. They suggest that when spermatogenesis stops, as in radiation damage, cryptorchidism or castration, the gonadotrophins are not removed from the blood, accumulate and are then excreted in the urine in abnormal quantity. Evidence in favor of each theory has been brought forward by its supporters, and at the present time both find adherents.

ASSAY OF ANDROGENS. Androgen may be assayed biologically, using the growth of the comb of the fowl or changes in the accessory sex organs

of mammals, or it may be assayed chemically by measurement of the 17 ketosteroids. In the assays utilizing the fowl, the capon or chick is used and the test material is given intramuscularly or applied directly to the comb. Measurement of the blood or urinary neutral 17 ketosteroids (p. 1040) is becoming more frequently used as an index of androgenic activity but it should be borne in mind that the androgenic potency of a given urine extract will not necessarily parallel 17 ketosteroid concentration.

HYPOGONADISM AND HYPERGONADISM IN THE MALE. Tumors of the testis in young boys may result in the precocious development of the secondary sex characters—growth of hair upon the pubis, in the axillae and over the face, deepening of the voice and enlargement of the penis. These effects are evidently due to hypersecretion of the male hormone, for they tend to subside after excision of the tumor. Hypergonadism with closely similar features occurs as a result of hyperfunctioning of the adrenal cortex (p. 1013). Failure of development of the accessory male sex organs and of the secondary sexual characters, a condition referred to as *hypogonadism* or *eunuchoidism*, is in most cases due primarily to a pituitary disorder. This can be tested by measurement of the FSH excreted in the urine. In other instances of eunuchoidism the testes are the primary site of disease, e.g., destructive new growths, mumps, typhoid fever, syphilis, etc. Here in the postpuberal individual the output of FSH in the urine will be higher than normal. Testicular atrophy occasionally results from prolonged and severe inanition or vitamin B₁ deficiency. Hypofunctioning of the testes may commence at any time during postpuberal life as a result of pituitary disease or of any of the conditions just mentioned. In this latter type of eunuchoidism regressive changes, although usually of mild degree in the accessory organs of sex and in the secondary sex characters may result.

The Prostate Gland

The prostate which surrounds the first inch or so of the urethra is composed of branched tubuloalveolar glands, grouped into about 20 lobules. Its stroma is fibroelastic in nature and contains many bundles of smooth muscle. The alveoli of the glands drain into some 20 ducts which discharge into the urethra. The gland is traversed by the ejaculatory ducts. Within the lumina of some of the alveoli, small concretions known as *corpora amylacea* are found (especially in older men). They are composed of a calcium phosphorus compound similar in chemical structure to apatite (p. 1062).

Glands lying in relation to the wall of the up-

per part of the urethra are present in the female. They are analogous to the male organ and are referred to as the *female prostate*.

The prostate does not appear to have any endocrine function. It secretes small amounts of fluid continuously into the urethra (from 0.5 to 2 cc per hour in man), and much larger amounts during coitus. This occurs before the seminal vesicles discharge their secretion. Both secretions are added to the sperm, of the two, the secretion of the seminal vesicles appears to be of the greater importance for the viability of the spermatozoa, or at any rate for fertilization.

The secretion of prostatic fluid is increased by stimulation of parasympathetic (sacral outflow) and sympathetic nerves (hypogastric).

Prostatic hypertrophy. The cause of prostatic hypertrophy is still a matter for speculation. The theory has been advanced that the production of a male hormone in excess is a factor. It is unquestionable that testosterone stimulates prostatic growth as castration causes prostatic involution. It is improbable, however, that hyperactivity of the testicular interstitial cells is a cause of prostatic enlargement in man, secretion of male hormone tends to decrease rather than to increase with advancing years. It has been suggested that the threshold of the prostatic tissue for the action of testosterone is lowered as age advances to an extent which more than compensates for the diminished production of the male hormone.

It has been mentioned that estrogen is excreted in the urine of the male and can be isolated from testicular tissue, it has also been shown by Zuckerman and Parkes that injections of estrogen into monkeys cause prostatic hypertrophy by fibromuscular overgrowth of the whole prostate together with epithelial stratification and distension of the uterus masculinus. Such effects can be counteracted by injections of male hormones. These facts, taken in conjunction with the observation that the concentration of the male hormone in the urine of elderly men may be reduced whereas the excretion of estrogen remains unchanged, have led some (de Jongh, Laqueur) to the conclusion that prostatic hypertrophy in man is based upon an imbalance between androgen and estrogen—a diminished production of the former, and, in consequence, a relative excess of the latter. In support of this hypothesis de Jongh states that injections of the male hormone in cases of prostatic enlargement prevents further hypertrophy and may actually

cause shrinkage of the organ. Moreover, R. A. Moore and his associates observed that prostatic tissue of the rabbit transplanted into the anterior chamber of the eye showed a greater growth response to estrogen than to male hormone administration. However, observations opposed to this theory can be cited, e.g., the absence of excessive amounts of estrogen in the blood or urine of subjects of prostatic hypertrophy, and the fact that injections of estrogen do not, apparently, aggravate the condition. Moreover, the effect of estrogen is mainly on the stroma, whereas the male hormone stimulates the epithelial element which is chiefly affected in hypertrophy of the prostate. The whole question of the causative factors in prostatic hypertrophy is rife with speculation and beset with contradictory observations and opinions. Established facts are few and difficult to obtain.

The epithelial cells of a prostatic adenocarcinoma are dependent for their growth and activity upon the male hormone, as is the normal epithelium of the prostate. It is upon this basis that castration has been employed in the treatment of prostatic cancer, the malignant growth, in many cases, undergoing regression after operation. Since androgen activity is antagonized or neutralized by estrogens, inhibition of the cancerous growth can also be induced by the administration of estrogens such as stilbestrol.

The hormonal treatment of male sex disorders. Although the testis hormone, in accordance with the principles of hormone action in general, does not stimulate the interstitial cells of the testes, it provides the perfect substitution therapy in cases of underdevelopment or regression of the accessory male sex organs. Methyltestosterone, testosterone cyclopentylpropionate or testosterone pellets may all be used.

The gonadotrophic principle derived from pregnancy urine (p. 1092) has been employed to stimulate spermatogenesis in an undeveloped testis or to restore the normal spermatogenic function which had been suppressed as a result of disease. Sterility in man is said to have been cured by this means, spermatozoa which before treatment were few and nonmotile have, according to report, been increased in number and rendered actively motile after a series of injections of the anterior pituitary like hormone. Notable success has followed the use of the gonadotrophic hormone of pregnancy urine in cryptorchidism, descent of the testes being induced. It has also been employed in various types of hypogonadism. The gonado-

trophic principle of the pituitary itself would be expected to give the best results but so far a reliable commercial preparation of this hormone has not been available.

Erection and Ejaculation

In order to carry to completion the sexual function of the male, semen must be deposited in the female genital tract. For this purpose the flaccid penis is converted into a rigid intromittent organ and at the orgasm expulsion of semen occurs through it. Thus two phases can be distinguished: erection and ejaculation. Both provide good examples of sympathetic-parasympathetic interaction although, since the nerve plexuses involved contain both sympathetic and parasympathetic fibers, it is difficult to study each system in isolation.

Erection is brought about by a vascular engorgement of the penis, produced by dilation of the arteries which supply the spongelike erectile tissue in the corpora cavernosa penis and the corpus cavernosum urethrae. This reaction was observed nearly a hundred years ago by Eckhard (1863) who found that electrical stimulation of the visceral rami of the sacral nerves in the dog induced penile erection via the vasodilator action. He called these fibers the "nervi erigentes" and the name has been retained. However, the integrity of the nervi erigentes is not essential for erection; for in the dog and cat destruction of the origin of the nervi erigentes in the spinal cord does not prevent erection following suitable stimuli such as manipulation of the glans or psychic stimulation. In the latter case erection does not occur when the lumbar part of the spinal cord is destroyed. It would seem that, in addition to the action of the parasympathetic nervi erigentes, sympathetic fibers arising in the lumbar cord are involved in the erectile process, although sympathetic stimulation by its vasoconstrictor effect may interfere with erection. Eckhard also found that mechanical stimulation of the glans would bring about erection only if the pudendal nerve was intact. Thus the pudendal nerve is afferent to glans stimulation. Efferent fibers from the hypogastric plexus also pass in the pudendal nerve to exert a vasoconstrictor action on the penis.

Ejaculation of semen is a frequent accompaniment of erection although the emission of semen can occur through a flaccid penis. In man stimulation of the pelvic sympathetic nerves produces discharge of semen from the ejaculating ducts due to seminal vesicle and prostatic contraction.

Following lumbar sympathectomy semen is no longer discharged from the urethra. Ejaculation still occurs but the semen may enter the bladder instead of the urethra because of nonclosure of the internal vesical sphincter. During physiological ejaculation the smooth muscle of the genital system is probably constricted by both parasympathetic and sympathetic impulses propagated under the control of the spinal cord. Contraction of the voluntary muscles such as the bulbospongiosus and ischio cavernosus muscles also occurs at this time.

Sexual Behavior

The gonadal hormones in addition to their actions upon the reproductive system act upon the nervous system to elicit characteristic patterns of behavior—sexual behavior. It may perhaps be taken for granted that the sexual behavior is in variably associated with fully functional gonads. Such may be deduced from the fact that the term estrous cycle has a behavioral basis. However, in the sheep one or more estrous cycles—*silent heats*—may pass at the commencement of the breeding season before the occurrence of overt estrous behavior. In the monkey ovulation may not occur during the summer although the menstrual cycles continue. Sexual activity does not appear to be diminished.

There is no question that the removal of the gonads may depress sexual activity although to an extent which varies between the sexes and from one species to another. In the female rat sexual activity is abolished whereas in the female rabbit coitus may occasionally take place. In the ovariectomized chimpanzee there is little sign of desire for intercourse but it is said that ovariectomized women may show as much erotic behavior after the operation as before. With regard to the male primate castration often fails to diminish the capacity to mate (chimpanzee) or to abolish the orgasm (man).

Full sexual activity in the ovariectomized or castrated individual may be restored by treatment with the appropriate sex hormones. Further it is possible to evoke components of the pattern of sexual behavior of the opposite sex by administration of androgen e.g. to a spayed female and *vice versa*. Basically overt sexual behavior does not appear to depend upon a learned response but is due to a fundamental action of the sex hormones upon the nervous system. Young has shown that in guinea pigs the performance of the male is improved by exper-

ence, the sexual activity of males reared in isolation is inferior to that of animals reared in a group and may be permanently impaired.)

The gonadal hormones might produce their behavioral actions either by an effect on the peripheral receptors or by a direct action on some integrating center in the central nervous system. In the former case the hormone could act by sensitizing the genitalia to excitation but this possibility has been eliminated by the finding that removal or denervation of the genitalia does not inhibit sexual behavior or reduce sexual aggression.

The second possibility—that of a direct action of the gonadal hormones upon the central nervous system—has received detailed examination. It is now clear that normal estrous behavior can continue in the cat, rabbit, guinea pig and rat following removal of the cerebral cortex although none appears in the spinal animal. It may therefore be presumed that some subcortical but supra-spinal neural structure is involved in the behavioral mechanism. Dempsey and Bloch in 1939 studied the guinea pig and found that a transection of the brain which passed through the rostral end of the mammillary bodies did not abolish estrous reflexes but that transection posterior to the mammillary bodies did cause loss of these reflexes. This observation implies that some area in the region of the hypothalamus may be concerned in the production of sexual behavior in the guinea pig and since that time evidence has accrued which indicates that the hypothalamus itself is of importance. Among the salient observations we may note that (a) sexual behavior may be abolished by hypothalamic lesions, (b) reproducible electrical activity has been recorded in the hypothalamus following artificial stimulation of the vagina of the cat and (c) the application of estrogen to the posterior hypothalamus of the spayed cat has been found to induce full and typical sexual behavior at a time when no effects of the estrogen upon the reproductive organs could be found. The insertion of similar amounts of estrogen into the cerebellum, preoptic region, caudate nucleus, thalamus or amygdaloid nucleus did not evoke sexual behavior in similar circumstances.

In summary it appears that some integrating mechanism exists in the upper midbrain or hypothalamus which is sensitive to the blood concentration of gonadal hormones. If these hormones are present in amounts above a certain threshold level then specific sensory stimuli (e.g. visual, auditory, olfactory) normally derived from a possible mate act through this mechanism to excite reflexly the pattern of sexual behavior typical of the species. In the human it seems that

this basic neural mechanism has become largely dominated by cortical factors, so that learning and conditioning play an increasingly important role. The continuance of active sexual behavior after castration in the adult human may well be dependent on this latter fact.

The Thymus

Structure The thymus arises from the third brachial cleft (and sometimes the fourth) on either side, each anlage going to form one of the lobes of the thymus. Each thymic lobe is composed of a number of lobules in which an outer portion or *cortex* and a central portion or *medulla* may be distinguished. The *cortex* resembles lymphoid tissue, being constituted of masses of small round cells—*thymocytes*—identical in appearance with small lymphocytes. The epithelial element of the embryonic structure is almost entirely replaced during development by the ingrowth of these lymphoid cells from the surrounding mesenchyma. A small number of elongated reticular cells are seen scattered among the lymphoid elements. The *medulla* also contains lymphocytes but in fewer numbers, the reticular cells are thus shown up more prominently and are seen to form a definite reticular stroma. Scattered throughout the medulla are round or oval elements from 30 to 100 microns in diameter known as *Hassall's corpuscles*. These bodies, which are the remnants of the original epithelial elements, are composed of cells arranged concentrically, they stain with acid dyes and therefore stand out conspicuously against the surrounding basophilic substance.

Possible functions The thymus of the infant is of relatively large size but during later childhood its weight in relation to body weight gradually decreases, little change in its absolute weight (25 to 40 grams) occurs, after the age of puberty a definite involutionary process commences. Although the involutionary changes, which consist of a reduction in the number of lymphocytes and reticular cells and their replacement by fat, are most marked during adolescence, they continue slowly throughout the rest of life. The corpuscles of Hassall disappear more slowly than the other elements.

It is admitted by most observers that the thymus serves a lymphopoietic function. Beyond this, little is definitely known concerning its physiological role. It is enlarged in exophthalmic goiter, myasthenia gravis, adrenal insufficiency and in certain leukemic states. Thymic enlargement has also been considered to be a feature of the so called *status thymicolymphaticus*, a condition believed to consist of hypoplasia of the vascular system, a general increase in lymphoid tissue throughout the body, and a tendency to fatal syncope. In infants and young children who have died suddenly

as a result of some trifling shock or during anesthesia have been thought to be subjects of this disease, it has been thought that enlargement of the thymus was in some way responsible. An investigation earned out in 1931, by Turnbull and Young, for the Medical Research Committee of Great Britain failed to substantiate this belief. In the post mortem examination of a number of children's bodies no relationship was found between the size of the thymus and vascular hypoplasia to the amount of lymphoid tissue in other parts of the body. In subjects dying suddenly as a result of shock or during anesthesia the thymus was not larger than in subjects dying from other causes. These investigators conclude that there is "no evidence that so called status thymicolymphaticus has any existence as a pathological entity." The possibility has been suggested that such cases of sudden death in infants are due to failure in function of the adrenal cortex (p. 1043).

The great body of experimental work which has been carried out in the past in efforts to elucidate the functions of the thymus has yielded little evidence which would enable it to be classed definitely among the glands of internal secretion. There is certainly no feature of its minute structure which suggests a glandular function. Numerous investigators, nevertheless, have claimed that their findings pointed to the thymus as playing an endocrine role. The problem has been studied both by the use of extracts of thymic tissue and by observing the effects of extirpation of the organ. Among the functions claimed for the thymus as a result of these two lines of investigation are the regulation of calcium metabolism and the control of skeletal growth. Defective mineralization of the bones has been described following thymectomy; others believe that this operation results in dwarfing. Gudernatsch found that feeding thymus tissue to tadpoles stimulated their growth but delayed metamorphosis. Thymectomy in pullets and pigeons is said to result in their laying eggs with uncalcified shells.

Much of the earlier work on the thymus is very difficult to appraise, owing to the indecisive nature of the data or to the conflict between the results obtained by different workers in the field.

Andersen has made the interesting observation that rats exercised to the point of exhaustion show atrophy of the thymus and hypertrophy of the adrenal cortex. Selye has described similar changes following a variety of injurious agencies as part of what he has termed the "alarm reaction."

The Pineal Body or Epiphysis

Origin and structure This is a small glandlike structure (about 10 mm. long in man) somewhat

resembling a pine cone (pinex) in shape, situated just beneath the splenium of the corpus callosum and resting in the groove between the superior colliculi. The pineal arises as a diverticulum of the roof of the third ventricle. The cavity of the original pouch eventually disappears, the fully developed gland being composed of a solid mass of cells. The histological features of the pineal are very diverse, the picture varying from species to species and with age. In general however, it may be said to have a pseudoalveolar structure, the cells being arranged in masses or lobules surrounded by a highly vascular connective tissue.

Involuntary changes are said to commence in the human pineal body about the seventh year. In children past the age of seven laminated bodies composed of phosphates and carbonates of calcium and magnesium—the so called "brain sand"—make their appearance.

The functions of the pineal body are quite unknown. Its structure has suggested an endocrine function but there is really little definite evidence from which such a conclusion may be drawn. It may be merely vestigial.

SECTION EIGHT

THE NERVOUS SYSTEM

61

INTRODUCTORY: THE PHYSIOLOGICAL PROPERTIES OF NERVE

The Structure of Nervous Tissue

The structural unit of the nervous system is the *nerve cell* or *neuron*. Other elements—*neuroglial cells*—lying among the nerve cells provide a supporting framework.

The neuroglial cells possess numerous branching processes which interlace with one another to form a dense felt work between the neurons (fig 61 1). These interstitial cells of the central nervous system are present in both the gray and white matter, they vary greatly in size and shape and their processes in number and arrangement. Upon a basis of these differences they have been classified into three main types—*astrocytes*, *microglia* and *oligodendroglia*. The microglia are considered by most observers to be reticuloendothelial elements (ch 11). They are migratory and phagocytic, wandering into the nervous tissue from the meninges along the blood vessels. In inflammatory processes involving the central nervous system these cells are increased in number. The oligodendroglia are believed to play a part in the formation of the myelin material which sheathes the nerve fibers. Though neurons do not multiply in the adult body and when destroyed are not replaced, certain neuroglial cells possess the power of active proliferation. This may occur to a marked degree in pathological processes. The recent observations by Tasaki that neuroglial cells grown in tissue culture produce slow action potentials suggests caution in assuming that functions of these are restricted to mechanical and metabolic actions.

The Neuron

The neuron consists of a *body* or *soma*, and two types of process—the *dendrite* and the *axon* (axis cylinder process, fig 61 2). In vertebrates, the bodies of the nerve cells lie within the gray matter

of the central nervous system or in outlying ganglia e.g., posterior spinal root, cranial or sympathetic ganglia. The white matter of the brain and spinal cord and of the peripheral nerves is composed of bundles of nerve fibers. The core of each nerve fiber is formed by a process of a nerve cell, and many of them are surrounded by a sheath of myelin which gives them a white appearance. The gray matter receives a rich blood supply from the vessels of the pia mater (1000 mm/mm² of capillaries), the blood supply to the white substance is much less profuse (300 mm/mm² of capillaries).

There are a number of different types of nerve cell, those in which axon and dendrite arise by a common stem are called *unipolar*, and those in which the axon and the dendrite or dendrites spring from opposite or at least different parts of

FIG 61 1 Three types of neuroglial cell A, oligodendroglia, B, astrocyte, C, microglia

FIG 612 Showing different parts of the neuron

the soma are called *bipolar* or *multipolar*. The cell bodies or somata are of various sizes and forms—stellate, round, pyramidal, fusiform, etc.

After fixation and staining by special techniques, various structures are seen in the cytoplasm or *perikaryon* of the nerve cell body, (a) *neurofibrils*, (b) *Nissl bodies* or *tigroid substance*, (c) *Golgi apparatus* and (d) *mitochondria*. The neurofibrils appear as fine filaments which stream through the cytoplasm from dendrites to axon (fig 613), they enter the latter process and extend to its terminations. The Nissl bodies are granular masses stainable with basic dyes. They give a striped or tigroid appearance to the cell. They are absent from the region of origin of the axon and vary in size and number with the state of the neuron, they undergo disintegration (*chromatolysis*) in a fatigued or injured cell or in one whose axon has been sectioned (p 1118). The internal reticular apparatus of Golgi is a coarse network seen within the cells when special methods—e.g., impregnation with silver chromate—are employed which leave the Nissl bodies and the neurofibrils invisible. It is a debatable question whether the Nissl substance is present in the living cell in the particulate form observed or whether the latter represents the precipitation from colloidal solution of some material—probably a nucleoprotein—by the methods of fixation employed.

The mitochondria are minute bodies scattered through the cytoplasm. They take the form of short rods, filaments or beads, they are not peculiar to nerve cells, and appear to be centers of metabolic activity. The surfaces of most cell bodies are covered by a fine network—the *superficial reticulum of Golgi*. The nucleus of the nerve cell contains one and sometimes two nucleoli but, as a rule, no centrosome. The nucleus stains poorly, as a rule, due apparently to its paucity in chromatin. The absence of a centrosome indicates

that the highly specialized nerve cell has lost its power of division. Nerve cells once destroyed are replaced merely by neuroglia.

The arrangement in series of neurons in form conducting pathways of two or more links and of variable lengths is effected by the contact (but not union) of the axon terminal of one nerve cell with the body or dendritic process of another. This functional union is called a *synapse* (ch 63).

Though the nerve cell frequently possesses more than one dendrite the axon is single. The axon may be long and contribute to one of the tracts of the central nervous system forming the white matter, or terminate as a peripheral nerve fiber. Such cells are referred to as *Golgi I type*. In the *Golgi II type* cell, the axon is short and ends within the gray matter by making contact with another neuron. The axon arises from a small elevation on the surface of the cell body—the *axon hillock*. It may give off short collateral branches or may run as an unbranched fiber, not dividing until it has reached its destination. The dendrite is the receptive process of the neuron, the axon the discharging process, i.e., the former transmits the impulse toward,

FIG 613 Showing neurofibrils in a cell from the anterior gray column of the human spinal cord. az, axon; ia, interfibrillar spaces; n, nucleus; x, neurofibrils passing from one dendrite to another; y, neurofibrils passing through the body of the cell (from Ranson, after Bethe and Heidenhain).

the latter away from the cell body. Nerve fibers which carry impulses to the central nervous system are termed *afferent*, those conveying impulses from the central nervous system to the periphery are called *efferent*. Purely sensory (afferent) nerves are therefore composed, strictly speaking, of dendrites, and purely motor (efferent) nerves of axons. A mixed nerve contains fibers of both types. This unidirectional conduction is due to the properties of synapses for nerve fibers can be made to conduct in either direction.

Structure of the Nerve Fiber

The axons and dendrites so long as they remain within the gray matter are protoplasmic extensions of the cell body, but upon entering the white matter they become invested by a layer of lipid material called *myelin*. This covering is known as the *myelin sheath* (fig. 61-2). In the peripheral nerves, but not in the central nervous system, the myelin sheath is enclosed in turn by a nucleated membrane, the *neurilemma* or *sheath of Schwann*. The myelin sheath is interrupted at regular intervals at the nodes of Ranvier where the neurilemma dips in to the axon. In peripheral nerves, each internode is invested by a single Schwann cell.

Toward its termination the nerve fiber loses its myelin covering, being then clothed simply by the neurilemma; the fiber may terminate as a naked axis cylinder or become enclosed within some form of *specialized end organ* (ch. 62). The processes arising from sympathetic nerve cells (postganglionic fibers) are devoid of a myelin covering. They are invested simply by a sheath of Schwann and are therefore called *amyelinated* or *nonmedullated* fibers. In invertebrates, large (giant) nonmedullated fibers are found sometimes 500 μ to 10 μ in diameter. Myelinated fibers conduct much faster than nonmyelinated fibers of the same diameter. There is a relationship between the diameter of nerve fibers and the speed at which they conduct nerve impulses (p. 1125).

Myelination of Fiber Tracts in the Central Nervous System

The nerve fibers in the various conducting pathways receive their myelin sheaths at different ages and it is generally believed that the myelination of a given tract and the time at which it commences to function coincide. The sensory tracts become myelinated first, those of the posterior columns of the spinal cord between the fourth and fifth months of fetal life (human). The spinocerebellar tracts are myelinated later and the motor paths, e.g., corticospinal (pyramidal) tracts do not commence to receive their myelin sheaths until the second month of life and are not completely myelinated until about the second year, or about the time when the child has learned to walk. The

fibers of association paths, for the most part, myelinate at still later dates.

Neurotropism

The nerve fiber grows by extrusion of filopodia much as the protoplasm of an amoeba is thrust out in filiform and lamellar pseudopodia. The guiding of growth along a particular orientation has received much attention in the last half century. This, called *Neurotropism*, is found to be closely bound up with the structure of the medium in which growth occurs, for an axon will not grow into a structureless fluid but will follow the submicroscopic structure in gelled protein or creep along any surface of separation of two suitable components in the medium. *Contact guidance* appears to direct the fiber on its way; its immediate surroundings determine the direction of the developing filament and distant action suggested as *galvanotropism* (following electrical gradients) or *chemotropism* (following chemical gradients) do not appear to be very important factors except in so far as they may orientate the matrix. This partly explains the great importance of the tube of Schwann cells in regeneration, but some kind of symphysis also exists between Schwann cells and the fibers which they surround. Many problems of development in the central nervous system remain unanswered. In the central nervous system the orientation of growth is orderly and this for contact guidance requires order in the medium through which it is taking place. In tissue culture, fibers will follow the strains imposed on a blood clot since these produce structural orientation of its fibrin filaments. The relative movement of parts which occurs in development leaves orientated strains and structures in the ground substance and this may be an important factor in determining the direction of nerve outgrowth.

Nerve Degeneration and Regeneration

When a nerve fiber is divided, the portion separated from the body of the cell, undergoes degenerative changes. The degenerative process does not start first at the point of section and progress to the periphery but all parts of the nerve fiber even to its finest terminals are involved virtually simultaneously. The first change is noted in the neurofibrils which become tortuous and show irregular thickenings. The myelin sheath next becomes swollen and breaks up into small ovoid segments (fig. 61-4). Later decomposition of the myelin occurs, droplets of kaphalin and lecithin

FIG 614 Degenerating nerve stained with osmic acid. A shows appearance of distal segment of nerve fiber 2 days after section; note large masses of myelin derived from medullary sheath. B, 5 days after section: smaller myelin particles together with droplets of fatty acids and fragmented neurofibrils. C, retrograde degeneration in cell body: disintegration of Nissl bodies.

then appear, derivatives of the latter—choline, glycerophosphoric acid and unsaturated fatty acids—can be detected. There is a progressive and rather rapid fall in the acetylcholine (ch 71), cholinesterase and thiamine contents of the degenerating nerve. The fatty acids are responsible for the brown staining of the degenerated nerve when treated with osmic acid. The nuclei of the neurilemma proliferate, and the cytoplasm becomes swollen and vacuolated. The neurofibrils undergo fragmentation; they and the protoplasm surrounding them finally undergo complete disintegration, the debris intermingling with the material of the disorganized myelin sheath. Subsequently the degenerated materials disappear, and all that remains of the nerve fiber is the empty neurilemma tube. The foregoing changes were first observed by Waller and are spoken of as *Wallerian degeneration*. Alterations which were not recognized by Waller also occur in the neuron on the proximal side of the section (*retrograde degeneration*). The nerve fiber as far centrally as the first node of Ranvier shows changes similar in nature to those just described. In the cell body itself, swelling of the cytoplasm and nucleus occurs and the Nissl granules undergo disintegration (*chromatolysis*). Atrophy of the cell body may ultimately result.

Regeneration. This occurs in peripheral nerve

fibers, but not in those of the central nervous system, the presence of a neurilemma being essential for the process. Section of the sensory root of the trigeminal nerve, for example, for the relief of severe neuralgia of the face, is not followed by regeneration of the fibers within the brain. Nor does regeneration of the optic nerve, whose fibers do not possess neurilemma sheaths, occur.

Regeneration is accomplished by a downgrowth of the neurofibrils from the proximal segment of the cut nerve. These enter the empty neurilemma sheath of the distal segment and in time traverse its entire length. The rate of growth in man varies from 1.0 to 4.5 mm. per day; it is influenced by many factors, namely, the nerve involved, whether there is complete severance of the nerve (*neurotmesis*), the distance separating the sections, and whether the axons alone are crushed, the supporting structure remaining intact (*axonotmesis*). The cells of the neurilemma form a protoplasmic matrix for the sprouting neurofibrils. The neurilemma of the lower segment grows upwards, and if the gap is not too long joins that of the upper segment which has formed around the developing axis cylinder. The myelin sheath is developed some time later. The young axis cylinders may traverse the tissues for relatively long distances in order to enter the neurilemma of the lower segment. The force responsible for this remarkable phenomenon (*neurotropism*) is unknown. The attraction may be due to the liberation of chemical substances by the proliferating neurilemma cells of the lower segment. If the gap separating the two segments is wide and occupied by scar tissue, an effectual block may be offered to the regenerating fibers, these nevertheless continue to grow in a tangled, curled fashion and may produce a localized mass of tissue composed of nerve fibers embedded in connective tissue (*neuroma*). In those cases of nerve injury in which, as a result of pressure or crushing the axis cylinder is interrupted without division of the neurilemma, the conditions for regeneration are the most favorable.

The remarkable rapidity of regeneration of preganglionic sympathetic fibers has been demonstrated by Ilamovici and Hodes. In a three-stage operation upon cats large sections of the sympathetic chains below their cervical portions were excised. Stimulation of the cephalic end of a cervical sympathetic stump as early as 54 days after the last stage of the operation caused pupillary dilation and retraction of the nictitating membrane.

The regenerating fibers of one nerve will grow into the sheath of the lower segment of another, though less readily than into its own sheath, and even the fibrils of a sensory nerve will grow into the distal segment of a motor nerve or vice versa. The central stump of one nerve will not, however, grow into the central stump of another. The proximal end of the hypoglossal or spinal accessory, for example, has on many occasions been anastomosed to the distal end of a paralyzed facial nerve with a successful functional result. Bal-ance and Duel, experimenting with cats, anastomosed the central end of the hypoglossal to the peripheral cut end of the cervical sympathetic, and reported that the normal pupillary reactions were restored. Restoration of function does not follow the union of a motor with a sensory nerve, nor of a cholinergic with an adrenergic nerve (ch 71)

It has been shown by Tello in animals and by Duel in man that when a nerve has been severed a much better functional result is obtained if from 2 to 3 weeks are allowed to elapse before the divided nerve is sutured. The reason for this is that the degenerated material in the distal segment has had time to be cleared away, thus, an unobstructed neurilemma tube is left for the downward growth of the neurofibrils of the upper segment. Otherwise, apparently, some of the neurofibrils upon meeting the degenerated debris are diverted from their course.

Degeneration of the facial nerve in the facial canal as a result of middle ear disease (Bell's palsy ch 1203) *trismus*, etc., has been treated with outstanding success by Duel. The affected portion of the nerve is excised and a graft constituted of a section of the anterior femoral cutaneous nerve is used to fill the gap. For the reason just given the latter nerve is sectioned and left in place for 2 or 3 weeks before it is employed in the grafting operation.

The Physiological Properties of the Nerve Fiber

EXCITABILITY AND CONDUCTIVITY

The nerve fiber may be stimulated electrically, thermally, chemically or mechanically. Any one of these types of stimulus causes a change in the nerve at the point of stimulation which may be termed the *local excitatory state*. If this attains a certain value a wave of excitation is transmitted along the nerve fiber. The propagated disturbance is referred to as the *nerve impulse*, and its passage from point to point along the fiber as *conduction*.

THE CHARACTERS OF A STIMULUS

A stimulus may be defined as any change in the environment of a tissue which causes it to react. In experimental work the electric current is usually employed as the stimulus on account of its convenience and the accuracy with which it can be measured. It also leaves the tissue undamaged. A stimulus produces a local change of state in the nerve, if this is of sufficient strength to set up propagated activity which spreads over the cell surface, it is said to be adequate. For this to occur, a stimulus must reach a certain (a) strength, (b) duration, (c) rate of change.

Intensity or strength The least stimulus which excites is said to have threshold intensity. Stimuli of less strength are subthreshold (subliminal). When an electrical stimulus is used, the intensity is the current sent through the tissues and under many conditions, as resistance is substantially constant, it may also be measured in terms of voltage.

The subthreshold stimulus produces a local change which persists for a few milliseconds after the stimulus, and if a second sub-threshold stimulus occurs during this time, a nerve impulse may be set up. The local excitatory state is accompanied by a local electrical change which can be recorded close to the stimulating electrodes (fig 61 5).

Duration If a constant current is passed through medullated nerve (or muscle) excitation occurs when the circuit is made or broken, but in order to excite at make, the current must flow for a certain period of time to bring about the local changes that culminate in a nerve impulse. For brief current pulses, there is a reciprocal relationship between strength of current and duration of its flow. This can be determined as a strength/duration curve (fig 61 6). The strength can be varied with a simple potentiometer and the duration determined by a rheotome which allows current to flow through the tissue for a brief period.

The strength/duration curve shows that for brief current pulses the strength must be very great to excite. If a brief, ineffective pulse is followed by another in the reverse direction any ionic changes produced by the first are reversed by the second. As a result, alternating currents of high frequency may be passed through a tissue without producing sufficient movement of ions to culminate in excitation even though they are sufficiently strong to produce considerable heating of the tissue. This is made use of in a number of ways as *diathermy*. Currents from a diathermy

FIG 615 Electrical changes at stimulating electrode produced by shocks with relative strengths successively from above 1.00 (upper 6 curves), 0.96, 0.85, 0.71, 0.57, 0.43, 0.21, -0.21, -0.43, -0.57, -0.71, -1.00. The ordinate scale gives the potential as a fraction of the propagated spike, which was about 40 mV in amplitude. The 0.96 curve is thicker than the others, because the local response had begun to fluctuate very slightly at this strength. The width of the line indicates the extent of fluctuation. (Inset) Responses produced by shocks with strengths successively from above, 1.00 (upper 5 curves), 0.96, 0.85, 0.71, 0.57, obtained from curves in upper figure by subtracting anodic changes from corresponding cathodic curves. Ordinate as above. (From A. L. Hodgkin, *Proc Roy Soc Lond* (1938-39), 126: 87-121)

generator producing alternating current (a million or more cycles per second) may be passed between electrodes on the two hands, and body temperature can be raised using the internal resistance of the tissue between the electrodes to evolve heat as it does in the radiant in an electric stove. Diathermy currents are also used in surgery to produce coagulation of bleeding points and to cut soft tissues, when a small electrode is drawn through the tissue the local release of steam within the cells gives a clean heat-sealed cut. It has been widely employed in brain surgery.

The period throughout which there is a reciprocal relationship between strength of current and the duration of its flow is called the *serviceable* or *utilization time* (*temps utile*). It is measured in thousandths of a second. When, for instance, a current of a certain voltage and having a duration

of say 3 milliseconds (msec) just fails to excite the tissue, then either increasing the voltage or prolonging the duration of the current causes a response. Or, if a current of a certain voltage and duration is just capable of exciting the tissue, reducing either of these factors renders the stimulus ineffective. The length of the utilization time varies in different tissues, but for the frog's striated muscle it is about 50 msec. Beyond the utilization period the relationship between intensity and duration no longer holds. Therefore when the current is of long duration its effectiveness depends entirely upon its intensity. The intensity of a current which when allowed to flow for an indefinitely long period is just capable of exciting the tissue (intensity threshold) is called the *rheobase*. The relationship between strength and duration of current is shown in figure 616.

CHRONAXIE The strength/duration curves from various tissues are of similar shape but differ in their time-scale, and it is convenient to be able to define this time-scale for any tissue. The *chronaxie* is the measure normally employed and is obtained by finding the minimal current which will excite if of long duration, the *rheobase*, next finding the time which a stimulus twice this strength must last to be effective. The factor 2 is arbitrarily chosen by convention and gives a convenient point at about the middle of the strength/duration curve. The *chronaxie* may therefore be briefly defined as the shortest duration of a current necessary for excitation when its strength is twice the *rheobase*.

Determinations of chronaxie may be carried out by the use of (a) a steady current which by means of a special type of rheotome is allowed to flow through the tissue for a very brief accurately

FIG 616 Strength duration curve, chron, *chronaxie*

measured period, (b) *condenser discharges*. The duration of a condenser discharge is proportional to the capacity (C) of the condenser, provided the resistance (R) in the discharge circuit remains constant. By charging condensers of different capacities (measured in farads) to different potentials, currents of any desired duration or voltage can be employed. In order to render any variation in the resistance of different tissues negligible a high resistance (15 000 to 20 000 ohms) is introduced into the discharge circuit. In determining the chronaxie by means of condenser discharges the current of minimal voltage required for excitation is first determined, a very high capacity, i.e., one with a long discharge, being used. The threshold voltage (rheobase) is then doubled and the lowest capacity is found (shortest duration of discharge) which will produce a response at the higher voltage. The result is obtained in microfarads. Since the time, or chronaxie, is proportional to the product of the capacity and the resistance in the discharge circuit, the result can be converted into seconds by the following formula

$$\text{Chronaxie} = C \text{ (farads)} \times R \text{ (ohms)} \times K$$

$$(K \approx 0.37)$$

Rapidly reacting tissues have a shorter chronaxie than the more slowly acting. The chronaxies of smooth muscle and its nerves are longer than those of skeletal muscle and somatic nerves. The tissues of cold blooded animals have, in general, longer chronaxies than the tissues of higher forms. Flexor muscles have shorter chronaxies than extensors and the chronaxies of the more rapidly acting white muscles are shorter than those of the red. Nerve fibers of larger diameter and of more rapid conduction respond to shorter durations of current than do the thinner and slower fibers. The chronaxies of sensory nerves are in general about the same as those of the motor nerves of the same size. The chronaxie of the ventricular muscle, contrary to expectation, is shortened by vagus stimulation, or by drugs such as acetylcholine which slow the cardiac rate, and lengthened by accelerator stimulation or by drugs, e.g., atropine and adrenaline, which cause acceleration. The chronaxie of the junctional tissues is about three times longer than that of auricular or ventricular muscle. The chronaxie of the gastric muscle is also shortened by vagal stimulation. The chronaxie is lengthened by cold and shortened by a rise in temperature. Stretching cardiac or smooth muscle reduces the chronaxie, and that of skeletal muscle is lengthened by fatigue and shortened by adrenaline. The utilization time (*temps utile*) of a tissue varies with its chro-

naxie, being about 10 times the value of the latter. Thus the chronaxie of the frog's sciatic nerve is 0.3 msec, the rheobase is reached in 3 msec.

Chronaxie is altered by temperature, by ionic changes, and by many substances of physiological activity, but is stable if conditions are kept constant.

For the motor fibers of the frog's sciatic nerve, it is about 0.3 msec at 17°C, frog's striated muscle 3 msec, frog's cardiac muscle 20 to 30 msec, frog's stomach 100 msec. In mammals, chronaxie of large nerve fibers may be as short as 0.1 msec.

Electrode size. The chronaxie depends upon the rapidity with which electrical charge can diffuse away from the site excited. This will be much more rapid if the site is small than when it is large. Thus the chronaxie of muscle is shorter when measured by electrodes ten microns in diameter than when large electrodes are used. With medullated nerve fibers stimulation occurs at the nodes of Ranvier, the myelin sheath restricts the current flow to these, which form in effect small electrode sites of anatomically fixed size and the size of the external electrode makes little difference.

Following investigations of this by Watts and by Rushton, chronaxie measurements are usually taken with large electrodes to give a figure related to the tissue constants and independent of the electrode used.

Chronaxies in the human subject have been investigated under various physiological conditions and in many pathological states by Bourguignon and others. Condenser discharges are employed, an indifferent electrode being placed upon the skin over the sternum and the stimulating electrode as the cathode upon the skin overlying the nerve or muscle to be investigated. The chronaxies in the newborn child are about 10 times longer than those of the adult. The longer chronaxies are in agreement with the much slower movements of the infant. In diseases of the central nervous system all muscles which are the seat of paralysis show lengthened chronaxies and in progressive nervous disease those groups of muscles of similar chronaxies are usually attacked more or less simultaneously.

Reaction of Degeneration

The reaction of degeneration is a phenomenon commonly seen following nerve injuries in man and gives a valuable index of the abnormalities which are present. A motor nerve may be stimulated through the skin by either the faradic (interrupted) or the galvanic (constant) current. The muscle contracts so long as the faradic current

flows but only during the make (closure) or break (opening) of the galvanic current, for a given strength of current closure shocks are more effective than opening shocks. In testing the reactions one electrode is placed upon the skin of some indistant part of the body (*indifferent electrode*) and another smaller electrode (*stimulating electrode*) is placed upon the skin overlying the nerve trunk or muscle which it is desired to stimulate. In the latter instance the nerve terminals within the muscle are stimulated not the muscle fibers themselves. The stimulating electrode is applied over that part of the muscle which gives a response with the least strength of current, this is spoken of as the *motor point* and corresponds to the point of entrance into the muscle of the motor nerve. When the stimulating electrode is attached to the positive pole of the battery it is called the *anode*. The current enters the muscle by this electrode and leaves the body by the indifferent electrode which is called the *cathode*. When the galvanic current is reversed, the stimulating electrode becomes the cathode and the indifferent electrode the anode. Normally the least strength of current is required when the cathode overlies the muscle and the circuit is closed. The response which follows such a shock is called the *cathodal closing contraction* (abbreviated CCC). The next most easily elicited response is the *anodal closing contraction* (ACC), i.e., when the stimulating electrode is in the anode and the current is closed. The *anodal opening contraction* (AOC) is less easily evoked than the last, and the *cathodal opening contraction* (COC) requires the strongest current of all. The four reactions in the order of the strength of current required for their elicitation may be expressed thus

$$CCC < ACC < AOC < COC$$

The normal relationship between current strength and these responses is also shown in table 611.

The investigation of these reactions is of considerable value in the detection of degeneration of a motor nerve and in the diagnosis of a lower from an 'upper neuron' lesion (ch. 65). Lengthening of the chronaxie of a nerve occurs during the earlier stages of its degeneration, it therefore fails to respond to the brief shocks of faradic stimulation but a sluggish contraction of the muscle follows

stimulation with the galvanic current. Later the nerve becomes quite incapable of being excited by either the faradic or the galvanic current. When the nerve terminals have degenerated the chronaxie of the muscle is lengthened and the faradic current applied directly to the muscle causes no response, the muscle responds, however, though in an abnormal manner, to the galvanic current, the fibers being *directly* stimulated. The response of the muscle shows the following features: (a) Sluggishness of contraction and relaxation. (b) The response is elicited with a weaker current than normally, i.e., the muscle is hyperexcitable to the galvanic current. (c) The anodal closing contraction (ACC) may often be elicited more readily, i.e., with a weaker current, than the cathodal closing contraction (CCC). Thus, $ACC < CCC$.

These changes in the electrical responses of nerve and muscle, namely, loss of excitability of nerve to faradic and galvanic stimulation, failure of the muscle to respond to faradic stimulation and the abnormalities of the reaction to galvanic stimulation just described constitute the *complete reaction of degeneration* (CRD). When the nerve is still capable of being excited by galvanic but not by faradic stimulation but the muscle responds weakly or not at all to the faradic current, the reaction of degeneration is said to be *incomplete—partial reaction of degeneration* (PRD).

Electrotonus, Electrotonic Currents, the Rate of Change in the Intensity of the Stimulus—Accommodation in Nerve

ELECTROTONUS. It was shown many years ago (1859) by Pfliiger that the passage of a constant electric current through a nerve altered the properties of the nerve in respect to *excitability, conductivity, and electrical state*. The effects are produced both at the *anode* (positive pole) and at the *cathode*, and are referred to as *electrotonus*, the anodal effect is called specifically *anoelectrotonus*, while the effect at the cathode is called *catelectrotonus*.

The effects occur in sensory as well as in motor nerves, but they can be demonstrated most conveniently in a motor nerve attached to its muscle (fig. 617). If the electrodes are placed upon the nerve with the cathode nearer the muscle, i.e., the current is *descending*, and the nerve then stimulated near the cathode with induction shocks which, ordinarily, are submaximal, the muscle gives a maximal contraction owing to the increased excitability of the nerve. The excitability at the anode can be shown in a similar way to be reduced. When the electrodes are reversed, the anode being the nearer the muscle and the current *ascending*, the nerve again shows increased excitability in the region of the cathode and reduced excitability in

TABLE 611

Strength of current	Reaction
Weak	CCC
Medium	CCC and ACC
Strong	CCC, ACC, AOC
Very strong	CC tetanus, ACC, AOC and COC

FIG 617 Diagram illustrating the arrangement for demonstrating anelectrotonus and cat-electrotonus. With a strong descending current (upper figure), break excitation at the anode is blocked at the cathode, and with a strong ascending current make excitation at the cathode is blocked at the anode. An., anode; Cath., cathode.

FIG 618 Illustrating altered excitability of nerve during the passage through it of a weak ($\frac{1}{2}$), medium ($\frac{1}{2}$) and strong ($\frac{1}{2}$) constant (polarizing) current. A, anode; B, cathode. The horizontal line represents the normal excitability of the nerve; the curves above and below this line indicate increased and decreased excitability, respectively, of the nerve. The crossings of the horizontal line by the curves, 1, 2, and 3, indicate the points where anelectrotonic and catelectrotonic effects neutralize one another, i.e., they represent indifferent points in the interpolar region A-B. (From Lombard after Pfleger.)

the anodal region. When the current is interrupted, opposite effects are produced before the nerve returns to its normal state, namely, a rise in excitability at the anode and a depression of excitability at the cathode.

The anelectrotonic and catelectrotonic effects spread along the nerve on either side of the electrodes. At a certain indifferent point between the poles one effect neutralizes the other. With strong currents the indifferent region is nearer the cathode than the anode, i.e., anelectrotonus extends farther into the interpolar region than does catelec-

trotonus, with weak currents it is nearer the anode (fig. 618).

The effect of the constant current upon conduction can be shown by stimulating the nerve in the interpolar region. When the anode is nearer the muscle, anelectrotonic depression of conductivity tends to block the impulse from reaching the muscle, complete block is produced by a strong current. There is no interference with the passage of the impulse toward the muscle when the electrodes are reversed.

The stimulating effects of making and breaking a constant current vary with the strength of the current. With a current of moderate strength stimulation of the nerve occurs at the cathode when the current is "made" (or closed) and at the anode when it is "broken" (or opened), for excitation is increased at the cathode in the one instance and at the anode in the other. The cathodal "make" effect is always greater than the anodal "break" effect, so that, with weak currents the excitation at the anode does not occur, a response is obtained only upon making the current. With very strong descending currents, a response is obtained only on the "make" because on the "break" the impulses set up at the anode are blocked by catelectrotonic depression near the muscle. With strong ascending currents excitation occurs only on the "break" because on the "make" the impulses are blocked by anelectrotonus depression near the muscle (see table 61.2 and fig. 61.8).

Electronic currents. During the passage of a constant current through a nerve the resistance of its membranes causes the current to spread laterally along their surfaces as well as toward the core of the nerve. The change in the electrical state within the nerve is thus diffused for a distance on either side of the electrode (fig. 61.9). If a galvanometer be led off from the outer side of either electrode, i.e., in the extrapolar region, a current flows through the instrument in the same direction as the constant current. The current flows toward the anode and away from the cathode (and from anode to cathode in the interpolar region). These *electrotonic currents* are due to changes in polarization of the membranes or interfaces within the

TABLE 61.2

	Ascending Current		Descending Current	
	Making	Breaking	Making	Breaking
Very weak currents	C	O	C	O
Moderate currents	C	C	C	C
Very strong currents	O	C	C	O

C = contraction, O = failure to contract

FIG 619 Electrotonic currents P, constant current, A, anode, C, cathode, G, galvanometer (After Schafer)

nerve structure by the constant (polarizing) current. When the polarizing current is broken the electrotonic currents flow in the opposite direction. The production of electrotonic currents by a constant current can also be shown in an artificial moist conductor model consisting of a conducting wire running down the center of a glass tube filled with saline. The changes in the electrical state of the nerve are the cause of catelectrotonus and anelectrotonus described in the preceding section.

When the current is "made" and the "local potential" at the cathode, which may be designated V , reaches a certain value excitation of the nerve occurs. The critical value of V at which the nerve is excited, i.e., the threshold of excitation may be designated U . The decay in the "local or cathode potential" upon cessation of the current, i.e., the rate of return of V to its original or resting value V_0 , is expressed by the formula $dV/dt = (V - V_0)/K$. K is the time constant for the return of V to V_0 ; it has a value of around 0.35 msec for frog's nerve and is related to the chronaxie which equals $0.693 \times K$. In order for excitation to result a certain rate of change in the intensity of the stimulus is required. The nerve "accommodates" itself to the stimulus if the change in intensity of the latter is not sufficiently rapid. A stronger stimulus is therefore required for excitation when the rate of rise in intensity is slow than when it is rapid. Hill has introduced a second time factor which he calls the *time constant of accommodation* (λ). If the critical value of V for excitation, i.e., the threshold designated U , and substituting U and U_0 for V and V_0 , and λ for K , in the above formula we have $dV/dt = (U - U_0)/\lambda$. For the calculation of the time constant of accommodation (λ) the reader is referred to the original paper.

¹ The reason for measuring the decline of V to V_0 is given by Hill in the following words: "We might have defined the time constant in terms of the rate of change of V when a current is put into the nerve. This would have required the choice of a particular form of current. There would have been no difficulty, but it might have given the impression that λ has something to do with the current, it has not, it is a property of the nerve itself, it expresses the time factor in the tendency of the nerve to revert to its resting condition."

The time constant of accommodation is altered by several conditions, the most notable being changes in calcium ion concentration. An increase in concentration of ionic calcium reduces the value of λ , that is, the neuromuscular tissues accommodate more readily, which means that more rapid changes in stimulus strength are required for excitation. Reduction in ionized Ca, as in tetanic states, exerts the reverse effect—increased value of λ , and reduced accommodation of the neuromuscular tissues which are in consequence excited by relatively slow rates of change in the strength of the stimulating current. If the calcium ion concentration is sufficiently low there may be a complete absence of the phenomenon of "accommodation."

THE NERVE IMPULSE

The nerve impulse is a self-propagated disturbance. That is to say, the energy for the transmission of the impulse is derived from the nerve fiber over which it passes. Nervous conduction therefore depends upon the state of the fiber at successive points reached by the impulse. The impulse resembles a spark traveling actively along a train of gunpowder rather than a wave transmitted passively through air or water. In either of the latter two instances in contrast to the first, the energy is derived from a source other than the medium through which the wave travels and the force and amplitude of the wave become gradually reduced with distance. To carry further the analogy drawn between the impulse and the burning train of gunpowder—if a section of the powder fuse is dampened in advance of the spark, the latter becomes less intense as it passes through the dampened section, and travels more slowly. Upon reaching a succeeding dry portion the spark flares up again to its previous intensity and velocity, and, so long as the powder remains dry, is transmitted without change to the end of the fuse. In a comparable way, if the activity of a segment of nerve is depressed by treatment in a chamber with a narcotic (alcohol or ether vapor) the impulse undergoes a reduction in amplitude and velocity in its passage through the narcotized region, but upon reaching the untreated nerve beyond, regains its original value, and is transmitted unchanged to the termination of the nerve. The question then arises whether the strength of the impulse in its passage through the narcotized section of nerve is suddenly reduced or whether the reduction is progressive. In other words, would the impulse suffer a greater reduction if it were made to traverse a long section of narcotized nerve than if it passed through a short stretch?

Formerly it was thought that a gradual or progressive impairment of conduction, i.e., *conduction with a decrement*, occurred. The mode of propagation of the impulse over a narcotized nerve was, therefore, supposed to be essentially different from that along a normal nerve. If, for example, the narcotized section were long enough, complete extinction of the impulse would result in this region, therefore, the impulse would resemble a wave transmitted through air or water. From his experiments, in which the long nerve of the Japanese toad was employed, Kato could obtain no evidence that there was a progressive decline in the strength of the impulse. He came to the conclusion that the impulse suffered sudden reduction upon entering the region of narcosis and underwent no further reduction during its transmission along the narcotized section. Conduction was therefore *decrementless*. Kato's findings have been confirmed by Davis, Forbes, Brunswick and Hopkins (see fig. 61 10) but it is pointed out that on theoretical grounds there must exist a short transitional portion of the nerve at the junction of the normal and the narcotized section where progressive decline in the impulse occurs. Beyond this the impulse is conducted throughout the length of the narcotized section without further reduction.

Conduction Rates

The velocity of the nerve impulse varies in different nerve fibers in accordance with their diameters: the thicker fibers conducting more rapidly than those of smaller diameter. In the large motor fibers of the mammal the rate is from 80 to 120 meters per second. Sensory nerves of the skin being of smaller diameter have slower conduction rates. Nonmedullated fibers conduct more slowly than medullated. Some of the fibers subserving pain sensation and those of the sympathetic nervous system have a very slow conduction rate (see also pp. 1129 and 1143).

The following table from Hull gives the conduction rates in the nerves of several different animals:

Medullated nerve	mammal	37°C	about 120 m per sec
Medullated nerve	dogfish	20°C	about 35 m per sec
Medullated nerve	frog	20°C	about 30 m per sec
Nonmedullated nerve	crab	22°C	and 1.5 m per sec
Nonmedullated nerve	mammal	37°C	, about 1 m per sec

FIG. 61 10 Upper drawing diagram of nerve (peroneal of cat) in narcotizing chamber to illustrate set up of an experiment on conduction of impulses through narcotized nerve. *S* stimulating electrode. Leadoff electrodes at 1, 2, and 3 within the chamber and 4 outside. Circuit completed through an indifferent electrode at 5. *G*, galvanometer for recording action currents. Nerve in chamber exposed to alcohol vapor. The results of this experiment gave no evidence of conduction with a decrement. The action currents from all three leads within the chamber were reduced to practically the same degree. Lower drawing contrasts the different views advanced regarding conduction of the impulse through a narcotized region of nerve. It will be noted that in all three the impulse regains its full value upon entering normal nerve. (From Davis, Forbes, Brunswick and Hopkins.)

Nonmedullated nerve olfactory of pike 20°C
0.2 m per sec

Nonmedullated nerve in fishing filament of *Physalia* 26°C average 0.12 m per sec

Nonmedullated nerve in Anadon 0.05 m per sec

Compare the velocity of sound in air at 0°C
331 m per sec

By an indirect method of measurement Carmichael and his associates found the rates of conduction in various human postganglionic sympathetic nerves to be from 0.85 to 2.30 m per sec. The lower figures were obtained for the nerves of the leg; the higher ones for the nerves of the chest.

The "All or None" Principle

A stimulus which is just capable of exciting a nerve fiber (threshold stimulus) sets up an impulse which is no different from one set up by a much stronger stimulus. The impulse set up by the weak stimulus is conducted just as rapidly and is just as strong when judged by the action

current developed or the mechanical response of the muscle, as one set up by the strong stimulus. Briefly, the propagated disturbance set up in a single nerve fiber cannot be graded by grading the intensity or duration of the stimulus—the nerve fiber gives a maximal response or none at all. To make use again of the train of gunpowder analogy—the flame of a match applied to the powder fuse will start a traveling spark no less intense than one started by the flame of a torch. The restoration of the strength of the impulse to its original value after passing from a narcotized region into normal nerve (p. 1124) also shows the “all or none” nature of nervous conduction. The well known fact that a strong stimulus applied to a nerve trunk causes an action current of greater amplitude, and a greater muscular response than a weaker stimulus is due to the fact that the nerve trunk is composed of many fibers each of which supplies a group of muscle fibers. The weak stimulus excites only a proportion of the units of the nerve, a maximal stimulus excites them all. For example, the *cutaneous dorsa muscle* of the frog is supplied by a nerve which contains only 8 or 9 fibers, each of these innervates about 20 muscle fibers. Keith Lucas found that when the nerve was stimulated by shocks, gradually increasing in intensity, the muscular responses did not show a similar continuous rise in amplitude, on the contrary, the responses of the muscle increased in a series of well-defined steps, that is, increasing the stimulus intensity produced no effect for a time upon the amplitude of the muscular response, but then a slight increase in strength of stimulus produced a sudden rise in amplitude. The steps were never greater in number than the number of fibers, and were due, it was concluded, to additional fibers becoming excited as the strength of stimulus reached a certain value.

It must also be remembered that the all or none principle applies only for the condition of the

nerve at the point where, and the moment when, the impulse arises. A stimulus which will give rise to a response of a certain magnitude under one condition of the nerve may give a much smaller response under other conditions, e.g., during the relative refractory period (see below), narcosis, oxygen lack, etc.

The Absolute and Relative Refractory Periods of Nerve

For a brief interval following the passage of an impulse along the nerve fiber a second stimulus, however strong, is unable to evoke a response. This interval is called the absolute refractory period. In a frog's sciatic nerve at a temperature of about 15°C the absolute refractory period has a duration of between 2 and 3 msec. Its duration is roughly the same as the action potential “spike” (see pp. 1127–1128). It is much shorter in mammalian nerve (10 to 0.4 msec in large medullated nerve fibers).

This period during which the nerve is absolutely refractory is succeeded by one in which the nerve, though it will not respond to as weak a stimulus as it did before the passage of the impulse, will respond to a somewhat stronger one. The excitability of the nerve gradually increases and the strength of stimulus necessary for excitation becomes progressively less (fig. 61.11). In the end, the restoration of excitability is complete and the nerve responds to a stimulus of no greater strength than that which is capable of exciting a resting nerve. This period following the absolute refractory phase and during which the excitability gradually rises to normal is called the *relative refractory period*. It lasts for from 10 to 20 msec or at any rate the excitability of the nerve has returned to about 95 per cent of the resting value by this time. (Full recovery however may not be attained until the lapse of 100 msec.) It should be pointed out that the failure of the nerve to conduct a second impulse is not due simply to lowered excitability at the point in the nerve where the original stimulus was applied, for during the absolute refractory period a stimulus applied to any other point upon the nerve likewise fails to set up an impulse. The passage of the impulse along the nerve leaves in its wake a change of state like a trail of ash after the ignition of a powder fuse. For the moment the impulse consumes the entire resources of the nerve fiber (Adrian). The burned fuse must have its store of energy replenished by laying a fresh train of powder grains before a second spark can traverse the path

FIG. 61.11 Recovery of excitability in nerve perfused with fluids of different pH. (After Adrian)

of the first. So also, a certain time is required for the changes associated with the passage of the impulse to become reversed and the nerve restored to its resting condition (polarized state, see also p. 1130)

The refractory period renders a continuous excitatory state of the nerve impossible just as the corresponding period in cardiac muscle assures rhythmic contractions and prevents summation and tetanus. Fusion or summation of impulses does not occur. The refractory period obviously must also limit the frequency of the impulses. In the mammal the absolute refractory period is about 1.0 to 0.4 msec. The intervals between impulses cannot be shorter than the absolute refractory period; the maximum impulse frequency is therefore around 1000 per sec. At this rate the impulses are travelling in the relative refractory period of their predecessors and are weaker and more slowly conducted. In frog nerve with its refractory period of from 2 to 3 msec. the maximum impulse frequency is between 250 and 300 per second.

THE ELECTRICAL CHANGES IN NERVE

The Current of Injury

When a pair of electrodes are placed a short distance apart upon the surface of an uninjured and resting nerve (or muscle) and connected through a galvanometer, no current flows and no deflection of the instrument occurs, since the entire surface of the nerve (or muscle) and, therefore, the tissue beneath each electrode, is of the same electrical potential. When however, one part of the tissue is injured the membrane at this point becomes depolarized (see membrane theory, p. 1130) and, in consequence, negative to the uninjured surface. When the two electrodes are now placed one on the injured and the other on the uninjured part and connected through a galvanometer a constant current flows through the instrument from the uninjured (+) to the injured (-) section and in the opposite direction through the length of the tissue. This is known as the *current of injury* (or *demarcation current*) (fig. 61 12, I).

Very large nonmedullated nerve fibers are found in some invertebrates and Hodgkin and Huxley were able to thread an electrode into the giant axon of the squid from the cut end.

The electrode inside the fiber is found to have a resting potential 80 mv. below that of one on the outer surface of the fiber. Glass micropipettes about $\frac{1}{2}$ micron in diameter at the tip filled

FIG. 61 12. I current of injury. II current of action. Description in text. The small arrows indicate the flow of the current in the galvanometer leads, the large arrow in II A indicates the direction of spread of the wave of contraction which is represented by the stippled area.

with saline, can be used as electrodes. Puncturing cells with such very small electrodes does not lead to a rapid deterioration of the cell; by this means similar resting potentials have been found across the surface of many cells, including vertebrate nerve cells and fibers.

The Current of Action

Active tissue is also relatively negative to resting tissue. If, therefore, two electrodes are placed upon a section of nerve and connected through a galvanometer as shown in fig. 61 12 II, A stimulation of the nerve at S causes a movement of the galvanometer indicator first in one direction and then in the other.² The movement may be photographed when a diphasic curve—a wave above the base line followed by one in the opposite direction—is obtained. This is the result of the propagation of the wave of excitation along the nerve from one electrode to the other. When the wave reaches the tissue beneath the first electrode this region becomes negative to the resting tissue beneath the second electrode. A current flows through the galvanometer from the resting

² Today a cathode ray oscillograph is employed (p. 1128) which when combined with a valve amplifier, enables weak currents of short duration to be measured and recorded.

to the active region. A wave above the base line is inscribed in the record (fig 61 12 II, B). During the lapse of time from the passage of the wave from beneath the first electrode to its arrival at the second no current flows, and the galvanometer indicator returns to the zero position (fig 61 12 II, C). The arrival of the excitation wave beneath the second electrode now renders the tissue here negative to the resting tissue under the first electrode, and a current flows through the galvanometer, but in a direction opposite to that of the current previously set up. As the nerve beneath the second electrode returns to the inactive state the galvanometer comes to rest. A wave below the base line is thus recorded (fig 61 12 II, D and E). The diphasic electrical change is called the *current of action*. If a current of injury is set up by crushing the nerve beneath the second electrode, an action current initiated by stimulating the nerve on the side near the first electrode, since it will be opposite in direction to the current of injury, will cause a reduction in the strength of the latter, as indicated by a movement of the galvanometer. The reduction thus caused in the strength of the current of injury is spoken of as the *negative variation*. The excitation wave does not reach the tissue beneath the second electrode since it is blocked by the injured tissue so a second oppositely directed wave does not appear, i.e., the variation is *monophasic*. The injury potential can be compensated for by balancing against it an opposing current, a record of a monophasic action potential—the “spike potential”—is thus obtained.

When the giant nerve fiber of the squid is stimulated, the action potential recorded between electrodes inside and outside the fiber obliterates the resting potential and continues to a reversed potential or overshoot giving a total ‘spike’ potential of about 110 mv. Similar results are obtained with vertebrate nerves pierced by micro-electrodes.

The action potential of the nerve cannot be separated from the propagated disturbance and plays an essential role in exciting the nerve ahead of the active region. Hodgkin showed that if a local anaesthetic were used to block conduction, when an impulse arrived at the blocked region, the excitability to electrical stimulation beyond the block increased. This coincided with the current flow ahead of the nerve impulse. The impulse normally propagates owing to the excitation of regions ahead of the impulse by their passive depolarization by current from the active region.

Moreover, in medullated nerve, Huxley and Stampfli showed that the current flow is restricted to the nodes of Ranvier and so propagation occurs by activation jumping from node to node. This is called saltatory conduction, it enables medullated nerve fibers to conduct much faster than nonmedullated axons of the same size.

After potentials. Following the main action potential or “spike potential” as it is now usually called, a series of smaller electrical changes appear in tracings obtained by the more sensitive methods of recording. These are known as *after potentials*. They appear following a series of spikes, but in their simplest form, after a single response. They consist of an initial negative potential (i.e., of the same direction as the spike) followed by a positive potential of much smaller magnitude (about 0.2 per cent of the height of the spike), but of longer duration. The negative after potential has a duration in rapidly conducting fibers of about 15 msec., the positive after potential of 70 msec. or more. The after potentials show much greater variability with experimental conditions than does the spike.

The Compound Nature of the Action Current Recorded from a Nerve Trunk

Erlanger, Bishop and Gasser studied the action potential of mixed nerve trunks by means of the cathode ray oscillograph.

Unlike any instrument previously employed for this purpose, e.g., the string galvanometer or the capillary electrometer, the moving part of this instrument—a stream of electrons—possesses practically no mass and is in consequence inertialess. It is therefore capable of recording very rapid changes in electrical potential. The instrument consists of an evacuated tube, an electron stream from a hot cathode strikes a fluorescent screen upon which it produces a spot of light. On either side of the electron stream is placed a vertical plate. A potential difference is created between the pair of plates, the electric field thereby set up across the path of the stream deflects it horizontally, and sweeps it across the screen. The spot of light is thereby converted into a horizontal streak. By means of a rotating commutator the deflections are repeated from 10 to 20 times per second. A second pair of horizontal plates is placed one above, the other below the electron stream. These are connected with the nerves whose action current is timed to reach them at the instant that the stream is deflected horizontally by the vertical plates. A vertical deflection of the electron stream results with the production of a standing wave which is photographed and a permanent record thus obtained. The speed of the horizontal move-

ment of the spot of light enables the time scale to be calculated, and can be varied by altering the potential applied to the horizontal pair of plates, the horizontal movement corresponds to the movement of a kymograph, though of course its rate is very many times faster. The upward deflection is analogous to the rise of a muscle lever. The magnitude of the action potential is determined from the height of the wave. Before reaching the recording system the action current is amplified several thousand times by passing it through a valve amplifier.

Upon analysis of the electrical potentials of mammalian nerves, Erlanger and Gasser showed that the "spike" is actually compound and represents the fusion of the potentials of three main types of nerve fiber, which are referred to as the A, B, and C groups. Several properties of nerve are correlated with the diameters of the fibers, the larger the fiber diameter, the higher is the conduction velocity, the lower the threshold of excitation, the greater the magnitude of electrical response, but the shorter its duration, and the shorter the refractory period, latent addition² and chronaxie. The relationship of conduction velocity to diameter of the nerve fiber is a linear one (fig. 61 13). The amplitude of the recorded potential is also linearly related to the fiber diameter.

The A group is composed of the largest fibers, 1 to 20 micra in diameter, with conduction rates from 5 m per sec. or less for the smallest fiber to 100 m per sec for the largest. This group has been analyzed into four subsidiary groups labelled α , β , γ , δ in accordance with and in this order of fiber diameter (fig. 61 14). The A groups are all myelinated, are both sensory and motor and are found in such somatic nerves as the sciatic and saphenous nerves. The alpha fibers of this group are absent from cutaneous nerves.

Less study has been made of the B and C groups. The B fibers are myelinated and have diameters from 1 to 3 micra, and conduction velocities from about 3 m per sec to 14 m per sec. The B fibers are found solely in autonomic (preganglionic and in some myelinated postganglionic) nerves. The C group, composed of the smallest fibers (less than 1 micron in diameter), are unmyelinated and have a conduction rate of around 2 m per sec or less; many are found in cutaneous and visceral nerves. The A group of fibers make by far the greatest contribution to the compound spike potential, and the C group the

² This is the period during which a subliminal stimulus is capable of summing with a previous one and of raising excitation to threshold value.

FIG 61 13 Linear relation between diameter and conduction velocity of mammalian nerve fibers. Each point represents a determination of the maximum conduction velocity of meters per sec and of the diameter in micra of the largest fiber of an individual nerve. Dots = adult nerves. Circles = immature nerves. (After Hursh.)

FIG 61 14 Cathode ray oscillograph records of the action currents in the sciatic nerve of the bull frog after conduction from the point of stimulation through the distances (in millimeters) shown at the left. The action potentials might be compared to runners in a race who become separated along the course as the faster contestants outstrip the slower, thus in a record at 82 mm from the point of stimulation three waves are shown whereas at 12 mm the potentials are fused and only one large wave appears. The delta wave is not shown in the record. (Modified from Erlanger, Bishop and Gasser.)

least. The electrical potentials recorded from both A and C fibers show both negative and positive after potentials, but the B group shows no negative after potential with a single response, though it appears upon repetitive stimulation. The B fibers are the most susceptible to asphyxia, the C fibers the least so.

The linear relationship between fiber diameter

and conduction velocity holds also for growing nerves of young animals (Hursh). During growth the diameters of the nerve fibers in the nerve of the leg, for example, increase as the nerve lengthens. Conduction velocity increases proportionately, so that the time taken for an impulse to travel from the toes of a kitten a few days old to the spinal cord is the same as for a full grown cat. Thus the kitten and the cat react to stimulation with about equal promptness.

The diameters of the regenerating fibers in a sectioned or crushed nerve also enlarge gradually and conduction velocities increase accordingly (Berry and associates), the relationship again being a linear one. The maximum conduction velocity is not reached until maximum diameter of the fiber is attained. If the axons of the nerve alone are interrupted, the sheaths of the nerve fibers remaining intact, the diameters and conduction velocities may reach those of the normal nerve, this rarely occurs if the nerve has been completely severed.

THE MEMBRANE THEORY (BERNSTEIN) OF NERVOUS CONDUCTION

Conduction, according to this theory, is a surface phenomenon. The nerve fiber is surrounded by a semipermeable membrane or surface film which is polarized when the nerve is at rest. That is, the surface film separates a layer of cations on its outer side from a layer of anions on its inner side. A stimulus applied to the nerve increases the permeability of the membrane at the point of stimulation with the result that a redistribution of ions and depolarization of the membrane occur. This point of the nerve becomes thereby relatively negative to the inactive (polarized) section of nerve immediately adjacent. A potential differ-

ence is set up and a current flows between the active and inactive sections. This secondary current in turn causes depolarization and activation of the adjoining region which, being now relatively negative to the next section, results in a current being again set up between these two which depolarizes the latter. The currents set up between contiguous, inactive and active regions serve as successive stimuli and the wave of depolarization spreads down the nerve, the disturbance set up by the original artificial stimulus is in this way propagated automatically (see fig. 61.15). Thus, nerve impulses are "transient self mending electrical leaks travelling along nerve fibers" (Sherrington). The depolarized state persists for a short time after the passage of the impulse, during this time the nerve is refractory. The return of excitability is dependent upon the restoration of the polarized state. According to the membrane theory the nerve impulse is a propagated wave of depolarization.

In recent years the membrane theory has become more firmly established by the experiments above, showing the role of the action potential in propagation, it had, however, to be elaborated to cover the experimental finding of overshoot, where the action potential exceeds the resting potential so that a transient reversal of potential occurs. The axon contains a great excess of K ions over the surrounding fluid and a deficit of Na ions, these differences are maintained in the resting nerve by metabolic activity.

The use of radioactive sodium and potassium to replace part of the normal potassium and sodium in a giant axon from the squid, or fluids round it, has enabled the ionic changes to be followed in detail and it is possible to detect and measure very small quantities of these substances by the radiation emitted from radioactive breakdown. When the nerve is conducting impulses, the escape of potassium ions is greatly accelerated into the surrounding fluids and sodium ions enter the fibers. The concentrations are restored to normal after activity, but the permeabilities for potassium and sodium do not change together. The reaction of the surface membrane is much more complex than postulated in the simple Bernstein theory.

By placing an iron wire in strong nitric acid a model can be made along the surface of which a physicochemical change can propagate. The wire becomes coated with a thin film of oxide which prevents its solution in the acid (the iron becomes "passive"). If the oxidized film is scratched or re-

FIG. 61.15 Illustrating nervous conduction according to the membrane theory (see text)

moved electrolytically by an adequate electric stimulus, the protective film is removed and the wire is attacked by the acid. Gas is evolved, and the change propagates along the wire at a speed of several meters per second (varying with temperature). After this activity, a thick oxide film is left on the wire which is refractory to further stimulation for a few seconds until it has slowly dissolved, to leave a thin oxide film that gives the passive state, when it can be reactivated. The propagation resembles that in nerve, for the reaction oxidizing the exposed wire causes local currents to flow, reducing the film in neighboring regions by electrolysis and so causes the activity to propagate in the same sort of way as does the action potential in nerve. An action potential can be recorded from two electrodes near the iron wire which give a diphasic variation as the active region passes. If short lengths of glass tubing are threaded on the wire to restrict the current flow to "nodes", "saltatory" activation occurs, greatly accelerating the conduction of activity along the wire.

METABOLISM OF NERVE AND BRAIN

It has been thought until comparatively recent years that a negligible expenditure of energy accompanies the transmission of the nerve impulse, the latter was believed to be immediately dependent upon physical rather than upon chemical processes. Though it was recognized that conduction eventually failed in the absence of oxygen this fact did not prove that conduction itself was due to oxidative processes. In order to show this it would be necessary to demonstrate an increase in the oxygen consumption and in the carbon dioxide production during activity. An increased carbon dioxide production of active nerve over that of resting nerve was observed by Tashiro in 1913. This was confirmed by Parker, and an increased oxygen consumption during excitation was shown by Penn. Earlier attempts (Helmholtz, 1848) to demonstrate heat production in active nerve were unsuccessful, but in 1926 Hill, using a thermopile composed of over two hundred thermocouples, detected a rise of $\frac{1}{10,000}^{\circ}\text{C}$ in the temperature of a nerve as a result of stimulation lasting 10 seconds.

HEAT PRODUCTION IN NERVE

The resting sciatic nerve of the frog in oxygen at 20°C was found by Beresina to generate 4.14 calories^{*} per gram of nerve per minute. In nitrogen

^{*} Small calories

the resting heat production falls gradually, reaching, at the end of about 3 hours, to 20 or 25 per cent of the value in oxygen, and remains steady at this low level. Upon the readmission of oxygen to the asphyxiated nerve, heat production rises rapidly, extra heat being produced over that produced previously by the nerve in oxygen. This extra heat amounts to some 15 or 20 per cent of the "missed" heat in nitrogen (i.e., of the amount equal to the difference between heat production in oxygen and in nitrogen). The heat generated in nitrogen is attributed mainly to an oxidative process dependent upon a store of oxygen in the nerve tissue, and to the breakdown of carbohydrate to lactic acid, and possibly also to phosphocreatine breakdown. In the steady state the heat production is attributed to lactic acid production from carbohydrate. The extra heat produced upon the readmission of oxygen is probably in part waste heat in the process of phosphocreatine resynthesis, and possibly also due to the oxidation of some of the lactic acid accumulated during the anaerobic period.

During stimulation of the nerve in oxygen, at the rate of 250 shocks per second, an increase in heat production occurs of 40×10^{-4} calories per gram of nerve per second. At this rate of stimulation the heat resulting from a single impulse is about 1.4×10^{-7} calories per gram of nerve fiber. Though the heat production per gram of resting nerve is nearly as great as that of resting muscle, during activity the heat produced by nerve is only $\frac{1}{400,000}$ of that generated by muscle of equal weight and stimulated to the same degree.

As in the case of muscle the heat produced during activity is given off in two batches—the initial heat and the delayed or recovery heat. The initial heat is less than 4 per cent of the total heat^{*} the ratio of initial to delayed heat being 1:30. The rate of generation of the initial heat is some 5000 times greater than that of the delayed heat (fig. 61.16). The former coincides with or follows immediately upon the 'spike' potential being an intense explosive outburst which with a single stimulus, lasts for only a few milliseconds. The delayed or recovery heat which is given out after the period of activity declines rapidly at first and then more slowly.

The delayed heat is accompanied by the consumption of oxygen and is evolved in two stages. The first of these lasts for a few seconds, and the

^{*} Hill found that the initial heat of crab nerve was only 2.25 per cent of the total heat which however, was much greater (2.5×10^{-3} per second per gram of fiber) than that of frog nerve. Beresina and Fend obtained similar values for crab nerve.

FIG. 61.16 Diagrammatic representation (not to scale) of the heat production due to each nervous impulse indicating how the observed heat resulting from a tetanic stimulation is built up of these units. The horizontal lines represent the delayed heat starting at a maximum rate of 0.05

C units and slowly falling to zero in about 10 mms. The vertical lines represent the initial heat which probably is largely produced during less than 4 sec. at a rate 5000 times greater than that at the start of the delayed phase (After Gerhard.)

quantity of heat is of small magnitude the second lasts for from 10 to 30 minutes and contributes the greater proportion of the delayed heat. Increase in the strength of the stimulus does not increase the heat production whereas increase in the frequency of stimulation causes an increase in heat production up to 25 per cent. The heat per second however does not increase proportionately with the increase in frequency of stimulation so the heat per impulse is actually reduced. When the shocks are at the rate of 280 per second the heat production per second is maximal and the heat per impulse (since each impulse is travelling in the relative refractory period of its predecessor) is only a quarter of that generated by a single isolated impulse. The heat production of the central nervous system is enormously greater than that of nerve fibers amounting to from 600 to over 2000 $\times 10^{-6}$ per gram per second for the spinal cord of the frog.

CARBON DIOXIDE PRODUCTION AND OXYGEN CONSUMPTION

The resting sciatic of the frog produces in the neighborhood of 0.6 cu. mm. CO_2 per gram of nerve per minute. The corresponding O_2 consumption is about 0.7 cu. mm. The resting respiratory

* The cause of the initial heat is unknown. It may be chemical in nature and due to the break down of phosphocreatine or may be derived as Hill suggests from an electrical source namely the discharge of an electric double layer—a condenser—located at the surface of the fiber. See A. V. Hill, *Chemical wave transmission in nerve*. Cambridge University Press 1932.

quotient is therefore around 0.8. During activity an extra 0.25 cu. mm. of O_2 per gram of nerve per minute is consumed and a somewhat smaller quantity of extra CO_2 produced. The extra metabolism of the nerve resulting from activity has an R.Q. of about 0.90 (Meyerhof and Schmidt).

The extra oxygen consumption resulting from nerve activity occurs during the period of delayed heat. It continues for a considerable time—15 minutes or more after the impulse has passed. The quantity of oxygen consumed agrees well with the heat produced at this time, upon the basis that the latter is the result of the oxidation of ordinary food materials. Like the heat production the oxygen consumption per impulse falls with a rise of frequency of stimulation though of course the total consumption per minute increases. Increasing the strength of the stimulus beyond that necessary to excite all the fibers does not increase the oxygen consumption.

Chemical Changes in Nerve[†]

(1) IN THE ABSENCE OF OXYGEN. Placed in nitrogen a resting nerve undergoes a reduction in its glycogen and free sugar contents and an accumulation of lactic acid. The lactic acid production proceeds slowly and in about 3 hours has reached a maximum rate of 7 mg. per 100 grams of nerve per hour. It then falls gradually to zero. The total acid production is about 100 mg. per 100 grams of nerve (0.1 per cent). This is not attained until the end of 24 hours at which time the carbohydrate store of the nerve becomes exhausted. Immersion of the nerve in a solution of glucose (but not of galactose or fructose) causes lactic acid production to continue at the maximum rate (7 mg. per cent) for days—or until conversion of the added glucose has occurred. When the nerve is stimulated in nitrogen there does not result however as in the case of muscle deprived of oxygen an increased accumulation of lactic acid. Also when oxygen is readmitted lactic acid does not disappear or does so very slowly. Oxygen consumption of the nerve is somewhat greater than usual after a period in nitrogen—an indication that nerve runs into debt for oxygen during a period of anoxia. In the absence of oxygen nerve unlike muscle, continues to respond to stimulation for a considerable time. It shows a progressive fall in excitability but does not fail to conduct until the lapse of about 3 hours. The action current or the current of injury is gradually reduced during

[†] The formation of acetylcholine in nervous tissue is dealt with in Chapter 71.

this time but rises again when oxygen is readmitted. A fall in phosphocreatine content and a rise in inorganic phosphorus also occur.

In the asphyxiated nerve the delayed heat production declines no more rapidly (if anything less so) than the initial heat, whereas in the case of a muscle contracting in the absence of oxygen most of the recovery heat is abolished (p. 877). In nerve, therefore, both conduction and the recovery process can apparently be accomplished for a time after the external oxygen supply has been cut off.

(2) *IN THE PRESENCE OF OXYGEN.* In the case of the excised resting nerve free sugar gradually disappears but the glycogen content remains unchanged and no lactic acid is formed. These observations indicate that the function of the resting nerve is probably maintained in part by energy derived from the combustion of sugar. Energy is also probably derived from the breakdown of phospholipins. During activity phosphocreatine is broken down but the glycogen content of the nerve remains unaltered. Sugar does not disappear more rapidly than during rest, nor is lactic acid produced. The glycogen-lactic acid cycle which is so prominent in the metabolism of muscle therefore appears to play no part in nerve fiber conduction. The immediate source of the energy for conduction is believed to be derived from the breakdown of phosphocreatine which is resynthesized after the passage of the impulse. The ultimate source of the energy for the recovery process in nerve is unknown.

It has been thought that the nerve fiber was incapable of oxidizing lactic acid or of synthesizing lactic acid to glycogen, but, as mentioned above, when an accumulation of lactic acid occurs as a result of asphyxia small amounts do disappear upon the readmission of oxygen. Also, in a nerve soaked in sodium iodoacetate the phosphocreatine disappears and the nerve soon fails to respond but if lactate be supplied the survival time is considerably lengthened and oxygen consumption increased (Feng). (The addition of lactate causes no increased oxygen consumption by normal nerve.) These and other observations indicate that the inability of the nerve to oxidize lactic acid is not absolute but that, under certain circumstances at any rate, such does occur.

Small quantities of ammonia (about 0.3 mg. per cent per hour) are produced by resting nerve and about double this amount during activity. The source of the ammonia is probably adenylypyrophosphate. The inorganic phosphate also increases during activity as a result of the breakdown of

phosphocreatine and adenylypyrophosphate and, possibly, of phospholipins.

Potassium of nerve. The nerve fiber is exceptionally rich in potassium. Cowan found that the potassium concentration in the nerve of the crab is some 13 times greater than that in crab's blood. Ratios as high as 65:1 for the potassium concentrations on the inner and outer sides of the membrane have been reported for vertebrate nerve. It is upon this difference in the potassium concentrations that the resting potential (polarization) of the nerve is believed, according to the Bernstein hypothesis, to depend. But when the nerve is stimulated or deprived of oxygen, potassium diffuses rapidly into the surrounding fluid, but is restored again (repolarized) during rest or, in the case of the asphyxiated nerve, after the readmission of oxygen. A nerve at rest and adequately supplied with oxygen does not lose potassium and a potential difference between the surface of the fiber and its interior is maintained. Increasing the concentration of potassium in the fluid bathing the nerve will tend to reduce the potential difference, this procedure also reduces the excitability of the nerve and with high concentrations excitability is completely lost but is restored again when the nerve is placed in sea water. The amplitude of the action current or of the current of injury is also markedly reduced by raising the potassium concentration on the outer side of the nerve. Furthermore, when the nerve is exposed to cold, 'blocking' of the impulse occurs at a higher temperature than usual if the nerve has been soaked in a solution containing a high percentage of potassium.

The metabolism of the resting nerve may be considered in terms of the membrane theory (p. 1130) to be directed toward securing a certain degree of impermeability of the surface film for the maintenance of the polarized state. The chemical changes associated with activity result in increased permeability and depolarization. During recovery the membrane is repolarized, the energy being furnished by oxidative processes. The potassium is returned to the fiber and the sodium that has entered is 'pumped' out.

The brain (gray matter) when supplied with oxygen oxidizes glucose and, unlike the nerve fiber under the same conditions, produces lactic acid, though in small amounts. Lactic acid is also produced slowly when glucose is added to brain slices *in vitro* with free access to oxygen. Glucose is present in brain tissue in about the same concentration as in blood, and is the main substrate for the

respiration of the gray matter. The respiratory quotient of the brain is around unity. As compared with muscle the gray matter contains only small amounts of glycogen. When the latter is added to brain slices it is broken down very slowly to lactic acid. Hexosephosphate, according to Ashford and Holmes, is not an intermediary in the oxidation of glucose by brain tissue, but the production of pyruvic acid appears to be an essential step. The utilization of glucose by brain tissue is made evident by its addition to brain slices, an increased consumption of oxygen then occurs. The oxygen consumption of brain tissue *in vitro* is also increased by the addition of fructose, mannose, galactose, and hexose diphosphate and monophosphate, and to a much less extent by other sugars. Next to glucose, fructose and mannose are most readily oxidized by brain slices. Lactate and pyruvate are utilized about as readily as glucose. Glutamic acid and alcohol are utilized by brain tissue to a small extent.

In hypoxia and during convulsive seizures, large quantities of lactate are produced by brain tissues, but as already mentioned, only minimal amounts when the oxygen supply is adequate. The large production of lactate under anaerobic conditions and the minimal amounts produced when the oxygen supply is adequate raises the question whether the formation of lactic acid plays any role in the normal function of the brain. It appears, at any rate, that it does not play an indispensable part in the oxidation of glucose, for nicotinic, iodoacetate or hydroxymalonate inhibits the oxidation of lactate but permits glucose to be oxidized. During convulsions, or when from any cause the oxygen supply is inadequate, the brain, like muscle, uses phosphocreatine. Similar changes are produced by injury to brain tissue. Though other fuel can be oxidized by the brain, glucose, lactic acid and pyruvate are the only ones, and especially glucose, which are utilized normally to any significant extent. In excised brain tissue "the utilization of glucose is faster than that observed in hepatic, cardiac, or renal slices" (Himwich). A respiratory quotient of unity supports the conclusion that the main fuel of the brain is carbohydrate, but more direct evidence for the oxidation of glucose can be cited. Himwich and Fazekas, for example, determined the glucose and oxygen contents of the arterial blood and of blood drawn from the superior longitudinal sinus of anesthetized dogs. They obtained a figure of 13 mg. per 100 cc. of blood for the glucose utilization. The quantity of oxygen which by calculation

would be required to oxidize this quantity of glucose is 97 cc. The oxygen consumption actually observed was 93 cc. These figures are, of course, for the brain as a whole.

The gray matter shows a much higher oxygen consumption than does the white matter which is composed mainly of nerve fibers. Though the nerve fiber can contract a small oxygen debt, the gray matter cannot and, in consequence, is highly susceptible to oxygen deprivation. It has been estimated that the adult brain accounts for about one-quarter of the basal metabolism of the entire body at rest, or over 3 liters per hour, yet mental work increases the general metabolism to a negligible extent (ch. 44). The infant brain which, as compared with the adult brain, forms a larger part of the body has a relatively greater consumption of oxygen, its oxygen consumption is about half the total oxygen consumption of the body. Considering the high oxygen requirement of the gray matter, especially of the cerebral cortex, it is not surprising that it is so vulnerable to anoxia. Mental confusion, delirium and unconsciousness follow any considerable reduction in the oxygen supply to the brain. The delirium of pneumonia is due largely to anoxia rather than to toxemia, and the mental aberrations associated with high altitudes are well known. The metabolism of the cerebellar cortex, according to some investigators, is higher than that of the cerebral cortex. Himwich and Fazekas have made the interesting observation that in week-old puppies the medulla and midbrain have a higher oxygen consumption than has the cerebral cortex but the reverse relationship holds true in adult dogs. The increased oxygen consumption of the higher centers of grown animals appears related to their having acquired greater functional importance and assumed a position of dominance over the lower centers.

The very high oxygen consumption of gray matter as compared to white matter (nerve fibers) is not due to the presence of cell bodies, but apparently to the great number of synapses (ch. 63), for the posterior root ganglia, which are made up of unipolar cells without synaptic connections, have not a high vascularity or oxygen consumption, and are not more susceptible to ischemia than are nerve fibers.

The brain is also very sensitive to a reduction in its supply of glucose, and when the blood sugar level falls to a certain point, mental confusion, muscular incoordination, convulsions and loss of consciousness result. The hypoglycemic symp-

toms are quickly relieved by the administration of glucose, fructose or mannose but not by pyruvate or lactate. In the human subject insulin hypoglycemia greatly reduces the oxygen consumption of the brain, but this is quickly restored to normal by the injection of glucose (Himwich and associates). The reduction of the metabolism of the brain and its restoration to normal are closely associated in time with the hypoglycemic symptoms and their relief. Yet, strangely enough, the brain continues to utilize glucose in the absence of insulin, the respiratory quotient remains at unity and the arteriovenous oxygen difference is unaltered after pancreatectomy.

As might be expected from the relationship between the blood glucose level and the oxygen consumption, the effects of anoxia and of hypoglycemia are in certain respects closely similar, and are supplementary to one another. Hypoglycemic convulsions are induced more readily in the presence of anoxia, and the effects of the latter are more severe if the blood sugar is depressed.

There is no evidence that the lipids—*cholesterol, lecithin, cephalin and sphingomyelin*—which enter so largely into the composition of brain substance serve any special metabolic need, their function is probably to insulate neighboring nerve fibers from one another. Nor are fats or amino acids, with the exception of glutamic acid, utilized by the brain. This amino acid is capable of restoring consciousness to a subject of hypoglycemia, it is probably oxidized directly by the brain, but may also cause, through an adrenalinlike action, the liberation of glucose from the liver.

Theories of the Action of Anesthetics and Narcotics

There has been much speculation as to the manner in which certain drugs induce anesthesia or narcosis, but no theory is entirely satisfactory. There are three main theories, which may be termed the *lipid solubility, membrane permeability and metabolic theories*. The lipid solubility (Meyer-Overton) theory is concerned mainly with the manner in which the anesthetic enters the neuron, rather than with its mode of action upon the function of nervous tissue after it has penetrated the cell. This theory is founded upon a certain, but far from perfect, correlation between the action of anesthetic agents, and their solubility in lipid (which the cell membrane and other structures of the cell contain) but low solubility in water. The narcotic effects of the chemically inert gases,

argon, krypton and xenon are attributed to their ready solubility in lipid.

It was proposed by Lillie that the permeability of the cell membrane, with the consequent prevention of depolarization, upon which excitability depends, was reduced by anesthetic drugs.

The metabolic theory is based largely on the work of Quastel and Wheatly, who have shown that many narcotic drugs, notably the barbiturates, paraldehyde and urethane, depress the oxygen consumption of brain tissue *in vitro*, and reduce the oxidation of glucose. The metabolic activity of the brain *in vivo* is also inhibited in anesthesia. These inhibitory effects upon brain metabolism are dependent, presumably, upon the interference with the function of oxidative enzyme systems, possibly by blocking the interaction between flavoprotein and cytochrome *b*. An important objection to this theory is the failure to establish a satisfactory correlation between the concentrations of drugs which are effective in inhibiting oxidation *in vitro*, and the concentrations which cause anesthesia. Ether, for example, causes insignificant effects upon the oxygen consumption of brain slices in concentrations which induce general anesthesia. It is possible, however, that the concentrations of anesthetic drugs in the brain as a whole may be much lower than in certain special and restricted regions and that they have specific effects on the reticular system.

One point seems to be generally agreed upon with respect to anesthetic and narcotic agents, namely, that they act through a physical rather than through a chemical mechanism. All the evidence points in this direction. No consistent chemical structure is associated with their anesthetic or narcotic property, their actions are reversible, they do not appear to enter into any chemical reaction, and they can be recovered almost quantitatively from the tissues unchanged.

THE REFLEX ARC. RECEPTOR ORGANS. CUTANEOUS AND KINESTHETIC SENSATIONS

The involuntary muscular contraction which results from the stimulation of a sense organ is known as a *reflex*. The quick withdrawal of the hand from some agent which has inflicted pain or the contraction of the pupil when a light is thrown into the eye are familiar examples of reflex action. Control of the activities of various glands is also largely reflex in nature as are many of the reactions of the vascular, respiratory and digestive systems. The causal agent of the reflex may make an impression upon consciousness, as when a group of skeletal muscles contracts as a result of a painful stimulus, or the initiating stimulus as well as the reflex act itself may be entirely unperceived as in the case of reflexes involving the secretion of glands or the activities of smooth muscle, e.g., of the blood vessels, heart or digestive tract. In some mammals many reflexes are present at birth, but in others (including man) only a few are present, and development of the central nervous system is very far from complete. The basic reflexes appear to be genetically determined, and provide a groundwork of inherited behavior that blends with control by higher centers.

The Reflex Arc

The anatomical basis of reflex action is the reflex arc which in its simplest form consists of

(a) An *afferent limb* composed of the *receptor organ*, which upon excitation, gives rise to nerve impulses and the *neuron* whose processes transmit the impulse to the central nervous system. In the case of the spinal reflex arc the cell bodies of the afferent neurons are situated in the posterior root ganglia.

(b) An *efferent limb* constituted of a motor neuron which conducts impulses from the central nervous system to an *effector organ*—muscle or gland. In the case of motor spinal reflex arcs, the axons of the efferent neurons leave the cord by the anterior nerve roots and travel in the peripheral nerves, their cell bodies are situated in the anterior horns.

(c) A *center* situated in the gray matter of the central nervous system and consisting of the cell body and dendrites of the efferent neuron and its junction (synapse) with the central process of the afferent neuron.

The afferent and efferent limbs may connect directly in the center, or one or more nerve cells may be interposed between the two. These are spoken of as *connector*, *internuncial*, or *intercalated neurons* (fig. 62.1). The stretch reflex (p. 1162) as shown by Lloyd is carried out through a reflex arc of only two neurons, but the great majority of the spinal reflex arcs in higher animals consist of several neurons, and in most reflexes each afferent neuron makes connection through collateral branches and internuncial neurons with a large number of motoneurons.

Injury, leading to loss of function of any one part of the reflex arc, is sufficient to destroy the function of the whole.

The Receptor Organs

The afferent fibers end peripherally either as *bare unmyelinated filaments* or in *accessory structures* called *receptors* (fig. 62.2). These are specialized to respond most effectively to one or other type of stimulus. When stimulated appropriately an impulse or a series of impulses is sent along the afferent fiber. Receptors are situated in the skin, muscles, tendons, etc.; and in such special organs as those of sight, hearing, smell and taste. They are also contained in the walls of the respiratory and digestive tracts, mesentery, carotid sinus and other internal structures. Through receptors in these various situations messages (nerve impulses) are continually being transmitted over somatic and autonomic pathways to the central nervous system.

Those receptors which respond to stimuli arising outside the body, e.g., in the skin, eye, ear, etc., are called *exteroceptors*. Of these, ones which make perception at a distance possible, i.e., those situated in the visual, auditory or olfactory sense

FIG 62.1 Diagram of a simple reflex arc

FIG 62.2 Diagram to show the nervous connections between the central nervous system and the periphery (muscle and cutaneous receptors) (from Adrian, *The Basis of Sensation*)

organs, are sometimes referred to as *distance receptors* (telereceptors). Receptors lying in the mucous linings of the respiratory or digestive tracts are spoken of as *interoceptors*. *Proprioceptors* are those which respond to stimuli originating within the body itself, e.g., in the skeletal muscles, (p. 1146) tendons, joints, heart, carotid sinus, gastrointestinal wall, etc. Though each variety of receptor responds most readily to one particular type of stimulus—*adequate stimulus*—many will respond in some degree to stimuli of other types. The retina, for instance, can be stimulated mechanically or electrically and the receptors of taste, though responding most effectively to chemical stimuli, may also be stimulated by an electric shock applied to the tongue. A terminology based upon the type of stimulus which excites them adequately is sometimes used to designate different varieties of reception organ. Thus, *tango* (touch), *chemo* (taste, smell and the receptors of the carotid and aortic bodies) and *photo* (light) receptors are spoken of

ANALYSIS OF SENSATION

The problems of the senses have been studied by two approaches. First, by using human subjects much can be learned by investigating what physical and chemical events they are able to detect and discriminate, but this involves much more than the sense organs, for example, a subjective

threshold may depend on the state of the central nervous system as much as on the sensory receptors concerned. Secondly, objective methods of analysis can be used. Investigation of the action of receptors in setting up nerve impulses has received a great impetus in the last forty years by the improved methods of detecting nervous activity electrically. Much of this has been done in animal experiment, but structural similarities of sense organs in man and animals make it possible to apply this knowledge to interpret human sensory problems.

CUTANEOUS SENSATIONS

The sensations which may be aroused by stimulation of the skin are *touch*, *cold*, *warmth* and *pain*. Each of these sensations, except the last, is evoked from regions where sense organs possessing distinctive structural features are found. Small areas are mapped out upon the skin which are specific for one or other sensation. The areas are called *touch*, *cold*, *heat* or *pain 'spots'* respectively in accordance with the sensation which their stimulation arouses (fig. 62.3). It must be emphasized that these spots are outlined by subjective methods, and maps vary from time to time in the same individual. They must not be confused with objectively demonstrable nerve endings. The latter are the basis from which 'spots' reach consciousness, but the central nervous system may select or reject components of the sensory discharge during transmission to the cortex. It must, also, be pointed out that it has recently been demonstrated that parts of the human skin which contain few endings that can be differentiated histologically, nevertheless have a wide range of subjective sensation that can be evoked by appropriate stimulation. It is possible that the site of the nerve ending within the skin may confer some specificity on it or that as yet unrecognised features of its structure may be concerned, but the elaborate encapsulated endings are found in skin surfaces of high sensory significance, e.g. finger tips etc.

If the mixed nerve supplying receptor organs is excited directly by the application of the type of stimulus, e.g., touch, heat, etc., for which the receptor itself is adapted to respond, the characteristic sensation is not, as a rule, aroused, a painful sensation usually results.¹ Moreover, reflexes

¹ Hembecker, Bishop and O'Leary have reported that tactile as well as painful sensations may be aroused by the electrical stimulation of the nerve trunk. The experiments were carried out upon the exposed nerves of human subjects. Stim

FIG 623 Showing cold spots (A) and hot spots (B) within an area on the palm of the hand. The sensation in each case was most intense in the black areas, less intense in the lined and mildest in the dotted areas. In the blank portions no definite sensation was aroused (after Goldscheider)

can usually be elicited much more readily by stimulating the receptors than by applying the stimulus directly to the afferent nerve, and certain reflexes cannot be evoked at all by direct excitation of the nerve fiber. Pressure upon the pad of the hind foot of the 'spinal dog', for example, causes a strong extension of the whole limb—the *extensor thrust*—whereas no form of stimulus applied directly to the afferent nerve itself will produce this reflex (Sherrington). The afferent fiber before terminating in the receptor organ or as a free nerve filament loses its myelin sheath and neurilemma and ends as a naked axis cylinder often branched or convoluted.

LIGHT TOUCH. Tactile sensation—the sensation aroused by light contact—is subserved by three types of receptor, *Meissner's corpuscles*, *Merkel's disks* and a basketlike arrangement of nerve fibers

of low intensity applied to the nerve aroused the sensation of touch, those of greater intensity a sensation of pain. No other type of sensation was experienced by the subjects

surrounding the base of hair follicle (fig 624). *Meissner's corpuscles* are situated in the papillae of the skin, just beneath the epidermis. They are unevenly distributed, being sparsely scattered over such a region as the volar aspect of the forearm but numerous in the skin of the hand, foot, nipple and lips, and in the mucous membrane of the tip of the tongue. They are well organized structures, consisting of irregularly coiled nerve endings with capsules of connective tissue. *Merkel's disks* consist of groups of three or more cup-shaped disks with a reticulated appearance (Fig 624F). The nerve fiber upon approaching a group of such structures breaks up into branches, one going to each disk. *Merkel's disks* are found in the skin of the snouts of pigs and other mammals and in the fingertips, lips and mouth of man. The basketlike arrangement, surrounding the base of a hair follicle consists of a number of short, vertical, nerve filaments which end in small bulbous expansions. They are stimulated by any slight movements of the hairs.

Inequality of pressure with consequent deformation of the skin surface is the essential factor in the stimulation of touch receptors. If the pressure is distributed equally, and, therefore, no deformation of the skin occurs, a tactile sensation is not

FIG 624 Cutaneous receptors. A, Meissner's corpuscle (touch); B, Krause's end bulb (cold); C, Ruffini's end organs (warmth); D, Pacinian corpuscle (deep pressure); E, bare nerve endings in cornea (pain); F, Merkel's disks (touch) (in part from Bainbridge and Menzie, *Essentials of Physiology*, Longmann, Green and Co.)

experienced, when, for example, a finger is dipped into mercury a sensation is aroused only in the narrow band of skin where it is deformed as a result of unequal pressures at the interface between the mercury and air.

The sensation of light touch is tested by bringing a wisp of absorbent cotton in contact with the skin, or by the use of von Frey's esthesometers. These consist of a series of hairs of graded thickness attached at right angles to wooden holders. The pressure in grams required to bend each hair is known. In order, therefore, to express the sensitivity of the skin to touch in terms of pressure the hair is found by trial which when pressed vertically upon the skin until bending occurs, causes the sensation. The sensitivity of the skin to touch varies widely in different regions. The minimal pressures required are given in table 62 1. When hairy parts, such as the back of the hand, are lightly brushed with a tuft of cotton wool the hairs serving as levers deform the skin, and thus cause stimulation of touch receptors situated in the neighborhood of the hair follicles. Shaving the hairs over such parts greatly reduces the sensitivity to touch. Other regions quite devoid of hairs such as the finger tips and lips, on the other hand, possess tactile sensibility.

TACTILE LOCALIZATION When a tactile stimulus is applied to a point upon the skin the normal subject is capable of recognizing the location of the stimulus with a high degree of accuracy. This faculty is termed topognosis. A tactile sensation has, thus, associated with it a localizing quality in addition to its specific characteristic, which has

TABLE 62 1

been called "local sign." Though there is a neural basis for point to point projection of skin areas to the cerebral cortex, the actual faculty of locating the point touched appears to be acquired by experience and not inborn. Localization is much more precise over some regions, such as lips and tips of the fingers, than over others, such as the forearm or thigh. In some nervous diseases this localization is grossly impaired. In certain lesions of the cerebral cortex the subject usually, according to Horsley, when asked to locate the stimulus indicates a point some distance from it on the proximal side. In some diseases, notably hysteria, the subject feels the stimulus at a corresponding point on the opposite side of the body, or in a limb on the side opposite to that to which the stimulus was applied, this phenomenon is called allochiria.

The localization of a cold, hot or painful sensation is very inaccurate unless the stimulating agent actually touches the skin. Thus heat radiated from a small object about 1 mm from the cutaneous surface gives rise to a diffuse sensation. The more accurate localization when contact is made with the skin is evident though the subject experiences no sensation of touch. It is likely, nevertheless, that the tactile receptors are excited that the failure to appreciate touch is due to masking by the stronger stimulus and that impulses arising in the touch endings are responsible for the more accurate localization of the other types of stimulus when these are applied directly to the skin.

TACTILE DISCRIMINATION (TWO POINT SENSIBILITY, COMPASS TEST) If two stimuli are applied simultaneously, two distinct sensations are felt provided the distance between the two stimulated points is sufficiently great. Thus, when the points of a pair of compasses are blunted or covered with cotton wool and applied to the finger tip the subject recognizes the duality of the stimulus if the points are more than about 23 mm apart. When they are separated by a shorter distance a single sensation is experienced. The minimal distance at which the recognition of two stimuli is possible varies in different regions, as shown in table 62 2.

In the case of the limbs the power of discrimination diminishes progressively from the distal to the more proximal segments, and hairless regions in general have a higher discriminating ability than those covered with hair.

A correspondence is also exhibited between the mobility of a part and its discriminating ability. For example, the minimal distance necessary for two stimuli to give rise to a double sensation is less

for the fingers and hand than for the arm, shoulder and back, and diminishes progressively over the skin of the face from the region of the ear to the lips

It should be pointed out that the values given in the foregoing table do not represent the distances separating individual touch receptors, and tactile sensation can be evoked from single stimuli applied successively from points only 0.1 mm apart. The density of receptors in the surface is only one of the factors enabling the central nervous system to discriminate characteristics of the stimulus

TICKLING AND ITCHING There has been much discussion concerning the origins of these sensations. The tickling sensation caused by light stimulation of the skin, as by a straw, appears to be due to the summed effects of stimulating both touch and pain endings.¹ Section of the lateral spinothalamic tract (which conveys pain impulses) results in the loss of the appreciation of pain but retention of the sense of touch—a tickling sensation cannot be aroused over the analgesic skin. On the other hand, the sense of touch is lost while that of pain is retained when the skin is rendered moderately ischemic; again, the tickling sensation cannot be elicited. The itchiness which is experienced in the region adjacent to a slight injury, or during the healing of a more severe injury when the skin is rubbed, is also dependent upon impulses travelling by both tactile and pain fibers, but the spontaneous itching (i.e., in the absence of any external stimulus) which is felt under the same circumstances may be due to the mild stimulation of pain endings alone. This type of itchiness is affected relatively little by ischemia. Both types of itching are attributed to a chemical

stimulator acting upon nerve endings and liberated by the damaged cells of the skin. This substance appears to be the same as that which causes the triple response. An extract of skin showing this response when injected into normal skin induces both types of itching. Histamine introduced into the skin has a similar effect. Rothman believes that itching is mediated by the C group of nerve fibers

Cold may be mediated by the end organs of Krause (fig 62 4B) and warmth probably by the end organs of Ruffini (fig 62 4C).² Mechanical or electrical stimulation, as well as the application of heat itself, will stimulate the latter end organs and give rise to the sensation of warmth. The receptors for warmth (Ruffini's) are situated in close proximity to the deep plexus of blood vessels when these latter dilate the endings are stimulated by the warmer blood coming from deeper regions. The cold receptors are also stimulated at temperatures above 112°F giving rise to a sensation not of heat but of cold. Cold, of course, is a negative quality—the sensation being due to the withdrawal of heat. It would be more correct, therefore, to say that the cold receptors are stimulated at extremes of temperature above 112°F or below that at which the warm receptors respond. When mapped on the skin, cold and touch spots are much less numerous than touch and pain spots

Pressure upon the skin considerably greater than that which elicits the sensation of touch stimulates the more deeply lying receptors including the Pacinian corpuscles (fig 62 4 D). The

*Waterston and others have questioned the existence of definite heat and cold spots since it has been found that the points from which these sensations can be aroused change from time to time in number as well as in pattern. He states that when the skin is hyperemic the entire surface responds to warmth (punctate distribution being abolished) and he believes that the entire skin surface is potentially sensitive to this sensation, the apparent punctate distribution being due simply to fluctuations in the activity of different areas. The variability in sensation it has been suggested may possibly be related to a corresponding fluctuation in the capillary circulation. The observations of Bazett and associates indicate, however, that the diffuse nature of the temperature sensations in hyperemic skin can be best explained upon the basis of a more ready conduction of heat through the blood stream to neighboring end organs, thus when the cutaneous blood flow is profuse heat applied to a nonsensitive point in the skin would be conducted rapidly to adjacent warm spots. The observations of Bazett and his colleagues upon the sensitivity of the prepuce support the conception of heat and cold spots and the existence of discrete receptor organs for these sensations as well as for touch (Arch. Neur. Psych. 1932, 27, 489)

TABLE 62 2

Different cutaneous areas compared with regard to the minimal distance which must separate two stimulated points in order to arouse a double sensation

(After Meyers)

Region	Minimal Distance

sensation of pressure is not however, a true cutaneous sensation, the Pacinian corpuscles are situated in the subcutaneous tissues or inner layers of the dermis as well as in tendons, periosteum and other deep-seated structures, their nerve fibers run chiefly, not in the cutaneous nerves, but in the sensory fibers of mixed nerves supplying muscles, tendons, joints and blood vessels. Since the sense of deep pressure is preserved after sectioning the cutaneous nerves, the loss of light touch, a purely cutaneous sense, may, therefore, be undetected in a lesion affecting this sensation, unless the contact is made very lightly, as by a wisp of cotton wool, with the skin, otherwise receptors in the subcutaneous tissues may be stimulated.

Pain is subserved by naked nerve endings, there being no organized end organ for this sensation. The pain nerves of the skin are described by Woollard as consisting mostly of non medullated fibers which terminate in the superficial layers of the dermis in delicate loops lying parallel to the skin surface, or as long naked neurofibrillae. Only occasionally do fibrils penetrate the epidermis. Bare nerve endings mediating pain are also present in the cornea (fig. 62 4E) and in serous surfaces (peritoneum, pleura, etc.), touch, cold and warm endings are absent and the corresponding sensations cannot be aroused from these locations. Although it has been the general belief that the cornea contains only pain endings and that any stimulus, if intense enough to evoke a response at all, causes pain. The sensation of cold can, however, be elicited from the cornea, and according to some, the sensation of touch without pain can be aroused by a very mild stimulus such as a jet of isotonic saline. Certain structures, e.g., the tooth pulp, the middle meningeal artery, the arteries at the base of the brain and some of the vessels of the scalp contain no sensory fibers except those which give rise to pain. Other structures, on the contrary, e.g., the substance of the brain and the mucosa of the cheek opposite the second lower molar tooth, are insensitive to pain.

Most of the pain impulses arising in the skin travel to the central nervous system in the somatic nerves, but some of those from deeper structures join autonomic nerves. All enter the central nervous system by the lateral divisions of the posterior spinal nerve roots or the cranial nerves. The pain endings do not respond selectively to one variety of stimulus but to any type whether mechanical, chemical or thermal, provided it is sufficiently intense. The pain stimulus, whatever

it may be, has one property in common, namely, that it is of a nature to cause injury. The sensation of pain therefore serves a protective purpose, giving warning of injurious stimuli. Stimuli which arouse painful sensations also provoke reflex actions which have the following features: (a) They comprise movements for protection or defense, or for the withdrawal of the part from the noxious agent. (b) They are prepotent, other less urgent reflexes being for the time inhibited. (c) They are imperative and can override voluntary control. Such reflexes are called *nociceptives*.

PERCEPTION OF AND REACTION TO PAIN

Pain thresholds. A distinction should be drawn between the perception of pain and the reaction which results, e.g., contraction of facial muscles, vocalization, narrowing of eyelids, changes in pulse rate or rise in blood pressure, sweating, and vasomotor responses. The threshold can be conveniently measured by focussing heat from a lamp on the forehead for 3 sec. and measuring the intensity which becomes painful. The subject indicates the perception threshold verbally and the reactivity threshold may be found by detecting when a change of skin resistance occurs by a wheatstone bridge and galvanometer.

In man the perception threshold, under similar conditions, remains remarkably constant between normal persons, and for the same person from day to day, or from hour to hour of the day. The threshold is altered, however, by such extraneous influences as a loud noise, gripping some object or clenching the jaws, which may raise it by 40 per cent. The threshold may be definitely raised by a placebo, and some distraction, such as pain or discomfort, in one situation may reduce the perception of pain in another. The twitch applied to a horse's nose during a minor operation is a familiar example. Even other sensations, e.g., touch, pressure (rubbing), warmth, etc., may raise the pain threshold. The analgesic action of counterirritation is, in some instances, dependent upon such an effect. Hypnosis also raises very considerably the perception threshold, as do alcohol and, of course, other analgesic drugs.

The threshold of reaction to pain varies widely between different subjects. In those of a stoical, phlegmatic temperament, in prize-fighters, Negroes and North American Indians the threshold is high whereas in 'high-strung', neurotic persons it is low. Alcohol and analgesic drugs raise the reaction threshold to a greater degree than they do the perception threshold (Wolff and Hardy).

Cutaneous pain A blindfolded subject is unable to distinguish between the pain caused by a pin prick, a hot point, a punctate electrical stimulus or the plucking of a hair, provided no associated nonpainful sensation gives the patient a clue as to the nature of the stimulating agent. These pains would all be described as sharp "bright" or pricking. A burning pain is experienced when the sensation is more prolonged, whether caused by heat or ultra-violet light or by a chemical or mechanical irritant. There is no spatial summation of pain stimuli, i.e., the threshold for pain is not influenced by the extent of the area stimulated. Nor, in contrast to stimulation by touch or warmth, adaptation to a painful stimulus does not occur, pain continues to be felt as long as the stimulus is applied. The biological significance of this is obvious.

First and second pain It is a common experience that a single painful stimulus applied to the skin, if intense enough, may give rise to two sensations separated by a short interval. The first pain is short and sharp, the second, more prolonged and severe. The observations of Lewis and Pochin upon this phenomenon indicate that pain impulses are conveyed from the skin by two sets of nerve fibers, one of which is rapidly conducting, the other with a much slower conduction rate. They found that ischemia of the skin of the arm, induced by arresting the circulation, abolished the first response to the needle prick, the second response being unaltered for a time but later becoming reduced. Cocaine, on the other hand, abolished the second response before the first. It was shown moreover, that the time interval between the two responses was prolonged as the length of the nerve between the point of stimulation and the central nervous system was increased, a fact which seems to demonstrate decisively the existence of a fast and slow pathway for the transmission of cutaneous pain. The time interval between the two responses is 1.9 sec. when the stimulus is applied to the toe, 1.3 sec. to the knee and only 0.9 sec. to the upper limit of the thigh.

The first painful sensation of the dual response appears to travel by fibers conducting at 30-8 M. per sec. and is mediated by myelinated fibers; they are more susceptible to asphyxia, the second pain response is transmitted by the slowly conducting C group of fibers (conduction rate of less than 2 m. per sec.), they are more readily affected by cocaine.

The rapidly transmitted pain appears to be the

sensory basis for protective reflexes. Pochin found that the "fast pain" is abolished in tabes but the "slow pain" is retained. In this disease the response to pin prick is delayed, the withdrawal reflex abolished, and the larger fibers are the first to be destroyed.

A third type of pain response follows some little time after certain forms of injury, e.g., scorching, scalding, sunburn or the application of an irritating agent, and persists for a variable period. Even a slight burn may cause a dull pain which continues for many minutes. This pain evidently is caused by the release of a chemical substance from the damaged tissues and not by direct action of the stimulating agent upon the nerve terminals. Arresting the blood supply to the part intensifies and prolongs the pain. The chemical excitant does not appear to be potassium, nor acetylcholine, nor is it due to altered pH. It has not yet been isolated chemically.

Dissociation of cutaneous sensations In disease, the several modalities of sensation, touch, cold, warmth, and pain may be lost separately, or they may be temporarily dissociated by artificial means as by asphyxia, cocaine or the application of cold. Thus the cutaneous sensations, touch, cold, warmth and pain are lost in this order when the skin is made ischemic. If the skin is cocaineized, the appreciation of cold is lost first, then follow in order the senses of warmth, pain and touch. Cooling the skin causes first, failure of cold sensation, then in succession the sensations of touch, pain and warmth are lost. Also, after section of a cutaneous nerve, the area of pain loss is smaller than that of touch; there is thus a boundary zone from which a response to a painful stimulus, such as that of a pin prick, can be obtained but which is insensitive to light touch.

Deep sensibility Pain in the deep structures, muscles, bones and joints, etc., the sense of pressure in the subcutaneous tissues, and sense of position and movement (e.g., kinesthetic sense) of joints come in to the category of deep sensibility. Deep sensibility is mediated by afferent fibers in the mixed nerves. Pain arising in deep structures differs in certain respects from superficial pain. It is poorly localized (ch. 43), and is often of a dull, aching or "sickening" character as compared with superficial pain which tends more usually to have a "bright", sharp or burning quality. Deep pain is more often accompanied by nausea and vomiting, slowing of the pulse, and a fall in blood pressure, whereas cutaneous pain is more commonly associated

ated with a quickening of the pulse and a rise in blood pressure.

Muscles, tendons and fasciae are especially susceptible to painful stimulation by chemical agents. The injection of a few drops of a 6 per cent saline solution into one of these structures causes pain. Muscle is relatively insensitive to pricking or cutting but pain is aroused by pressure, e.g., pinching or squeezing, or by exercising under ischemic conditions (p. 1143). Severe tension acts also as a pain stimulus for muscle, tendon or fascia. Pain occurring in ischemic muscle during activity is due to a chemical irritant produced by active tissues and which accumulates and stimulates the pain endings when the circulation to the part is arrested or considerably reduced. This substance is referred to as factor P by Lewis and his associates. The soreness of healthy muscles which comes on some hours after exercise may be of the same nature.

Periosteum and cancellous bone are very sensitive to the various types of mechanical stimulation but compact bone is insensitive to drilling or sawing. The arteries give rise to painful sensations when pricked, but the walls of the veins, except the larger intracranial veins, are usually insensitive.

Visceral pain and referred pain are dealt with in chapter 43, *central pain* in chapters 66 and 67, and *headache* in chapter 67.

Hyperalgesia. In many persons an area of tenderness develops around even a small cutaneous injury and spreads for a considerable distance in all directions. The soreness starts within a few seconds, increases to a maximum in from 15 to 30 minutes and lasts for hours or, with a more severe injury, for days. The threshold for pain as tested by a needle prick is lowered only slightly over the area, but the pain when aroused is diffuse, and unusually intense and prolonged. This phenomenon has been studied by Lewis and his associates. Injury was produced by prolonged faradic stimulation of the skin, by crushing a small cutaneous fold with forceps or by direct stimulation of a cutaneous nerve trunk or one of its branches. A similar area of cutaneous hyperalgesia may result from an injury or an inflammatory process involving deep lying tissue or mucous membrane. Thus, stimulation of a dental nerve or of the mucous membrane of the maxillary antrum is followed by tenderness of the overlying skin of the cheek. Lewis' experiments point to a specific system of nerves in the skin as being responsible for the hyperalgesia. They are not sympathetic filaments,

for the phenomenon is observed in skin completely deprived of its sympathetic innervation. Lewis concluded that the nerve fibers responsible were distinct from pain fibers and suggested a separate innervation of 'nocifensor' fibers, this has not been supported by more recent work such as that of Weddel on the distribution and sensitivity of fibers in human skin. It is now thought that the nocifensor fibers are the same as the fine branching fibers subserving slow pain. Impulses arising in the damaged region spread via branching fibers to release a chemical excitant in neighboring areas, this alters the responsiveness of the endings of other fibers round the area of damage.

A similar process has been demonstrated in animal experiments by recording the action potentials from small skin nerves.

Epicritic, Protopathic and Deep Sensibilities

Head and his associates, from the study of a large number of peripheral nerve injuries, grouped the several superficial sensations into two classes: (1) *epicritic* and (2) *protopathic*. The sensations grouped under *epicritic sensibility* included light touch over hairless parts, the power of localizing the point touched, the detection of two individual sensations when two points are touched simultaneously, and the appreciation of finer grades of temperature, cool and warm i.e., temperatures ranging between about 40° and 25°C. *Protopathic sensibility* is a more primitive type of sensation and more widely distributed. It includes pain and the temperature sensations aroused by extremes of heat and cold—above 40° to 50°C and below 20° to 25°C. In other words, protopathic sensibility possesses a high threshold but, though the stimulus must be strong in order to arouse a sensation, this once aroused is intense, diffuse, poorly localized and peculiarly unpleasant in quality. These latter qualities of protopathic sensibility are particularly prominent in the absence of epicritic sensibility, which therefore has been considered to exert a restraining influence upon the former. The glans penis possesses only protopathic and deep sensibilities.

For the purpose of studying these two types of sensation Head underwent an operation in which his radial nerve and the cutaneous branches of the musculocutaneous nerve were severed at the elbow. After the operation there was complete loss of cutaneous sensation over the radial half of the back of the hand. Surrounding this was a narrow zone in which epicritic sensibility alone was lost; protopathic was retained. This is due to overlapping

of the protopathic innervation of the adjacent unaffected skin area. Over a small triangular area of skin at the wrist the relationship between these two sensations was reversed, protopathic sensibility was lost but epicritic retained. Stopford has since shown that this latter type of dissociation of the two groups of sensations is also characteristic of section of a posterior root—the area of protopathic loss being much greater than epicritic. In Head's experiment evidence of returning sensation (due to regeneration of the nerves) was noticed on the 43rd day after operation when the zone of protopathic sensation was found to have become broader and to have encroached upon the totally insensitive area. The original area insensitive to light touch remained unreduced. Within about six months protopathic sensibility had returned over nearly the entire area, yet the extent of the epicritic loss remained unaltered. The first signs of the return of epicritic sensation was not observed until a year after the operation and was not complete after the lapse of two years. Deep sensibility was not affected by the nerve section referred to above, it is not mediated by fibers running in superficial nerves. Moderate pressure could be everywhere appreciated. This is an important point to remember in the investigation of nerve lesions since it shows that crude methods for studying the sensations of touch may fail to reveal any loss. The superficial touch receptors are stimulated by light contact with a wisp of cotton or by the pressure of a fine hair, whereas a pressure not very much greater, as with the point of a pencil will stimulate the deeper lying pressure receptors whose nerve fibers may be intact. As a result of these experiments in which dissociation of the three types of sensation were clearly demonstrated, Head and his associates concluded that each sensation was mediated by a separate and structurally distinct group of fibers. Unquestionably, a deep sensibility is conveyed by fibers separate from those responsible for cutaneous sensations, but that epicritic and protopathic sensations has each its specific fiber group has been seriously questioned. The work of Erlanger and Gasser and of Ranson appeared to lend support to Head's interpretation. The C fibers of the former authors were suggested as the possible mediators of protopathic sensation, and the A group of epicritic. Ranson had previously described unmyelinated fibers in the cutaneous nerves which since they were believed to mediate pain might offer an anatomical basis for the primitive protopathic sensations. The existence of protopathic sensation only in the glans penis and the dissociation of the two sensations which as shown by Stopford result from section of the posterior roots also supported Head's conception of two distinct sets of fibers. Experiments by other neurologists on the other

hand have failed to substantiate this contention (see Trotter and Davies). Some would explain the two classes of cutaneous sensation following nerve section upon the basis of different rates of regeneration of the receptor organs, the terminals of the pain fibers being thought to regenerate first. Fine discrimination, according to Heinbecker, is dependent upon the number of active end organs within a given area. The zone of protopathic sensibility surrounding an anesthetic area caused by nerve section is ascribed simply to the presence, in reduced numbers, of intact afferent endings which have overlapped the field of distribution of the sectioned fibers.

The recognition of these two types of sensation is of distinct value from a clinical standpoint and reflects the fact that conscious appreciation of a sensory message depends on all its components, removal of part of the message leads to the appearance of abnormal sensations such as isolated protopathic pain.

Vibration sense pallesthesia This is the ability to perceive stimuli of a vibratory nature applied to the body surface as by means of a low-pitched tuning fork, or other vibrating instrument. They arise if the stimulus is applied to bone tendon and muscle and are therefore part of the system of deep sensibility. Pollock has shown that the vibration sense is retained though the superficial sensations have been lost, which indicates that it is conveyed by fibers other than those mediating the latter sensations, namely by the deep system. Receptors for vibration sense are probably also situated in the deeper layers of the skin, and in the subcutaneous tissues. Though the sense is usually elicited by placing a vibrating tuning fork upon a bone, e.g. the shin or some other superficial bone, it can be aroused by applying the instrument to the soft tissues. The structures which respond to vibration are the proprioceptors of tendon and muscle. The basis of this sense is probably the stimulation of receptors by rapid mechanical changes in pressure which will cause many receptors to set up impulses together in time with the tuning fork.

Testing the vibration sense is an important diagnostic aid in neurological conditions. It is impaired or lost (and often before the sensation of touch or kinesthetic sense is affected) in lesions of the peripheral nerves, or of the posterior columns of the cord, but is not affected if both tactile and kinesthetic senses are intact—a fact that supports the view that it is mediated by the same receptors which subserve both of these sensations.

Stereognosis (*G stereo*, solid + *gnosis*, knowl

edge), *stereognostic perception*. This is the ability to recognize, with the eyes closed, the size, weight and shape of objects placed in the hand or upon some other part. The absence of this sense is called *astereognosis*. When placed in the hand of a normal person while his eyes are closed, a coin, button, chain, ball or cube is easily identified from its size, weight, shape, texture (fur, wool, mesh) etc. Recognition may be made, though less readily, even if the object is laid upon the foot or pressed against the toes. Stereognosis is not a separate sense, but depends upon the senses of touch, spatial discrimination, cutaneous localization, and the kinesthetic sense. It is impaired or lost in lesions of the peripheral nerves or posterior columns of the cord, or of the somesthetic area of the cerebral cortex.

THE PROPRIOCEPTORS OF MUSCLES, TENDONS AND JOINTS

The receptors situated in skeletal muscles and in the tendons and joints furnish information to the central nervous system concerning the movements and positions of the limbs and other parts. Afferent fibers carrying this information make up from $\frac{1}{3}$ to $\frac{1}{2}$ of the fibers in a so-called motor nerve. As a result of the messages received by the nervous centers, the contractions of individual muscles and groups of muscles are coordinated to produce smooth, finely adjusted and effective movements which would be impossible in the absence of such guidance from the periphery. For this reason the term *kinesthetic* is applied to this group of receptors. A proportion of these afferent impulses arouse no sensation, their information being delivered to centers lying beneath consciousness. To others are due the sensations grouped in the section under deep sensibility. The receptors in the situations mentioned respond to mechanical stimulation, e.g., pressure or stretch. These types of stimulus are furnished by the strains and stresses set up in the muscles, tendons and joints during muscular contraction.

The sensory endings in the various situations mentioned above are of four main types: (1) *muscle spindles*, (2) *Golgi corpuscles*, (3) *Pacinian corpuscles*, and (4) *unencapsulated nerve endings*.

(1) *The muscle spindle* is a fusiform body from 0.75 to 4 mm long and from 0.1 to 0.2 mm broad lying parallel to and between the muscle fibers (fig. 62-5). It is constituted of a bundle of from 3 to 10 muscle fibers (*intrafusal fibers*) enclosed in a fibrous capsule. The latter is separated from

FIG. 62-5 1 Golgi ending in tendon, 2 intrafusal fiber showing a muscle flower spray and, annulo spiral endings.

the intrafusal fibers by a lymph space bridged across by delicate septa. The intrafusal fibers differ from the ordinary fibers of the muscle in being smaller and more circular on cross section, and in having a greater number of nuclei and coarser striations. The nerve supply of the spindle is double—afferent and efferent. The former enters the spindle about its center, the latter more toward one or other end. The efferent fibers are mostly small (7 to 10 μ) and go to end plates on the intrafusal muscle fibers. They are designated γ fibers to distinguish them from the larger α motor fibers supplying the rest of a muscle. The afferent fibers end in two ways. The large (17–18 μ) fibers coil round the middle of an intrafusal fiber to form an annulo spiral ending. Smaller fibers go towards the ends of the spindle and ramify to form endings, called from their appearance, flower spray endings of Ruffini.

(2) *The Golgi corpuscles* (fig. 62-5) are situated in tendons and consist of a bundle of tendinous fibers surrounded by a lymph space and enclosed within a fibrous capsule. Afferent nerve fibers enter the organ near its center and ramify upon its constituent fibers. Tension is the adequate stimulus for these receptors.

(3) *The Pacinian corpuscles* are oval bodies composed of concentric laminae, like the 'skins' of a sectioned onion. The afferent fiber penetrates to the center of the corpuscle. Pressure is the adequate stimulus. These receptor organs are found in tendons, joints, periosteum, especially beneath tendinous insertions, in fasciae covering muscles and in subcutaneous tissues (fig. 62-4D). They are also found in the mesentery.

(4) *Free nerve endings* lie between the muscle fibers, in tendons and in the fasciae and joints. They mediate deep pain.

THE RESPONSES OF RECEPTORS

When the action potential of a nerve trunk, e.g., frog sciatic, is recorded following maximal

stimulation, the potential recorded is a substantial fraction of that occurring across the membranes of the axons. About 30 mv may appear at electrodes on the surface, from experiments with microelectrodes it is known that the action potential of each fiber is of the order of 100 mv, the difference is due to the partial shortcircuiting of the action potentials by interstitial fluids and connective tissue, and because the internal resistance of the fibers is high, the potential at the nerve surface is lowered. When only a single fiber in a nerve trunk is active, the action potential recorded from electrodes on the surface may be only a few microvolts. The impulses occurring naturally in sensory nerves are not synchronized in the different units, and hence it was not possible to analyze them by recording action potentials until the invention of the valve amplifier enabled them to be magnified and then recorded, with insensitive but rapidly deflecting instruments such as oscillographs, for the last 20 years the cathode ray oscillograph has been generally used for this purpose. Adrian and his associates at Cambridge first recorded the activity of individual sensory fibers in various mixed nerves, e.g., in the frog's sciotic, set up by stretching the gastrocnemius, from fibers supplying touch receptors in the frog's skin, and from digital nerves of the cat during stimulation of receptors in the toe pad.

Sense organs in muscle. The response of a single muscle spindle to stretch was first investigated by Adrian and Zotterman. They employed the sterno-cutaneous muscle of the frog which arises from the abdominal wall and is inserted into the skin. The whole muscle contains only three or four muscle spindles and by removal of portions of the muscle, a preparation containing a single spindle with intact nerve fiber, was obtained.

- Stretching the muscle caused a *rhythmic* discharge of impulses up the nerve fiber. Increasing the stimulation by greater stretch did not increase the magnitude of the action potentials but the frequency with which they recurred increased up to over 100 per sec. This behavior has been found to be general and seen in many types of sensory receptor. The intensity of the stimulus is signalled by the frequency of impulses and these following the all-or nothing law are all the same size. When groups of receptors are studied they vary in threshold and an increasing stimulus leads to a greater total nerve impulse discharge both by more units coming into action and by the response increasing in frequency. Matthews employed the small extensor muscle situated on the side of the middle

toe of the frog which often contains only one muscle spindle. Impulses can be recorded from a branch of the peroneal nerve supplying it. The muscle spindle was stimulated by loading the muscle at various rates with different weights. It was found that (a) the frequency of impulses set up was roughly proportional to the logarithm of the load, (b) the frequency was much higher during rapid extension than if the load were applied slowly, (c) at 16°C the maximum impulse frequency was about 200 per sec. Upon altering the temperature the maximum frequency of impulses varied in much the same way as the refractory period of nerve. Matthews, by dividing muscle nerves until only one sensory fiber was active, found in mammalian muscle that the flower-spray and annulo-spiral endings in the spindles and the Golgi tendon organs are all stimulated by passive stretch. Those in the spindle responded to the rate of extension as well as its magnitude while those in the tendon were little affected by rapid stretch. The response of some endings ceased during active contraction which relieves the strain upon them (see fig 62 5), but some endings, thought to be the annulo-spiral type, which cease to respond if contraction is just maximal, accelerate their discharge if the stimulus to the nerve is supramaximal for contraction. This was attributed to contraction of the intralusal muscle fibers increasing the stress upon the nerve endings. The high threshold agreed with the known small size of the motor fibers ending within the spindles now designated as gamma fibers. Hunt and Kuffler have since confirmed that the sensitivity of the muscle spindle is controlled by the activity of the gamma fibers, these have been found to be activated from the central nervous system under a number of conditions.

The Golgi endings respond to stretch of the tendons whether passive or induced by contraction of the muscle and can thus signal the total tension in the muscle.

Adaptation. The rhythmic discharge of impulses set up by the stimulation of a receptor diminishes in frequency and may cease entirely though the stimulus remains at constant intensity. For instance, if a weight is placed on tactile receptors in the frog's skin, a burst of impulses in many fibers occurs during deformation of the skin but after one or two seconds this discharge may cease entirely. This phenomenon is spoken of as *adaptation* (see fig 62 6). Adaptation occurs at a very different rate in different types of receptor (see fig 62 7). Adaptation must be distinguished

FIG 626 Adaptation Graph of response during first second after sudden loading with a large load 100 gm Temperature 14°C (After Matthews)

FIG 627 Showing the response of nerve fiber and of different types of receptor to a continued stimulus. Adaptation is most rapid in the nerve fiber and slowest in the muscle spindle (from Adrian, *The Basis of Sensation*, Christophers, London)

from fatigue. If the stimulus is removed and re-applied, even after a very short interval, a new outburst of impulses appears. Adaptation is not produced by the setting up of impulses, for it may be shown that if electrically evoked impulses are backfired into a muscle spindle, no adaptation is produced. Adaptation is associated with the presence of the stimulus rather than with the activity of the tissue. End organs are not easy to fatigue, but fatigue is hastened by oxygen lack whereas adaptation is less altered.

The physiological importance of adaptation is very great. The unchanging state of the environment is of much less importance to an organism than new stimuli; adaptation acts to make new events in the environment have a major stimulating effect on the sense organs and leaves only a

small inflow to the nervous system under stationary states. This emphasis on new components in the sensory environment may be further enhanced by transformations within the central nervous system. We can see the result of such processes in human sensation and we speak of "becoming accustomed" to some environmental change which initially caused a large effect. We do not feel the contact of our clothes, a hot bath feels much hotter on first contact with it than a short time later. Only the nerve endings subserving slow pain appear not to adapt.

Some very slowly-adapting nerve endings are found, for example the otolithic organs of crustacea, and many of the vertebrate muscle proprioceptors adapt very slowly and a discharge continues for an hour or more if the stimulus is maintained. Again, the endings of carotid sinus, aorta and those excited by inflation of the lung, all have slow rates of adaptation. At the other extreme the endings surrounding hair follicles adapt so rapidly that when a hair is moved, impulses cease as soon as the hair comes to rest though displaced to a new position. A Pacinian corpuscle deformed suddenly may set up only one impulse.

The genesis of rhythmic discharge. At the nerve ending the stimulus operates to produce a state in which the axon is excited at regular intervals. In terms of the membrane theory of nerve, it is supposed that the appropriate stimulus acts by producing a partial depolarisation of the terminations, so allowing current to flow from more distant regions. This is confirmed by the recent demonstration of *generator potentials* occurring in simple sense organs. Thus Katz has demonstrated that in the frog's muscle spindle a long-lasting change of potential occurs near the terminations when stretch is applied, and that this remains after impulse generation and conduction by the axon are abolished by anaesthesia. Similar potentials have been demonstrated by Gray in the Pacinian corpuscle. In the crustacean stretch receptor the cell body lies peripherally, and micro-electrodes within it have been shown by Kuffler to record the local changes accompanying stretch of the muscle which initiated a rhythmic discharge. Rhythmic discharges can be evoked by constant current stimulation of many nonmedullated and some medullated nerve fibers, in some sensory end organs applied steady currents raise or lower the rate of rhythmic response by summing algebraically with the normal generator potential.

Specific sensations. Accessory nonneural por-

tions of the sense organ act to raise the threshold to some types of stimulation and lower it to others, and thus confer specificity in the sensitivity of the receptor. Thus, for example, chemical agents are unable to penetrate the lamellae of the Pacinian corpuscle at all rapidly, so ensuring insensitivity to chemical stimuli, while transmitting the effect of mechanical deformation. This specificity is rarely complete and, for example in the dog, pressure on the thermal endings will increase the response to a thermal stimulus, and pressure on taste buds will increase the response to chemical stimuli. It has long been known that structures in the retina can be stimulated by pressing on the eyeball and give a sensation of a light stimulus. The taste buds can also be stimulated electrically. The pain endings which have no encapsulation are most readily reached by chemical agents, and on injury occurring, cell breakdown products appear to be the normal stimulus.

In conscious sensations the quality ascribed depends largely on the pathway by which impulses arrive at the higher levels of the central nervous system. Thus impulses in the VIIIth nerve, whether set up by an electric stimulus applied via fluid in the external meatus or by air borne pressure patterns, are appreciated as sound, those from the IIInd nerve as light, whether due to light or pressure on the eyeball. Cutting Gower's tract abolishes pain sensations from areas one segment below the lesion (contralateral), only impulses ascending by this pathway arouse pain.

The various pathways to the brain come from receptors protected from some of the physical or chemical events in the environment and organised to be very sensitive to others, so conferring a specificity which enables the brain to separate events into recognisable categories.

REFLEX ACTION

In peripheral nerve the individual fibers conduct independently and little interaction occurs but in their central terminations interaction becomes the important process. It depends partly on proximity (fig. 63 I) and the absence of myelin at terminations but also on the release of transmitter substances and the movements of ions along electrical gradients.

In a complete animal any reaction depends in greater or less degree on many factors in its environment which affect its senses. In analysis of the mode of action of the central nervous system, components of central activity can be partially isolated as reflexes. This isolation may be assisted by surgical section of the central nervous system, as in the spinal or decerebrate preparation, or by anesthetics such as barbiturates which suppress differentially the activity of particular parts, or by controlling the environment so that a simple stimulus is presented in isolation as in testing the knee jerk.

In the intact animal or man, the reflexes that can be isolated are limited, e.g., pupil reflexes to light, the blink reflex, the knee jerk, and certain pain reflexes. More detailed and quantitative information has been derived from animals by methods which simplify the nervous system and where stimulus and response are capable of accurate measurement, as in the classical experiments by Sherrington and his collaborators, where the response was measured as contraction of a particular muscle or group. In the last 30 years, in addition, analysis of the impulse discharges entering and leaving the central nervous system has added much detail, the nature of electric changes accompanying reflex activity at electrodes inserted within the central nervous system have assisted the development of theories of the mechanisms concerned. All the simpler reflex pathways appear to be genetically determined, but the delay in development of the central nervous system after birth enables interaction of genetic and environmental factors to occur. In many species highly elaborate reflexes are present at birth and can be regarded as "race learn-

ing' in evolution, as without many of these survival is impossible.

The Spinal Preparation

Many reflexes can be studied in the spinal preparation. If this is made by decapitation under anesthesia after ligation of the blood vessels to the head, the respiratory center in the midbrain is removed, and, consequently, ventilation to the lungs must be maintained by means of a pump. This can replace the function of respiration in oxygenating the blood, but not that of controlling the elimination of CO_2 to maintain constant pH. This is grossly disturbed by loss of control by the respiratory center. In addition the loss of the controlling centers for blood pressure, heart rate, the vasomotor center in the midbrain, all lead to circulatory abnormality and greatly lowered blood pressure due to loss of tone of the blood vessels. However, the knee jerk, flexion reflex, and scratch reflex can all be seen for some hours after decapitation. If the spinal cord is severed below the outflow to the respiratory muscles, the animal can survive for long periods with hindlegs isolated from the rest of the central nervous system. When such severance of the cord occurs in man by accidents or gunshot wounds, there is loss of all normal sensation and voluntary control below the lesion.

Spinal Shock

Immediately after severance of the spinal cord, all activity below the lesion is completely absent but is followed by a progressive return of reflexes. In laboratory animals reflexes begin to return in a few minutes and continue to increase in activity and number for some weeks, the flexor reflex and knee jerk are the first to return. In primates, including man, recovery occurs much more slowly and imperfectly and is still continuing six months after the lesion. This depression is known as spinal shock, it is not due simply to the injuries produced in transection for after recovery of reflexes a second section lower down does not reabolish them. It appears to be a sign

of functional disorganization and insensitivity due to the absence of impulse discharges from the higher levels which normally reach many centers in the spinal cord

The Knee Jerk (See also Ch. 61)

The contraction of the knee extensors when the patella tendon is tapped is found in most mammals and similar reflexes occur in many muscles, in man, the ankle jerk seen in the gastrocnemius on tapping the tendo achillis. The jerk reflex is not of obvious purpose, but it is an exhibition of fundamental purposive mechanism by which muscles contract reflexly as a load is imposed on them mechanically. It is of great value in clinical examination and in elucidating reflex mechanisms. A tap causes an abnormal, brief activation of the mechanism by which muscular movement is related to the mechanics of the environment which is especially seen as postural contraction in muscles called on to support the body, often referred to as *antigravity muscles* (p. 1164)

Tendon jerks in man can be studied conveniently by recording the mechanical and electric changes in the gastrocnemius following a tap, a tuned and calibrated blow to the tendon, delivered by a mechanical tendon striker. The record of action potentials from the muscle gives the time of the start of activity in the muscle with more precision than a mechanical record. Some 30 msec after a blow to the tendon the action potential appears in the muscle, and the contraction develops 3 or 4 msec later. Most of the delay or latency of the response is time occupied in conduction to the spinal cord and back to the muscle; there are small latencies between the tap and the initiation of impulses in the afferent neurons, and between the arrival of nerve impulses at the muscle and the development and spread of action potential within it. The reflex can be graded by grading the tap on the tendon, it cannot be suppressed voluntarily, but can be increased by contracting other muscles, e.g., reinforcement by gripping the hands together. The motor impulses leave the spinal cord long before any reach the cortex to produce awareness of the tap.

HOFFMANN REFLEX. If electrodes are placed at A (fig. 63 2) over the course of the popliteal nerve, the same reflex can be set up by stimulating the sensory fibers electrically. The electrically evoked reflex is spoken of as the Hoffmann reflex after its discoverer. The sensory fibers concerned are of low threshold. By gradually increasing the stim-

ulus A, a point is reached where a Hoffmann reflex is obtained, preceded much earlier by a direct response from stimulating a few of the motor fibers. With a strong stimulus the direct response becomes very large, and the reflex disappears because of impulses also travelling antidromically to the spinal cord and producing a refractory state in the motor neurons. The delay between excitation at A and the direct motor response gives a value for the conduction time and end plate delay between A and the start of response in the muscle. Similarly, the reduction in reflex time when the stimulus at A replaces the tendon tap, gives a value for initiation and conduction of impulses to A, so that with the electrically evoked reflex, the time of conduction to the spinal cord, plus central delay, plus conduction back to A, is the interval on the record between the start of the direct response and that of the reflex response (Y, fig. 63 2). This interval (18 to 25 msec) is largely made up of conduction time, and allowing for this, leaves about 2 msec for the time taken between the arrival of sensory impulses at the spinal cord and the appearance of motor impulses leaving it. This is called the *reduced reflex time* and comprises conduction time within the spinal cord (partly in small branches of neurons which may conduct quite slowly) and also of true delay at the synapse.

In man the nerve action potentials have been recorded from the roots close to the cord by in-

FIG 632 Diagram showing elicitation of the patellar and Hoffmann reflexes, inset left oscillographic tracing of the muscle action potential in knee jerk, inset right, the Hoffmann reflex elicited by a shock delivered at A

serting needle electrodes by lumbar puncture. This method was successfully used by Magladerer and coworkers on the spinal cords of medical student volunteers at Johns Hopkins University. However, the central delays can be more conveniently measured at the exposed cord in spinal or decerebrate animals, and it has been so analyzed with increasingly accurate methods during the last forty years. Lloyd found a reduced reflex time of about 1.6 msec in the cat. In Lloyd's experiments the reflex could be set up either by a sharp tug from an electromagnet pulling the tendon of a muscle, or by an electrical stimulus to activate the same fibers. The fibers concerned are the large (16 to 18 μ) axons from which the annulo-spiral endings of muscle spindles are innervated; they can be selectively excited because their threshold is lower than that of smaller fibers. It is now thought that the earliest impulses to leave the cord in the jerk reflex have been interrupted by only a single synapse. It is known from degeneration experiments that many of the afferent fibers go directly to motor neurons and end in boutons terminaux scattered on their surface. Allowing for the conduction within the spinal cord, the delay between the arrival of impulses at the boutons and the initiation of impulses in the motor neurons is 0.6 to 0.9 msec, in some circumstances, e.g., oculo-motor neurons, studied

by Lorente de N6. A synaptic delay may be as low as 0.5 msec. It will be seen later that it can vary from these values when the excitation only just reaches threshold for motor discharge and is a minimum of 0.5 msec, when a previous volley has just entered the cord.

So far we have only considered the earliest component of the knee jerk reflex when a synchronous or nearly synchronous volley of impulses reaches the spinal cord. The initial response is often followed by further discharges of impulses which may travel by interneurons and arrive later at the motor neurons. While the knee jerk enables the activity of the monosynaptic pathway to be uncovered, it is not a pure monosynaptic reflex as normally evoked, and while it is convenient to speak of monosynaptic reflexes they are a simplification arrived at by neglecting the later activity or suppressing it by anesthetics. In the decapitate spinal preparation the muscles are flaccid and cannot support the animal's weight against gravity; in contrast, in decerebrate rigidity (ch 64) the limbs are vigorously extended by reflex contraction more than adequate to support the animal's weight. It was shown by Sherrington that this rigidity of muscles depended on a reflex action elicited by a stretch stimulus, for division of either sensory or motor roots abolished it, and it is inhibited by stimulating a cutaneous nerve

Stretch reflexes are exaggerated in decerebrate rigidity and absent during spinal shock, they return after some days in animals with divided spinal cords

Sherrington recorded the tension in the soleus muscle of the cat when the muscle was stretched (see fig 63.3). The principal structures responsible are the muscle spindles, the tendon organs are not the source of excitation for these can be anesthetized by infiltrating the tendon with novocaine without abolishing the stretch reflex. The spindles activate the motor neurons by the monosynaptic pathway and also by less simple paths. Sherrington gave the name *plastic tonus* to the condition of muscles exhibiting stretch reflexes, because when an attempt is made to flex the limb, the stretch reflex causes the muscle to resist displacement until considerable force is exercised. Then the tonus melts away (clasp knife reflex), the limb moves easily to a new position, but tested in the new position, again it resists flexion.

The position of the muscle spindles and their behavior when the muscle contracts (see ch 62) fits them to provide automatic self-regulating behavior, the spindle is situated in parallel with the rest of the muscle (see fig 63.4). When the muscle contracts, it takes the strain off the spindle and so reduces excitation of the reflex, lengthening the muscle increases the stretch reflex which resists the force causing the extension. This simple basis is refined by two additions, the small (γ) motor neurons which innervate the muscle spindle itself can accelerate its response and so act as control on the sensitivity of the reflex. It has recently been shown by Granit and Merton that many factors which alter the stretch reflex in decerebrate animals modify the activity of the γ motor neurons. We thus have a self-regulating action using the α motor neurons with delicate control exercised by the gamma fiber control of the muscle spindle itself. The other addition leads the plastic tonus to vanish with forced flexion, this appears to be due to the tendon organs.

The most important structures in the stretch reflex (chap 64) are the annulo-spiral endings (ch 62) and the large nerve fibers which innervate them. The role of the flower-spray endings is not yet fully understood. All normal muscular reactions and reflexes are superimposed on the background of the stretch reflex. This means that other activation arriving at the motor neurons finds them in a condition appropriate to the external mechanical load, and the requirements for control of muscular action are thus delegated to a very simple reflex pathway which, by its speed of

FIG 63.3 Response of quadriceps to stretch T of 4 mm, before M , and after P severance of its nerve. During the response M , a stretch of semi-tendinosus begins approximately at S , followed by a stretch of biceps at B . (After Creed, Denny, Brown et al., *Reflex Activity of the Spinal Cord*, Clarendon Press, Oxford.)

action, can co-ordinate muscular action to produce the same movement when a wide range of different conditions of resistance are encountered.

In engineering we speak of a *servo-system* when action is controlled by a mechanism designed to keep that action constant, for example, a centrifugal governor controls an engine to run at constant speed with changing load by regulating the throttle. The centrifugal governor imitates a sense organ and the throttle valve the motor neurons, and the feedback of information about the action to the controlling mechanism is the essential feature. Thus the simple proprioceptive reflex is present under all normal conditions, and other reflexes blend with it and so produce action

related to the mechanical reaction met with in the movement

Phasic and Postural Contraction

The steady contraction of muscle in the stretch reflex is maintained for long periods, and when the activity of individual motor units is studied, it is found that impulses are set up by individual motor neurons at frequencies up to nearly 50 per sec, and may remain substantially regular down to 1 or 2 per sec. A motor unit consists of a neuron in the spinal cord providing the axon which runs to the muscle and divides there, to innervate many muscle fibers (10 to 100). A single activation of a motor unit is the least response that can occur via the spinal cord. The tension exerted by a single motor unit when its nerve fiber is tetanized may amount to as much as 30 grams. The activity of single units has been studied by subdividing motor nerves until the activity of a single fiber can be recorded electrically, but a valuable indirect method was evolved by Adrian and Bronk. They found that when concentric electrodes consisting of a hypodermic needle with a wire, insulated except at its tip, running down its center, was thrust into a muscle, the muscle action potentials of the group of fibers comprising the motor unit, could be recorded. This technique makes it possible to find how a single motor neuron discharges under a variety of conditions. The method has been widely used in man as well as animals and much of our understanding of human muscle control has been derived from it. The slowly repeated discharge of motor neurons in tonic contraction would give tremor in the contraction were it not for the fact that different units fire independently and at differing rates so that the asynchronous activation of the individual units becomes fused into an apparently steady contraction. Increasing voluntary or reflex contraction in man (and animals) is brought about by an increasing number of units being excited and also by an increase in the rate of firing of impulses to individual units. Thus an asynchronous motor discharge is evoked by asynchronous bombardment of the motor neurons by simple or indirect pathways from a large number of sensory receptors. The phasic jerk reflex and the tonic postural contraction depend on common structures and when a tap is given to the tendon of a tonic muscle, many units are activated synchronously, after the jerk is over there is a brief absence of tonic activity — 'the silent period' — while the muscle re-extends

to the original length, the tonic discharge and contraction then continue as before. We thus have a self-regulating action using the α motor neurons with delicate control exercised by the γ fiber control of the muscle spindle itself.

Grading of Reflex Response

Sherrington found in many types of reflex that the response could be graded by grading the strength of the stimulus and this is also seen in the knee jerk in man and tendon reflexes in animals. As the stimulus is increased, there is a threshold at which a *liminal response* is obtained with further increase the reflex grows to a *maximal response*. Further increase may reduce or alter the response. It is, however, found that with the threshold stimulation which just fails to produce any reflex response impulses are in fact being set up in a number of afferent fibers, and there is a central threshold requiring simultaneous arrival of impulses in a number of fibers before a reflex occurs.

Summation and Occlusion

These facts, well known from Sherrington's studies on numerous reflexes are clearly seen in the simplest form in Lloyd's experiments stimulating dorsal roots in the spinal cord with gradually increasing shocks, and recording the size of the action potential both of the sensory fibers and of the motor fibers. The magnitudes are closely related to the number of sensory fibers activated and the number of motor neurons excited to carry impulses out to the muscles (see fig. 63.5). The graph in figure 63.6 shows that a certain number of sensory fibers must be activated before any reflex occurs. The reflex grows rapidly with further addition of active sensory fibers and gradually reaches a maximum when all of the large fibers are excited. The relationship is clearly not a linear one and underlies the properties described by Sherrington as 'spatial summation' and 'occlusion'.

When two afferent nerves give a reflex in the same muscle, convergence is said to occur, if both are stimulated simultaneously the contraction is not the sum of the two separate reflexes. If stimulation is near threshold it is greater, i.e., *spatial summation* takes place, if both are maximal, it is less than their sum. *Occlusion* is present.

If in figure 63.6 we imagine the sensory fibers divided in two and placed on two pairs of stimulating electrodes, the case closely resembles Sherrington's investigation of volleys set up in two

FIG. 63.5 Dorsal root ventral reflex discharges from the first sacral segment. The successive records illustrate the growth of the reflex discharge as the afferent (dorsal root) volley is increased in size. The figures to the right hand of each observation give the relative size of the afferent volley employed for that observation. Time = 5 msec. (After Lloyd.)

nerve branches reaching the spinal cord together. If both stimuli are set to the threshold in isolation, each may activate 10 per cent of the total ingoing fibers which fail to evoke a reflex. When both are stimulated together, 20 per cent of the fibers will be activated, and from the graph it is clear there will now be a large reflex owing to summation. For stimuli close to the threshold the summated response may be many times that of either alone.

If, on the other hand, both stimuli are set to activate all the fibers in each nerve, each alone will produce a 50 per cent maximal volley, and thus as may be seen from the graph will activate 90 per cent of the efferent units. However, both activated together cannot produce 180 per cent of the maximal response. The deficit between the actual response and the response calculated from the sum of the two, namely 80 per cent, is due to "occlusion" and reflects the anatomical fact that many neurons receive afferent excitation from fibers that branch and supply many others. It is known that any motor neuron may receive some hundreds of boutons terminaux from different fibers, it is deduced that for an impulse to be set up a minimum number of boutons must be simultaneously active. If a neuron has sufficient boutons activated, it fires a motor impulse, but further addition of more from the other nerve cannot lead the all-or-nothing structure to do more immediately. Hence it is usual to see summation between reflexes evoked by near-threshold stimuli while occlusion is often seen with stimuli activating a higher proportion of the fibers.

Something of the organization of boutons from different nerves is learned by finding the nerves

FIG. 63.6 Dorsal root ventral root reflex preparation. The size of the two neuron arc (2N) reflex discharge is plotted against the size of the afferent volley evoking the reflex. Inset: The initial portions of similar curves from other experiments to illustrate the variation in onset of the reflex discharge from one experiment to another. (After Lloyd.)

between which summation can occur. In general, sensory fibers from muscles that act synergically at the same joint produce summation while those from antagonistic muscles do not and may produce a depression of the reflex response known as inhibition. The response occurs primarily in the motor neurons supplying parts of the muscle close to the origin (muscle spindles) of the sensory fibers concerned. Thus the jerk reflex utilizing a monosynaptic pathway is anatomically localized and restricted by the pattern of central connec-

tions, and the flexibility of response is not nearly as great as when interneurons are concerned in reflexes considered later

Facilitation—Temporal Summation

When a volley of impulses is subliminal, no reflex takes place. Yet we cannot assume that no effect has been produced within the central nervous system, for as described above, two subliminal volleys together may produce a substantial reflex response. However, the two volleys do not need to arrive simultaneously to produce summation. It also occurs when the same nerve fibers are activated twice in quick succession, *temporal summation* can occur. The change of state in the central nervous system by which the second subliminal volley is rendered liminal is spoken of as *facilitation*. To study facilitation, a volley may be sent into the spinal cord, referred to as the conditioning volley, followed by a second the test volley, to see how the response differs from that obtained when the test volley is used in isolation. Temporal summation has been studied in many reflexes since the beginning of the century, but will be first considered in relation to the simple monosynaptic activity as in the tendon jerk. If the test volley and conditioning volley are simultaneous, and applied to different

portions of the nerve, we have *spatial summation*. As the two volleys are separated in time, the response to the test volley becomes less, the time course is shown in figure 63 7, obtained by Lloyd from the cat, the later activity of the polysynaptic pathways is evident in the upper curve. It will be seen that the response has fallen to about half at 3 msec, the facilitation continues to decay exponentially. The later part of this curve can only be obtained with weak stimuli for the activity of interneurons leads to additional phenomena which are responsible for the upper curve. It is clear that under these conditions, the change of state at the motor neurons outlasts the arrival of the afferent volley, and something persists for a number of milliseconds which is able to make a later volley more effective. Sherrington named the change of state in facilitation "the central excitatory state", and suggested that excitation had to accumulate somewhere in the pathway and reach a certain level before discharge of the motor neurons occurred. This has been substantiated in more concrete terms by recent investigations described later.

Flexor Reflexes

The purposive significance of these reflexes is clear. A noxious stimulus, such as pinching applied to a limb leads to its rapid withdrawal and concurrently a crossed extensor reflex is often seen with it. The flexor reflexes can be obtained in many mammals and man by a painful or noxious stimulus. The afferent fibers are those from the skin and the response can be obtained by stimulating wide regions of a limb by pin prick or an electrical stimulus. Stimulating a mixed nerve trunk is often followed by reflexes of flexion. The stimulus is abnormal in that fibers from different regions and of diverse function may be stimulated simultaneously, this does not normally occur with sensory stimuli. The limb is rapidly withdrawn and may be maintained flexed for several seconds following a strong stimulus.

As in the stretch reflex, phasic and sustained components in the reflex can be identified (fig 63 8), after nearly synchronous activity in rapid withdrawal, the motor units fire at rates of 5 to 40 per sec during the maintained flexion.

Facilitation may be readily demonstrated in flexor reflexes. Using an electric stimulus to a nerve to elicit the phasic component of the reflex, Sherrington and Eccles showed that as the stimulus was increased in strength, the latency shortened, when a threshold response was obtained, it

FIG 63 7 Facilitation of biceps reflex by afferent volleys in semitendinosus nerve. Amplitude of the test reflex expressed as per cent of control amplitude, is plotted as function of the time interval between conditioning and test volleys. To obtain the curve represented by dots, conditioning volleys of near reflex threshold strength were used. Stronger conditioning volleys caused the appearance of a second period of facilitation (crosses) (After Lloyd)

occurred later than when a stronger stimulus was used to evoke a large reflex. The reduced reflex time for the flexor reflex in the cat is about 25 msec, and a greater synaptic delay than in the jerk reflex is to be anticipated for the fibers innervating the skin do not appear to possess boutons on the motor neurons themselves, but all end on interneurons so that at least two synapses must occur in the path used by the flexor reflex. Temporal summation for this pathway is found over much greater intervals than in the monosynaptic pathway. With facilitation, the delay suffered by a volley of impulses reaching the spinal cord shortly after each other may be reduced to a minimum of a little over a milli-second. From such effects Sherrington formed his theory of a gradable central excitatory state which caused motor neurons to fire when sufficiently intense, and which persisted some time after the afferent impulses were over. Such a theory immediately suggests an interpretation of the reduction in latency when facilitation occurs. This is illustrated in figure 63.9. The central excitatory state postulated by Sherrington has since been shown to be closely related to electrical changes that can be recorded from central structures during activity.

Inhibition

Impulses travelling in sensory fibers from an antagonist muscles may produce a reflex response in those muscles but depress the response of the agonist. For this to occur, they must arrive at the spinal cord at least 0.5 msec before the impulses producing the reflex. We are no longer dealing with simple, invariable conduction such as is seen in peripheral nerve even in these simple, direct reflex pathways, reflex response may be prevented by nerve impulses of different origin. Such inhibition, which will be considered in detail later, may be prolonged, for instance a single excitation of a nerve supplying the skin can abolish the knee jerk completely in a spinal cat for up to $\frac{1}{2}$ sec.

Crossed Extensor Reflex

As the pathway in the central nervous system becomes more complicated there is an increasing modification of the impulse patterns in travelling through the spinal cord. In the crossed extensor reflex the latency may be many times longer than in reflexes considered above. With a weak stimulus repetition at $\frac{1}{10}$ sec intervals for a second or more may elicit the reflex. The discharge of

FIG 63.8 Flexion reflex showing after discharge. The duration of the stimulus is indicated by the pair of nearly vertical lines (After Sherrington)

FIG 63.9 Diagram of graded central excitatory state reaching a motor neuron threshold giving earlier response to a large volley of $\wedge$ and maximum shortening of latency with facilitation by a previous subliminal stimulus

impulses by the motor nerves is no longer closely related to each volley of afferent impulses but the firing rate of the motor neurons is independent and often asynchronous in different units. The reflex builds up slowly over several seconds and on cessation of the stimulus dies away slowly with after-discharge occurring in the motor neurons.

The crossed extensor reflex is normally seen blended with the tonic stretch reflex in the muscle examined and there is co-operation between the two reflexes. Thus when the stimulus is made so weak that no reflex occurs in the slack muscle when repeated with the stretched muscle a reflex may result. Similarly when the muscle is stretched a contraction results if a contralateral skin nerve is stimulated subliminally for producing a reflex. If the muscle be deafferented by cutting the sensory roots the crossed extensor reflex can still be elicited by stimulating a skin nerve on the other side. However now threshold is raised the onset is more abrupt, and the after discharge shortened. With the stretch reflex blended with it the response is less explosive.

The crossed extensor reflex is inhibited by stimulating a skin nerve on the same side, and may thus be replaced by a flexor reflex. There is then said to be algebraic summation of the

central excitatory state and central inhibitory state produced

Reciprocal Innervation

It has been seen above that afferent fibers from a muscle excite it monosynaptically, while those from antagonists inhibit it. Such reciprocal effects are found from many muscles, but the interconnection of central neurons, on which reciprocal innervation rests, are not solely or even primarily functions of the afferent fibers from the limb.

At the beginning of the century, Graham-Brown showed that under very deep anesthesia alternating movements of the limbs may occur. This was given the name of *narcosis progression*. Study of such phenomena shows that reciprocity occurs between the centers of antagonistic muscles even when all the sensory roots supplying them are cut. For instance, in the spinal cord of a cat with all lumbar sensory roots cut, stimulation of the cord or of roots above or below the lumbar enlargement provokes alternating movements of the limbs, and even under such conditions reciprocal contraction still holds. Activity ceases in one muscle when at its height in the antagonistic muscle. It becomes clear then that central connections must underlie reciprocal innervation as well as specific effects elicited via fibers from a particular muscle when these are intact. When the motor neurons of any muscle are excited, a diminution of excitability occurs in the motor neurons of the antagonist. The detailed nature of these central interconnections is not yet fully understood.

Fractionation

The reflexes considered above fall into the class of segmental reflexes in that they are largely determined by fibers entering a segment and excit-

ing or inhibiting the motor neurons within that same segment. Normally, intersegmental connections by propriospinal fibers co-ordinate activities at different levels and in the flexor reflex evoked by a pinch stimulus to the skin, excitation will reach two or three segments from the sensory fibers but may spread far outside these. The reflex flexion occurring in any particular muscle changes when the position of the sensory stimulation is altered. The motor neurons to a particular muscle form the final common path for many reflexes, and when different sensory nerves are stimulated, the activation varies considerably. This is spoken of as *fractionation*, and typical results are given in table 63.1.

Scratch Reflex

The scratch reflex is elicited by light stimulation of the flank and is readily elicited from a spinal (or normal) dog. Its purposive nature is obvious. Sherrington used a small star-wheel or mechanical flea which, when rolled along the skin, would evoke reflex scratching. Alternatively the skin may be stimulated with a weak electric shock. When the stimulus is moved on the skin, the balance of activity in the muscles alters to make the limb scratch close to the stimulated spot. Incoming sensory nerve impulse discharges thus possess *local sign* which determines the exact pattern of activity distributed among the motor neurons of the several muscles that are involved. Many reflexes require alternating movements, scratching, walking, swimming, etc., and alternating activity is easily provoked in the spinal centers. Such movements are spoken of as *clonic*, and the second movement is often assisted by sensory stimulation produced during the first movement. The interconnection of centers which underlies reciprocal innervation is also involved.

The propriospinal pathways link not only neighboring segments but also the lumbar and brachial enlargements in quadrupeds, and in *narcosis progression* there may be alternating activity in flexors and extensors in opposing phase on opposite sides, co-ordinated with similar movements in the forelimbs. The appearance of spinal shock below a section has already been mentioned, but when the cord is divided there are also modifications of reflex activity spreading forward from the section. The best known of these is the "Sherrington Schiff phenomenon." If in a decerebrate animal the spinal cord be divided between the lumbar and cervical enlargement, the hindlimbs immediately become flaccid and recover

TABLE 63.1

The tensions of the reflex responses for each nerve are expressed as percentages of the strongest contraction

Nerve	Hip flexor (tensor fasciae latae)	Knee flexor (Semi- tendin- osus)	Ankle flexor (Tibialis anticus)
Internal saphenous	100	56	87
Popliteal	3 or less	42	100
Peroneal distal to tibialis anticus	14	100	69

FIG. 63.10 Electrical changes in anterior roots of the frog in response to shock excitation. Ventral roots cut. A 14°C electrodes 1.5 and 11 mm. Single shock to ipsilateral sciatic at arrow. B 16°C electrodes 2 and 11 mm. Single shock to ipsilateral dorsal root. Cord cut through about 2.5 mm above and below exit of root. C, 16°C electrodes 1.3 and 10 mm. Single shock to ipsilateral peroneal nerve. D 15°C electrodes 2.5 and 11 mm. Repeated shocks to ipsilateral peroneal nerve marked by arrows (Time marker $\frac{1}{50}$ sec for A, C at foot of C $\frac{1}{10}$ sec on D) (From Barron and Matthews)

from shock slowly the forelimbs become even more active in decerebrate rigidity, and all reflexes in front of the section are enhanced and more easily elicited. This is attributed to removal of forward travelling impulses that have an inhibitory action on the forward centers.

Visceral Reflexes

In addition to the somatic reflexes underlying locomotion and protection a number of reflex actions involving the viscera can be elicited in animals with the spinal cord divided. Immediately following a spinal section there is loss of vasomotor tone, and it appears that continual tonic discharges from the vasomotor center in the medulla are necessary for the normal contraction of capillaries and arteries. With recovery from spinal shock, however, tone gradually returns to the vessels and it is supposed that the lower neurons concerned (in the lateral columns) which supply the sympathetic system gradually accommodate until their activity is maintained without supraspinal impulses reaching them. The sacral outflow is normally the final common path for the reflexes of defecation and urination, and these reflexes can be elicited in the chronic spinal dog by distention of the bladder or rectum although the pattern is abnormal. Similarly some sexual reflexes are also present. Goltz and Sherrington showed that with the spinal cord divided in pregnancy and parturition took place. Stimulation of the genitalia was followed by erection and copulation with the accompanying muscular activity. The reflexes of pilo-erection are mediated via the sympathetic system but cannot easily be elicited in the spinal preparation. When a spinal preparation is asphyxiated by stopping the respiration pump, many neurons concerned discharge

vigorously and reflex co-ordination is disrupted. A mass discharge of motor impulses may occur with convulsive movements, which no longer show reciprocal innervation; these are followed by defecation, urination and pilo-erection.

Electrical Activity of Central Nervous Tissue

Electrical changes can be led off from electrodes in or close to the spinal cord in a number of ways, and different components are emphasized with different arrangements of electrodes.

(a) *Electrodes on the surface* yield a negative and positive complex when any volley of impulses enters the cord which long outlasts the action potentials of the impulses.

(b) *Electro-tonic potentials* observed from the roots of the spinal cord indicate changes occurring within the cord in the fibers examined. Thus when an afferent volley reaches the spinal cord, a sequence of changes is recorded from the dorsal roots lasting some 100 msec and a different sequence of changes from the ventral roots. The latter are closely related to the discharge of impulses from motor neurons (fig. 63.10).

(c) *Focal potentials*. When a fine insulated wire or a saline filled micropipette is thrust into the central nervous system and records are made between this electrode and a distant electrode on non active tissues, a record is obtained which varies with the position of the electrode in the cord and shows a correlation with reflex activity.

(d) *Intracellular electrodes*. If fine glass micropipettes are drawn with a tip diameter of $\frac{1}{2}$ to $1\ \mu$ and are filled with a saline or strong KCl solution single cells may be punctured without their normal activity ceasing immediately—although in many cases the injury produces a

FIG 63.11 Intracellular potentials set up in a BST motoneuron by two afferent volleys in BSt nerve, the first being submaximal for group I fibers, the second being set up by a supramaximal stimulus. Note that summation to set up a spike occurred at the shortest interval (first record), the intervals of the second and fourth which are equal, being just critical. A and B show precisely the same responses but at high and low amplifications respectively. (From Brock and associates)

rapid discharge of impulses if they are severely damaged.

From observations by these methods it is clear that the arrival of a volley of sensory impulses results in a depolarization of some part of the motor neuron surface which, if sufficiently intense, culminates in a propagated impulse.

With asynchronous bombardment of the motor neurons, long-lasting depolarization of motor neurons occurs, and the rate of rhythmic discharge is related to the magnitude of the local potential.

When the monosynaptic reflex was studied by Eccles and his collaborators with intracellular electrodes, the local synaptic potential corresponding to Sherrington's CES had a rapid rise and lasted some 5 or 6 msec (fig 63.11). Summation between successive local changes could be seen to occur. When impulses from an antagonistic muscle were set up, which caused inhibition, the depolarization was counteracted by a hyperpolarization having about the same time course as the depolarization. However, stud-

ies both of intracellular and root potentials have shown that the volley-producing inhibition sent in isolation produces little or no hyperpolarization, but is effective in neutralizing depolarization caused by an excitation of the reflex.

It is thus possible to consider Sherrington's concepts, CES and CIS, as an index of the electrical state at the motor neurons which is closely related to their excitability. It should be emphasized that electrical changes in fluids imply movements of ions but that ions have a chemical nature as well as an electrical charge, and that the electrical and chemical aspect of events at the synapse are complementary and represent descriptions in the terms of charge or chemical nature of the same processes.

Theories of Reflex Action

The concepts of a central excitatory state and central inhibitory state, derived from reflex experiments, can be related to the depolarization and hyperpolarization of the neuron surface demonstrated for some components of simple reflexes. These demonstrate changes of state which outlast the action potential of the afferent volley. In the periphery, e.g. at the motor endplate, the importance of humoral transmitter substances is fully established, and clearly the central changes of state are consistent with long lasting transmitter substances being released on the synaptic surfaces. The presence of humoral agents or chemical transmitters has been sought within the central nervous system. Owing to the complexity of the situation it will be a long time before we can describe the processes of the various synapses in very exact chemical terms but a number of agents, including acetylcholine and adrenaline, have profound effects on central structures.

In many quarters it is held that as a neuron appears to be a pharmacological unit producing the same transmitter at all its terminations, the same incoming volley could only produce an exciter substance at one point and an inhibitory substance at another if an additional neuron were located in the second pathway. There is some evidence that this may be the case, e.g., the 5 msec by which an inhibitory volley must precede a testing volley to produce direct inhibition. Chemical transmission provides a simple basis for long lasting changes which can be extremely prolonged in regions where the enzymes destroying the transmitter are in low concentration, and it offers an explanation of the very

prolonged effects (several seconds) that may follow a single inhibitory afferent volley

However, a second theory has been developed (see Lorente de No) to account for long lasting activity. It suggests that closed chains of neurons have impulse activity circulating around them and may produce re-excitation of other neurons for long periods (see Wall). While this is an attractive idea which is consistent with many of the phenomena observed, no direct evidence of the reverberating chains has yet been found, and the stability of long lasting changes after gross surgical interference with parts of the spinal cord makes it difficult to accept this hypothesis for some of the common long lasting electrical and reflex events observed. However, it is clear that centers in the cord can interact by internal connections as in reciprocal innervation after deafferentation.

THE PHYSIOLOGICAL MECHANISMS GOVERNING POSTURE AND EQUILIBRIUM

Stretch or Myotatic Reflexes

One of the basic reflexes is the stretch reflex. It is present in all healthy skeletal muscles, but it is more pronounced in some muscles than in others and is more readily elicited and more pronounced under certain circumstances. When a muscle is stretched it responds by contracting. This is the stretch reflex. Pulling on the muscles stimulates the muscle spindles (see ch. 62 and p. 699) which are specialized sensory end organs lying among the muscle fibers. These spindles send afferent nervous impulses up the muscular nerve and into the spinal cord over the posterior spinal root. Within the spinal cord these impulses are transferred over a single synapse to the α motor cells of the anterior gray column of the spinal cord. These α cells, in turn, send impulses out over the anterior spinal roots, down the muscular nerve and into the skeletal muscle where they cause the muscle to contract. This reflex is normally present and serves particularly to maintain the body of the animal in an upright position. Such reflexes are, therefore, more pronounced in the extensor muscles. These reflexes become exaggerated after the cerebrum is removed by transecting the brainstem through the mesencephalon (decerebration). This produces a state known as *decerebrate rigidity* in which stretch reflexes are more easily elicited; these stretch reflexes are commonly studied under the abnormal circumstances of decerebrate rigidity. Naturally, section of either the related anterior or posterior spinal root, or dividing the muscular nerve, or destroying the related portion of the spinal cord interrupts the reflex arc and abolishes the response. The muscular response is proportionate, within limits, to the stretching force, and persists as long as the stretching is maintained. The muscular contraction ceases as soon as the stretching force is withdrawn, i.e., there is no after-discharge. The latent period of the stretch reflex is short—less than 20 msec. This reflex is readily inhibited by stimuli to the extremity which would ordinarily be painful (nociceptive stimuli), or by stimulation of the afferent nerves from the skin, or by stretching the antagonistic flexor muscles, or by applying excessive stretching force to the muscle itself or to its tendon. This latter inhibition gives rise to the lengthening reaction (see below). These forms of inhibition are largely devices to protect the muscle from overextension, and the animal from injury. In figure 641 are the graphic results of the classical experiments of Liddell and Sherrington demonstrating some of these points.

As noted above the stretch reflex is enhanced by decerebration. Such transection of the mid-brain abolishes controlling inhibitory impulses from the cerebral cortex, the basal ganglia and the anterior lobe of the cerebellum which are transmitted down the spinal cord from the bulbar reticular formation, while leaving intact the facilitatory mechanism in the more caudal portions of the reticular formation. Even with fixed lesions of the central nervous system the intensity of the muscular responses to the stretch reflex wax and wane under varying circumstances. This modulation of the reflex response may be brought about by changes in these facilitatory impulses which affect the stretch reflex directly, or by descending impulses which vary the response of the muscle spindle to stretch. This latter effect is produced over small neurons known as gamma efferents which arise in the anterior gray columns of the spinal cord and innervate the intrafusal muscle fibers within the muscle spindle. This control of the responsiveness of the peripheral sensory end-organ is in considerable measure exercised by the reticular formation of the brain stem. By varying the tension within the muscle spindle, its response to stretch is varied and, in turn, the reflex muscular contraction.

The afferent fibers of the myotatic reflex arcs are large calibered, myelinated, rapidly conducting fibers of the A group. The dark muscle fibers of the extensors, upon which the maintenance of posture depends, are also more plentifully supplied with these fibers.

The afferent fibers of the myotatic reflex arcs are large calibered, myelinated, rapidly conducting fibers of the A group. The dark muscle fibers of the extensors, upon which the maintenance of posture depends, are also more plentifully supplied with these fibers.

FIG 64-1 The stretch reflex of the quadriceps (cat). Muscular response (M) before and (P) after cutting nerve to the muscle. T is a record of the table fall which stretches the muscle. At the right is shown the effect of reflex inhibition, evoked between 1 and 1' by stimulation of afferent fibers in the ipsilateral peroneopopliteal nerve (from Lloyd and Sherrington)

plied with large diameter nerve fibers than are the proprioceptive fibers of flexor muscles. The stretch reflexes show reciprocal innervation, when a muscle reacts by contraction to a stretching force its antagonist relaxes. The myotatic unit which consists of muscle receptor, afferent nerve fiber, spinal center and motoneuron, "exhibits within itself in full measure the elementary mechanism of reciprocal innervation" (Lloyd)

THE KNEE AND ANKLE JERKS

A sharp tap upon the patellar tendon, when the knee joint is semi flexed stretches the quadriceps extensor muscle and causes it to contract. Similarly a blow upon the tendo-Achilles causes a quick contraction of the calf muscles. These brief contractions or jerks, as well as those described below for the upper limb, are "fractional examples of the stretch reflex" and are not due to stimulation of the tendon but stretching the muscle. A stretch of 0.05 mm or less in $\frac{1}{20}$ second being sufficient to elicit the response. A voluntary action, such as clapping the hands together, reinforces the reflex and increases the force of the jerk. The center for the knee jerk in the human subject lies in the 2nd, 3rd and 4th lumbar segments of the cord, it is innervated through the anterior crural nerve. The center for the ankle jerk is situated in the 1st sacral segment, the peripheral nerve is the sciatic. Lloyd has shown that only two neurons are involved in the reflex arc of the knee and ankle jerks, and of other myotatic reflexes, i.e., the impulse passes from afferent fiber to motor neuron without traversing an internuncial neuron (see also ch 62)

Any condition, such as decerebration or injury

to the descending motor pathways (ch 65), which enhances the stretch reflex increases the tendon jerks. They are abolished by an injury or disease involving the efferent or afferent limb of the reflex arc or the center itself (anterior horn cells). On account of its brief twitchlike character the knee jerk is sometimes spoken of as the "phasic reaction" of the stretch reflex, whereas the sustained contraction resulting from a continuous pull upon the tendon, and which is concerned in the maintenance of posture, is referred to as the "static or postural reaction" of the stretch reflex. The knee jerk is less subject to abnormal states, e.g., spinal transection, anesthetics, circulatory failures, etc., than are the postural reactions. In an animal such as the dog or rabbit, the knee jerk returns in a few minutes after spinal transection, in the monkey after some days. In man, though postural reflex activity is entirely lost, the muscles being quite flaccid, the knee jerk is elicitable in some degree in some 3 weeks or even earlier after a complete transverse lesion of the spinal cord (see ch 65).

The smooth and steady character of the contractions brought about through the ordinary stretch reflexes concerned with the maintenance of posture, is due to the asynchronous nature of the impulses set up by the numerous stretch receptors and the asynchronous reflex discharge of impulses down the motoneurons to the muscles. The muscle fibers are, therefore, never all relaxed nor all contracted at the same time. The sharp contraction of the quadriceps characteristic of the knee jerk, on the contrary, is brought about by the discharge of a volley of synchronous impulses and therefore by the fibers of the muscle contracting in unison.

Clonus. Under certain conditions a muscle or group of muscles instead of contracting smoothly and continuously may do so rhythmically in a series of rapidly repeated movements or jerks. Thus, in lesions of the central nervous system associated with hypertonus, sharp passive dorsiflexion at the ankle joint with maintenance of the foot in the dorsiflexed position by light pressure upon the sole, evokes a stretch reflex which con-

¹When the electrical responses are recorded from the muscle of an animal during the elicitation of a tendon jerk, cessation of the action currents is found to occur during the actual contraction of the muscle. Thus, the so called "silent period" is probably due to the muscle spindles being relieved of stretch as the muscle shortens (see p 1151). An additional factor is the synchronous nature of the discharge down the motoneurons, for, the latter being all excited in unison pass also simultaneously into the subnormal phase.

sists of a series of rhythmical contractions of the stretched muscles (ankle clonus). The sudden dorsiflexion causes a sufficient number of stretch receptors to discharge a synchronous volley of impulses along the afferent nerve to the spinal centers and a synchronous efferent volley to be discharged to the muscles. The continued stretch of the muscle caused by keeping the ankle in the dorsiflexed position sets up another synchronous volley as soon as the motoneurons have recovered each time from the subnormal phase of the preceding one. Thus, the clonic movements continue so long as the muscles are kept upon the stretch. Clonus can be evoked in a similar fashion in other situations.

SOME OTHER STRETCH REFLEXES (DEEP OR TENDON REFLEXES) OF CLINICAL IMPORTANCE

The jaw jerk. Tapping the chin with the mouth partly open, and jaw supported, stretches the masseters which contract and jerk the jaw. The reflex center is in the pons.

The biceps jerk is elicited by a sharp tap upon the biceps tendon in front of the elbow joint, the response consists of a quick contraction of the biceps with flexion of the elbow. The center for the reflex is situated in the 5th and 6th cervical segments of the cord, it is innervated through the musculocutaneous nerve.

The triceps jerk is evoked by a blow upon the triceps muscle just above the olecranon process of the ulna, contraction of the muscle and extension of the elbow result. The center for the response lies in the 6th and 7th cervical segments; the peripheral nerve is the musculospiral (radial).

The supinator jerk consists of contraction of the supinator muscle and flexion of the elbow, it follows a blow upon the styloid process of the radius. The center lies in the 5th and 6th cervical segments of the cord, the peripheral nerve is the musculospiral.

Rossolimo's reflex which is seen with hyperactivity of the stretch reflexes in the lower extremity, consists of flexion of the toes, including the hallux, when the toes are flicked on their plantar surfaces. A similar response (*Hoffmann's reflex*) which consists of a sudden flexion of the terminal phalanx of the thumb can be evoked by flicking the finger tips.

The Tone of Skeletal Muscle

As a result chiefly of the work of the Sherrington school the word "tone" or "tonus" as applied to skeletal muscle has acquired a clearly defined

meaning. Muscle tone is the steady reflex contraction of the muscles concerned in maintaining the posture characteristic of a given animal species. To use Sherrington's words "reflex tonus is postural contraction." Tonus has its basis in the "static reactions" of the stretch reflexes, and its seat is therefore mainly in the *antigravity muscles*. In most mammals these are extensor muscles and in decerebrate rigidity the animal exhibits an attitude which is a caricature of standing, due to an exaggeration of the tone of the extensors.

In man the antigravity muscles and consequently those which exhibit the greatest degree of tone are the retractors of the neck, the elevators of the jaw (masseters), the supraspinatus, the extensors of the back, the ventral muscles of the abdominal wall (probably), and the extensors of the knee and ankle (vastocruress, gastrocnemius and soleus). When these muscles are completely relaxed, as in an unconscious person, the body collapses. In the healthy conscious person stretch reflexes are largely instrumental in preventing this occurrence.

Though the fundamental basis of tonus in voluntary muscle is the myotatic reflex centered in the spinal cord, the tonic state is influenced profoundly by higher centers. Impulses from labyrinthine and neck muscle receptors (pp. 1166 and 1170) exert their influence upon this background of tonus established through lower spinal centers. Similarly pathways from cerebellar, midbrain and cerebral centers convey impulses which impinge upon the final common path, are capable of altering the degree of tonus, or effecting finer adjustments in the tonic state and of maintaining its normal distribution between groups of muscles (fig. 648, p. 1173). The tone of a given group of muscles may also be influenced through the spinal centers by impulses arising in other muscle groups (e.g., neck muscles and the muscles of the digits, ankle and wrist, as in the positive supporting reaction) and in skin receptors.

When the spinal centers are separated from higher centers there is an areflexic state of muscular flaccidity. Gradually this gives way to a state of hyperreflexia. The extensor tone, however, never is as pronounced as in decerebrate rigidity, whereas the flexor reflexes are more active.

A feature of tonic contraction is its economy in the expenditure of energy. Posture is maintained for long periods with little or no evidence of fatigue, e.g., in decerebrate rigidity in the maintained closure of the jaws, standing or sitting in the normal person, and in the clasp reflex of

FIG 642 The reflex effect of the labyrinthine and neck reflexes on red and pale muscle. Preparation with section of brain stem slightly anterior to superior colliculi. M. triceps, short lateral head (pale) double traced line, short medial head (red), single line. Neck dorsiflexed at ↑ and ventrified at ↓. Labyrinth in intermediate position in each neck posture. (From Creed Denny Brown Eccles, Liddell and Sherrington *Reflex Activity of the Spinal Cord*, Clarendon Press.)

the frog. The increase in metabolism is less than in the case of those ordinary contractions which result in movement, though the difference is not as great as was once supposed.² The work of Forbes and of Adrian and their associates indicates that the economy of energy is effected through different groups of muscle fibers contracting in relays, only a proportion of the total number of fiber groups of the muscle being active at any moment. Thus, active fiber groups mingled with inactive groups are scattered throughout the muscle. The alternating periods of rest and activity of the muscle groups explains the ability of the tonic contraction to be maintained for so long without showing fatigue.

RED AND WHITE MUSCLE

The skeletal muscles of many animals, e.g., birds, rabbit, cat, etc., can be clearly divided into two types: (a) red or dark and (b) white or pale. The former, as compared with the latter, are composed of smaller fibers having a granular and more opaque appearance, possessing more distinct longitudinal striations but less pronounced cross striations and containing a larger proportion of sarcoplasm.³ These red fibers contract more slowly, fatigue less readily, and are tetanized at a slower rate of stimulation than are the pale fibers. The pale fibers are translucent, show prominent cross striations and a small quantity of sarcoplasm.

² In the normal human subject postural contractions cause a rise of from 50 to 70 per cent in the basal metabolism. In certain nervous states, in which the body is maintained in fixed attitudes for long periods (catatonia), the increase in metabolism resulting from the tonic contraction of the muscles is less (20 per cent) than in the normal subject. The circulatory effects of sustained posture are also less pronounced in the pathological cases.

³ They resemble the intrafusal fibers of the muscle spindle (p. 1146).

FIG 643 A suspended decerebrate cat showing extensor rigidity. In A the labyrinths are intact. In B a decerebrate and labyrinthectomized animal. As a result of the destruction of the labyrinths the head has dropped, this position of the head induces reflex flexion of the forelimbs and extension of the hindlimbs (tonic neck reflexes, p. 1171) (After Pollock and Davis.)

Those muscles which execute rapid movements are usually, though not invariably, of the pale variety, whereas the slower movements are carried out chiefly by the dark muscles. It is probable that all muscles are a mixture of the two types of fiber, but that in some the red in others the pale type predominates. The segregation of the two types of fiber in different muscles is much more pronounced in some animals e.g. the fowl and rabbit than in others. In birds capable of soaring or of long flight the wing muscles are mainly of the red type. In man and the monkey the two kinds of muscle can be distinguished with the naked eye though the differences are not very pronounced. The predominance of one or other type of fiber, can however be readily made out under the microscope. The rapidly contracting flexor muscles are largely composed of the pale fibers, whereas each of the extensors usually has a superficially placed, rapidly contracting, pale component (or head) and a deep slowly acting dark head. No hard and fast line, however, can be drawn, since both types of extensor muscle exhibit tone, and both take part in phasic contractions (Fig. 642).

Decerebrate Rigidity

This is the term applied to the sustained contraction of the extensor muscles which supervenes upon transection of the brain stem at any level between the superior colliculi and the vestibular nuclei.⁴ It was first studied and described in de-

⁴ Decerebration can also be produced by tying the common carotids and the basilar artery at the center of the pons and thereby depriving the fore brain of its blood supply.

tail by Sherrington. The animal assumes a characteristic attitude with limbs stiffly extended, head retracted, jaws closed and tail horizontal or erect. When placed upon its feet the limbs support the weight of the body (fig 643A). The position is a caricature of the normal standing position. The knee jerk and other stretch reflexes (pp 1162, 1163) are exaggerated. The righting reflexes are abolished. tonic neck and labyrinthine reflexes are retained.

In some instances there is increased reflex excitability of the flexor muscles as well but the characteristic feature of decerebrate rigidity is the tonic contraction of the muscles which maintain the posture of the body against gravity (p 1152) the *antigravity muscles*. It may be pointed out that in the frog whose natural posture is squatting with flexed thighs, legs and arms it is the flexor muscles which are the site of decerebrate rigidity. Also in the sloth whose habit it is to remain for long periods suspended from a tree branch flexor rigidity is the characteristic result of decerebration. In the pigeon the flexor muscles which maintain the resting (folded) position of the wing exhibit rigidity and in the ape the muscles which hold the elbow semiflexed when the body is erect show increased tone. In man abolition of the function of the cerebral motor cortex results in a state of increased tone in the flexors of the arms and in the extensors in the lower extremities whereas decerebration at the mesencephalic level is associated with extensor spasticity in all four extremities.

TONIC LABYRINTHINE AND NECK REFLEXES IN THE DECEREBRATE PREPARATION (SEE ALSO P 1171)

Labyrinthine proprioceptors are responsible for the tone of the neck extensors; consequently after destruction of the labyrinths in the decerebrate preparation the head is no longer held erect but falls into the fully flexed position. The rigidity in the forelimbs in turn is maintained through proprioceptive reflexes initiated in the extended neck muscles as well as directly through labyrinthine reflexes (p 1171). After labyrinthectomy, therefore the flexed position assumed by the head sets up proprioceptive impulses from the neck muscles which lead to a reduction in the extensor tone of the forelimbs; these then become strongly flexed upon the chest (fig 643B). If the neck muscles of the labyrinthectomized animal are deafferented movements of the head are without effect upon the extensor muscles of either fore or hind limbs.

LENGTHENING AND SHORTENING REACTIONS

Attempts at passive flexion of the extended limb of the decerebrate (or chronic spinal) preparation are met by considerable resistance. If the force is increased beyond a certain point the stretch reflex (upon which the resistance depends) is inhibited and the limb gives way suddenly (*clasp knife effect*). It may then be easily flexed to any degree and remains in the new position. The elongation of the extensor muscles which permits the flexion of the limb is called the *'lengthening reaction'*. Upon moving the limb again into the extended position the extensor muscle shortens adaptively and again resists the limb being bent. This is the *'shortening reaction'*. These reactions give the muscles a certain plastic quality. The giving way of the extensor spasm in the lengthening reaction has been ascribed to the setting up of inhibitory impulses in the tendon and the muscle when the stretch stimulus reaches a certain intensity. The knee extensor is inhibited also by a contraction of the opposite knee extensor; this is known as the *'crossed extensor or Philipson's reflex'*.

A CONSIDERATION OF THE CENTRAL MECHANISMS CONCERNED IN THE PRODUCTION OF DECEREBRATE RIGIDITY

Bazett and Penfield succeeded in keeping animals (cats) alive for from two to three weeks after aseptic section through the midbrain. The animals showed extensor rigidity up to the day of death though as time elapsed the condition tended to be less constant; intervals of reduced extensor tone and increased flexor tone alternating with periods showing the typical decerebrate posture. The fact that extensor rigidity was present so long after operation makes it clear that the condition is not due to the irritation of fibers at the line of section; for these must have undergone degeneration before the end of the survival period. In a more recent investigation Bard and Macht demonstrated that if the hypothalamus is left intact even though severed from the midbrain and bulb and if the animals are given intensive care they may recover some useful movement of their extremities following transection through the upper mesencephalon.

Decerebrate rigidity is evidently due to the release from higher control of a center or centers situated below the level of the transection. This control of the stretch reflex (postural reflexes, muscular tone) is complex. The precentral motor cortex exerts the most marked inhibitory effect

upon these reflex muscular activities. In this portion of the cerebral cortex a narrow strip originally described by Marion Hines and commonly known as 4s is particularly active in this regard. Area 4s lies just anterior to area 4 or the area gigantopyramidalis which contains the Betz cells and immediately behind area 6, an agranular precentral area which contains no Betz cells. Neighboring cortical areas are probably also similarly although less effectively active. The opinion once held that this inhibitory effect over the postural reflexes is exercised by the gigantic cells of Betz in area 4 of the precentral gyrus and the corticospinal tract which arises from the precentral gyrus (the "pyramidal tract") is certainly erroneous. There is also evidence that some of the basal ganglia exercise a certain controlling influence, probably both inhibitory and facilitatory, over the postural reflexes but detailed information regarding the anatomy and physiology of this mechanism is lacking. In animals the anterior lobe of the cerebellum exercises an inhibitory control over the stretch reflexes. Destruction of this portion of the cerebellum in the cat results in a state akin to decerebrate rigidity whereas in a decerebrate cat electrical stimulation of this portion of the cerebellum causes a pronounced relaxation of the decerebrate rigidity. In man it appears that this cerebellar inhibitory mechanism is either far less effective than in animals or is absent altogether for no one has ever demonstrated any human cases in which cerebellar lesions have resulted in spasticity. The only alteration in muscular tone seen in human beings with cerebellar lesions is hypotonia.

In any consideration of the control of muscular activity by the central nervous system one is repeatedly impressed with the important differences between the organization of the nervous system of man as compared with lower animals. If one removes the precentral motor cortex (areas 4 and 6, or the frontal agranular cortex) from man, a severe and enduring spastic paralysis of the contralateral extremities develops. If, on the other hand, the "motor" cortex or the cortex of the sigmoid gyrus is removed from the cat or even if the entire cerebral cortex is removed any paralysis is fleeting and slight, and any alteration in the tonic state of the skeletal musculature is of little moment. These facts illustrate the constant care which must be exerted in interpreting any facts demonstrated in animal experiments in explanation of phenomena observed in man.

Area 4s exercises its inhibitory influence over

muscular activity by transmitting impulses to a centrally placed bulbar portion of the reticular formation. It is likely that the basal ganglia and the cerebellum also send their impulses there. The reticular formation also contains a laterally placed *facilitatory* mechanism which is capable of *enhancing* the postural reflexes. This *facilitatory mechanism* is connected with various other central neural structures but most notably with the vestibular apparatus and the vestibular nuclei. These nuclei may augment reflex activity either directly over the vestibulo-spinal pathways or by way of the reticular formation. It is obvious then that the reticular formation which contains both inhibitory and facilitatory mechanisms is capable of acting as a center for the regulation of the stretch and other postural reflexes and of muscular activity in general.

The view that spasticity is not merely the result of excessive spinal reflex activity released by the removal of suprasegmental inhibitory control but is due to an imbalance of the reticular formation between inhibition and facilitation is a distinct advance in our physiological thinking, but it represents an incomplete understanding of the problem and ignores many clinical facts. Some of the most striking examples of muscular spasticity from disturbances in the human central nervous system are seen in patients with traumatic or neoplastic lesions of the spinal cord. In such cases the entire brain including the reticular formation of the brain-stem has been excluded so far as concerns the skeletal musculature which is innervated by the spinal cord below the level of the lesion. Obviously in such cases the mechanism giving rise to the spasticity is a purely spinal one and the condition must represent a removal of descending inhibitory influences and a release of spinal mechanisms from suprasegmental control.

Decerebrate Rigidity in Man

In certain neurological disorders in man one encounters disturbances in muscular tone and of the postural reflexes including the stretch reflex. With lesions in the region of the midbrain one sees a state very akin to decerebrate rigidity in the laboratory animals. All four extremities are rigidly extended. The forearms are pronated. The muscles show the lengthening and shortening reactions, and the tonic neck and labyrinthine reflexes are elicitable. When the head is flexed on the neck, the legs are rigidly extended and the arms become flexed at the elbows. When the head is rotated to one side the extremities on that side

become rigidly extended while those on the opposite side relax or flex. When the head is rotated to the opposite side the pattern is reversed (fig 645). With decortication rather than decerebration the picture is somewhat different. The lower extremity is still usually spastic in extension but the upper extremity is usually flexed at the elbow, wrist and fingers. This is the situation usually seen in patients with a spastic hemiplegia caused by a destructive lesion in the internal capsule.

Diseases affecting the basal ganglia are commonly associated with increased muscular tone. This differs from spasticity in that it affects both flexors and extensors more nearly equally, and the degree of resistance to passive manipulation is more nearly constant throughout the range of motion. This rigidity seems to be dependent upon proprioceptive afferent impulses, as it disappears when the posterior spinal roots are divided. Thus it resembles the spasticity of decerebrate rigidity which is dependent upon the stretch reflex for its existence.

The Spinal State

Transection of the cord produces an immediate flaccid paralysis of the muscles below the point of section. Immediately after section in the lower cervical region the limbs hang limply, the muscles being quite toneless, the stretch reflexes and other extensor responses cannot be elicited, the knee jerk is abolished. The blood pressure falls and vascular and visceral reflexes are unobtainable. This condition is called *spinal shock*. Its duration varies with the species. The higher the position of the latter in the phylogenetic scale the more profound is the shock and the slower is the recovery. In the frog its duration is brief, in the rabbit, cat and dog the knee jerk returns within a few minutes (rabbit), or in an hour (cat) or longer (dog), but in the monkey, not for several days. Other extensor reflexes, however, remain in abeyance for a much longer time. In the cat and dog the picture immediately following spinal transection is different from that seen after decerebration. The extensor stretch reflexes are less active while the flexor responses to nociceptive stimuli are more easily elicited. Consequently, if the spinal cord of a decerebrate preparation is sectioned, the exaggerated extensor tone characteristic of the latter is replaced (behind the section) by an imbalance in favor of the flexor muscles.

Spinal shock also follows section through the medulla below the vestibular nuclei (*decapitate preparation*) (see also p. 1150).

In the cat and dog recovery from spinal shock gradually takes place in a few days. The blood pressure is restored to normal and the vascular reflexes can again be obtained. The reactions of the extensor muscles return, and the animal is able, though imperfectly and very briefly, to support the weight of the body when placed upon its feet (chronic spinal animal).

Spinal shock is attributed to the removal of impulses which in the intact animal descend from higher centers to reinforce the spinal centers. That it is due to this and not simply to an inhibitory effect of the local injury itself seems clear from the fact that after an animal has recovered from spinal shock a second transection made behind (lower than the original one) does not cause a return of the shock state. In the cat and dog the flexor reflexes are evidently dependent only to a minor extent upon the higher centers since they are capable of being executed by the spinal centers alone and are seen in their most exaggerated form in animals or human beings with a complete transection of the spinal cord. The fact that the extensor stretch reflexes are less active in the spinal animal is due to the loss of facilitatory impulses from the reticular formation and the vestibular nuclei but these reactions can also eventually be carried out by the spinal centers. In primates in which a greater degree of motor function is represented in the cerebral cortex the immediate effect of cord section upon reflex activity is much more profound than in the cat or dog. Recovery of reflex activity following transection of the spinal cord is in considerable measure dependent upon the condition of the animal or patient. Infection or impaired nutrition greatly retard recovery.

The "Thalamus" Animal

This term is given to an animal whose cerebral hemispheres have been removed leaving the optic thalami intact (see fig. 649, Section I). Such preparations retain their righting reflexes and can regulate their body temperature. They are also capable of carrying out coordinated reflex acts and show, often to an exaggerated degree, reactions which in the intact animal are associated with emotional states (fright, anger). Such reactions, which are termed pseudoaffective, are also exhibited by an animal whose cortex alone has been ablated (see ch. 66). In contrast to the decerebrate animal, the distribution of muscular tone in the thalamic cat or dog shows little departure from the normal, though pronounced extensor rigidity becomes evident when the animal is held suspended in mid air.

Primates on the contrary, are usually unable

FIG 644 Showing posture of a "thalamus" monkey. The underneath limbs are extended and the uppermost flexed. When the animal is turned over, the previously extended limbs (being now uppermost) are flexed, and those which were flexed (now underneath) are extended. (After Bier and Fulton.)

to walk after bilateral decortication, and there are profound alterations in the muscular tone of the limbs. The animal generally assumes a characteristic attitude. When lying upon its side the limbs of the under part of the body are extended and the uppermost limbs flexed. The uppermost limbs show a pronounced grasp reflex. Turning the animal on to its opposite side reverses the picture. The limbs which were underneath and extended are now flexed and show the grasp reflex, while the limbs previously uppermost, being now underneath, are extended. Righting reflexes (except those dependent upon vision) and the tonic labyrinthine and neck reflexes of Magnus and de

Kleijn are shown in a striking fashion (figs 644 and 645).

If the extirpation of the cerebral cortex is carried out piecemeal over a considerable period of time, and if the animal is given meticulous care as to nutrition and manipulation of its extremities, it is possible occasionally to produce an animal which can stand briefly and awkwardly and even take a few steps, but in general such an animal is quite disabled. The disability is much more profound than that seen in a decorticate cat.

Static and Statokinetic Reflexes of Magnus and de Kleijn

The reflex mechanisms governing the orientation of the head in space, the position of the head in relation to the trunk and the appropriate adjustments of limbs and eyes to the position of the head, are called into action by afferent impulses discharged from receptors situated in (a) the vestibular apparatus (semicircular canals or utricle), (b) the neck muscles, (c) the retina, and (d) in the body wall or limb muscles.

These are complex reflexes which are concerned with the posture of entire extremities and of the trunk as they are influenced by movements of other extremities, of the trunk and of the head and neck. They aid in maintaining the position of the body in space, in restoring the body to an upright position when its position has been disturbed, in progression forward, etc. A more detailed account of these postural reflexes follows.

General Static Reflexes

THE RIGHTING REFLEXES

The orientation of the head in space, and the ability to maintain the body in a certain definite (normal) relation to the head is a characteristic of animal life. A cat held back downwards and then allowed to fall through the air lands upon its feet, its head and body assuming in a flash, the normal attitude. A fish resists any attempt to turn it from its natural position and if placed in the water upon its back flips almost instantly into the normal swimming position. Even a cray fish rights itself from the back-down position.⁵ These

⁵ The otocyst of the prawn is homologous to the utricle of mammals. It is open to the exterior and at moulting time its lining is shed. The otoliths consist of grains of sand which the animal itself introduces into the otocyst. If, after moulting the animals are placed in a dish containing fine iron filings these are inserted and various forced movements of the head and body can be induced by bringing a magnet into relation with the ear.

FIG 645 Decerebrate child. Supraventricular cyst causing interruption of descending pathways at the level of the midbrain. Turning the head to one side causes extension of the arm of that side and increased flexion of the opposite arm. (Modified after L. E. Davis.)

FIG 64-6 On left position taken up by a thalamus rabbit with intact labyrinths. As it possesses the labyrinthine righting reflexes it carries its head in the normal position. On the right position taken up by a rabbit like the preceding but deprived of its labyrinths. The head is not raised towards the normal position. (After Magnus.)

righting reactions are complex and involve five separate types of reflex:

- (a) Labyrinthine righting reflexes acting upon the neck muscles
- (b) Neck righting reflexes acting upon the body
- (c) Body righting reflexes acting upon the head
- (d) Body righting reflexes acting upon the body
- (e) Optical righting reflexes.

The first four of these are demonstrated best upon a 'thalamus' animal (p 1168). When a 'thalamus' rabbit or a blindfold normal animal is suspended from the pelvis (fig 64-6) the head turns until it assumes its normal position in space, i.e., into the position it would occupy were the animal in its normal position. The maintenance of the head in the new position is due to *labyrinthine righting reflexes* acting upon the neck muscles. Turning the body of the animal through the air into different positions is followed by compensatory movements of the head, its orientation in space being thereby maintained. After extirpation of the labyrinths or destruction of the utricle alone, and suspension of the animal as before, the head shows no compensatory movements, it hangs limply like that of a dead rabbit.

When the blindfold or thalamic animal is laid resting upon its side on a table the head is raised into the usual upright position as a result of the labyrinthine reflexes just mentioned. The contraction of the neck muscles which rotate the head sets up in turn, proprioceptive impulses, which through a center in the upper cervical cord exert an influence upon the muscles of the body which rotate it (thorax first, then pelvis) into the normal relationship to the head. This is the *neck righting*

reflex acting upon the body. A labyrinthectomized animal when laid upon its side behaves in a somewhat similar manner. The reaction under the latter circumstances is due, however, to the asymmetrical stimulation (pressure of one side of the body upon the table) of exteroceptors in the body wall, and the reflex contraction of the neck muscles. This is the *body righting reflex acting upon the head*. If a board of a weight equal to that of the animal is laid upon its upper surface, the pressure being thereby disposed equally on the two sides, the compensatory movement of the head does not occur.

Again, when a blindfold animal or one which has been decorticated is laid upon its side and its head held down to the table, to eliminate the righting reflexes of labyrinthine and cervical origins, as well as the body righting reflex acting upon the head, the body nevertheless attempts to right itself by raising the hindquarters. This must be due to the asymmetrical pressure upon the body exerting a reflex effect upon the skeletal musculature, i.e., a *body righting reflex acting upon the body*.

This reflex is well shown by the labyrinthectomized dogfish, especially after blinding. When placed in the water (pressure being equal on all sides) upon its side or back the fish deprived of its labyrinths swims away in the false position. When, however, it comes into contact with the bottom or side of the tank (pressure then being exerted unequally) the righting reaction immediately occurs. Even worms possess this means of orientation.

The *optical righting reflexes* are initiated through retinal impressions. They are absent in the thalamic animal since their center is cortical (occipital lobes). Visual impressions play a prominent role in the orientation of the head in some animals, such as the monkey, dog and cat. If a labyrinthectomized dog is held in the air in order to exclude the body righting reflexes, it is capable of orienting the head, but is not able to do so if blindfolded. The optical righting reflexes are of minor importance as compared with the labyrinthine in animals such as the rabbit and guinea pig whose cortical development is more rudimentary, and who depend to a large extent upon subcortical visual centers. In the more intelligent animals the optical righting reflexes are abolished by decortication. Yet even the crayfish deprived of its otocyst, which is the homologue of the utricle of mammals, rights itself, though with less facility than normally, when placed upside

down in water. In this medium righting reflexes due to unequally distributed pressures upon the body surface must obviously be in abeyance, the righting reaction, then, is apparently entirely of retinal origin. That this is so is proved by blinding the animal, then the righting reaction is lost completely.

To sum up, the righting reflexes may now be given in their natural sequence. When the animal is placed upon its back the labyrinthine reflex acting upon the neck muscles turns the head into its normal relationship to the dimensions of space; the proprioceptive reflexes of the neck muscles then bring the body into its normal relation to the head. When resting upon a rigid support these reflexes are reinforced by body righting reflexes (on head and body). When the animal falls through air or water, these latter reflexes of course do not come into play. A labyrinthectomized but otherwise normal animal, such as the cat or dog, recovers its upright position when allowed to fall through the air, as a result of the operation of the optical righting reactions, the righting ability is lost, however, if the eyes are covered with a hood. Also, an air-breathing animal deprived of its labyrinths, though a good swimmer, drowns if thrown into deep water, since it cannot orient itself by the sight of surrounding objects. Deaf mutes, whose labyrinths are very frequently undeveloped, though able to swim may become disoriented and drown if they fall or dive into deep water.

Righting reflexes may be demonstrated in the human subject. A baby a few weeks old, for example, when lying prone raises the head into a nearly vertical position. When blindfolded and held by the pelvis in different positions in the air the head is moved toward the normal position.

Local and Segmental Static Reactions Supporting Reactions

Magnus speaks of the simultaneous reflex contractions of both extensor and flexor muscles and other opposing muscles whereby the joints are fixed and the limbs converted into rigid pillars for the support of the body against gravity as the *positive supporting reaction*. This reaction is initiated by—

(a) Impulses discharged from the proprioceptors of the flexor muscles of the terminal segments of the limbs—digits and ankle or wrist, the pressure of an animal's paw upon the ground by stretching these muscles provides the adequate stimulus which calls forth simultaneous reflex

contractions of the flexors and extensors of the knee (or elbow).

(b) Myotatic reflexes set up in the flexors of ankle and toes (plantar flexors), and of the corresponding forelimb joints, excessive extension at these joints is thus counteracted. Any tendency toward over-extension at the knee or elbow is also provided against through the reflex set up when the flexors of these joints are stretched. Similarly, any tendency of the knee or elbow to bend under the weight of the body calls forth a myotatic reflex from the extensors, which prevents any weakening of the supporting action of the limb.

(c) Impulses set up in the pressure receptors in the deeper layers of the skin of the sole when in contact with the ground, thus exteroceptive reflexes reinforce those of proprioceptive origin. The exteroceptor element is well shown in a decerebellated dog. When such a preparation is placed upon its back and the head strongly flexed, the hindlimbs are flexed in all joints. Light pressure with the finger upon the toe pad then causes an extension of the limb, and if the finger be moved with the limb as it extends so that only very light pressure upon the pad is maintained one has the sensation of the limb being drawn out by the finger. For this reason the movement has been called the 'magnet reaction'.

The relaxation of the muscles and the unfixing of the joints which enables the limb to be flexed and moved to a new position is called the *negative supporting reaction*. It is brought about by raising the pad off the ground and plantar flexing the toes and ankle. The exteroceptive stimulus and the stretch stimulus to the *plantar flexors* are thus removed. The reflex 'unlocking' of the limb is not, however, simply due to the removal of these stimuli, but has in addition a positive element, namely, the stimulus provided by plantar flexion and the consequent stretching of the dorsal flexors of the toes and ankle—relaxation of the extensors of the knee or elbow and contraction of the flexors result.

The supporting reactions, though seen best in a decerebellate animal, can also be demonstrated in the decorticate preparation or in one whose brainstem has been divided above the medulla oblongata. Segmental static reactions, e.g., flexion reflex and the crossed extension reflex have been described in chapter 63.

Statotonic or Attitudinal Reflexes

(1) *Tonic labyrinthine and neck reflexes acting upon the limbs*. These reflexes influence the tone

FIG 647 Diagrammatic representation of the positions of an animal's head each marked with the angle which the mouth cleft makes with the horizontal plane (After Magaùs)

of the skeletal muscles and thereby maintain the different parts of the body in an attitude appropriate to a given position of the head. They are investigated best in the decerebrate animal (p 1165), the righting reflexes being then largely abolished. The proprioceptors concerned are in (a) the *labyrinth* (tonic labyrinthine (utricle) reflexes) which are brought into play by alterations in the position of the head in space, (b) the *neck muscles* (tonic neck reflexes) which come into action when the position of the head is altered relatively to the body. In order to study separately the part played by each of these reflexes in any given reaction, the following procedures are adopted

A To exclude the neck reflexes

(a) Immobilization of the neck of an animal by means of a plaster of Paris bandage in order to prevent movement of the head in relation to the trunk. Any tonic effects resulting from a change in the animal's position must then be due solely to alterations in the position of the head in space (labyrinthine reflexes), or (b) section of the posterior roots of the first three or four pairs of cervical nerves

B To exclude tonic labyrinthine reflexes

(a) Fixation of the head alone in some suitable apparatus. The tonic effect resulting from movement of the body must then be due to an alteration in the position of the body in relation to the head, i.e. to movements of the neck, or (b) destruction of the labyrinths or section of the 8th cranial nerves

The labyrinthine reflexes exert an influence upon the tone of the extensor muscles which is in the same direction (increase or decrease) in all four

limbs. The influence of the neck reflexes, on the other hand, is usually in *opposite* directions in the fore and hind pairs of limbs. The greatest degree of extensor tone is exerted through the labyrinth mechanism when the animal is supine and the mouth cleft inclined at an angle of 45° (fig 647) above the horizontal plane, and is least when the mouth cleft makes an angle of 45° below the horizontal plane.

Extensor tone diminishes as the angle increases; it is minimal in the prone position with the mouth cleft at an angle of 45° below the horizontal plane.

In an animal on all fours the labyrinthine effect is, therefore, to increase or decrease the extensor tone in the muscles of all four limbs when the head is strongly extended or flexed, respectively. In the decerebrate labyrinthectomized animal the neck reflexes alone operating, flexion of the forelimbs and extension of the hindlimbs occur when the neck is flexed toward the sternum (ventriflexion) (see fig 643, p 1165). Extension of the neck (dorsiflexion) produces the converse picture, i.e., extension of the forelimbs and flexion of the hindlimbs. When therefore, the neck is ventriflexed in the decerebrate animal with intact labyrinths, the neck reflexes reinforce the tonic labyrinthine effect upon the forelimbs but antagonize that upon the hindlimbs; the usual result is relaxation of the forelimbs with strong extension of the hindlimbs. When the neck is extended the neck reflexes reinforce the labyrinthine effect upon the tone of the forelimbs but antagonize that upon the hindlimbs. The effect of the neck reflexes upon the extensor tone of the latter again predominates; the extension of the forelimbs is maintained but definite relaxation of the hindlimbs occurs.

Rotation of an animal's head (turning in the frontal plane of the skull) causes increased extensor tone of the fore and hindlimbs on the side of the body toward which the jaw is rotated (*jaw limbs*)⁵ and reduces the extensor tone of the opposite limbs (*skull limbs*)⁶. Inclination of the head toward one shoulder (lateral flexion) as when an animal turns a corner is accompanied by similar effects—extension of the limbs on the side of the body toward which the jaw (or snout) is inclined (*jaw limbs*) and flexion of the limbs on the opposite side (*skull limbs*).

Pressure upon the last cervical vertebra reduces the tone in all four limbs (*vertebra prominens reflex*).

⁵ Magaùs has introduced the term *jaw limbs* to indicate the limbs toward which the chin of man or the jaw of animals is rotated or inclined. The opposite limbs, i.e. the limbs to which the vertex of the skull is rotated, are called *skull limbs*.

FIG. 64.8 Photographs of a normal cat showing the animal's posture (on left) when its attention is attracted by an object placed above it. Photograph of the same animal (on right) when its attention is drawn to an object below it. The difference between the two positions of the forelimbs is very marked because in them the neck and labyrinthine reflexes reinforce one another: the hindlimbs are in much the same position in both cases since the two sets of reflexes cancel one another. (After Magnus.)

The significance of these reflexes and their importance in the coordination of the postural muscles may be realized when the attitudes of the intact animal are observed. Thus when an animal turns to one side the limbs of that side are stiffened in order to support the body's weight. A cat looking upwards to a bird in a tree extends the forelimbs and flexes the hindlimbs, thus giving the back a suitable inclination which improves the position of the head and eyes and places the body in a position preparatory for a spring (fig. 64.8). When looking into a hole or beneath a cupboard the flexion of the forelimbs and extension of the hindquarters gives an opposite but no less advantageous inclination to the body. Depression of the back in the region of the last cervical vertebra brings the animal into a crouching attitude.

Stato-tonic effects may be demonstrated in certain nervous lesions associated with a state analogous to decerebrate rigidity of animals (pp. 1165-1166). Turning the head to one side, for example, causes an increase in tone of the extensors of the jaw limbs and hypotonicity in the limb muscles of the opposite side.¹ When the head is in the position for maximal labyrinthine tone, i.e. when the patient is supine and the neck extended the extensor tone of the paralyzed limbs increases but becomes reduced in the prone position.

(2) *Tonic labyrinthine and cervical reflexes acting upon the eyes.* Tonic effects upon the eye muscles analogous to those described for the skeletal muscles result from changes in the position of the head. Labyrinthine and neck reflexes are responsible. Alteration in the position of the head with neck immobilized or movement of the head in relation to the body after labyrinthectomy is followed by compensatory eye movements. Turning the head downwards causes an upward movement of the eyes which are held in this position so long as the head position is maintained, the tone of the superior recti and inferior oblique being increased while that of the inferior recti and superior oblique is reduced. A corresponding compensatory movement of the eyes occurs when the head is turned upward. Similarly when the head is turned to one side the internal and external recti of the two eyes cooperate to deviate the eyes outward or inward in relation to the head. Briefly, the eyes are moved in a direction opposite to that taken by the head, thus their original positions in space are maintained and the visual field existing prior to the head movement remains unaltered. It should be pointed out that the actual movement of the eyes is a stato-kinetic reflex (p. 1174) and due to a different mechanism (semicircular canals) from that which maintains the eye position while the head is held in the altered attitude. The latter is a stato-tonic reflex, dependent upon the utricle.

SUMMARY OF THE CENTERS FOR GENERAL STATIC REFLEXES

Magnus found that all the static reactions mentioned in the foregoing section could be obtained unaltered after removal of the cerebellum, as could also most of the stato-kinetic reflexes to be described in the next section. Nevertheless this rather surprising fact does not necessarily imply that in the normal intact animal the cerebellum plays no part in these reactions. A contrary conclusion must be drawn from anatomical considerations and from observations in cerebellar disease in which disturbances referable to the labyrinth (e.g. abnormal positions of head falling, etc.) are

¹ This according to Magnus can also be shown in a certain percentage of normal infants and in hydrocephalus it may be well marked.

FIG 649 Diagram to illustrate the effects of sections through cat's brain at various levels. Line I, thalamic animal, righting tonic labyrinthine and neck reflexes retained, little disturbance of muscular tone. Lines II and III decerebrate rigidity. Line IV, behind vestibular nucleus, decapitate animal, extensor rigidity less marked, tonic neck reflexes retained. Section at level of second or third cervical segment of the cord—spinal animal—abolishes the tonic neck reflexes (after Magnus), III indicates Sherrington's original section.

manifest. Moreover, numerous connections between the labyrinths, the vestibular nuclei and the cerebellum have been demonstrated.

(a) *The righting reflexes.* All the labyrinthine righting reflexes, as well as the body righting reflexes acting upon the head, have their centers in the midbrain. The center for the optical righting reflexes is cortical, that for the body righting reflexes acting upon the head have their centers in the midbrain.

(b) *The stato tonic labyrinthine reflexes* acting upon the skeletal muscles have their center in the vestibular nuclei.

(c) *The neck reflexes* are centered in the upper two or three cervical segments of the spinal cord (see Fig. 649).

(d) *The centers for the tonic labyrinthine and cervical reflexes acting upon the eyes* are situated between the vestibular nuclei and the oculomotor nuclei.

Placing and hopping reactions. These have been thoroughly investigated by Bard. Bard and Brooks describe five placing reactions.

(1) If a cat is held in mid air with legs dependent and chin held up so that it cannot see anything below or in front, contact of the backs of the forepaws with the table's edge is followed by a quick movement of the limbs which brings the paws, soles down, precisely upon the surface of the table. (2) If the forelimbs of a cat are held down while the chin is brought in contact with the table near its edge, the forepaws when released are instantly raised and placed upon the table beside the chin, a movement which is usually followed by extension of the limbs and the assumption of a standing position. (3) If the fore or hindlimbs of a cat standing or sitting upon a

table are pushed over the table's edge, they are immediately lifted and placed in their original positions. (4) If one abducts, without holding, the limb of a standing cat, it is instantly returned to its previous position. (5) If a blindfolded cat is suspended in the air with forelimbs free and its head brought toward some obstacle, at the instant that the vibrissae come into contact with the object the forepaws are raised and accurately planted upon the surface of the object. The first three of these reactions are due to stimulation of receptors upon the body surface (exteroceptors) and probably also of proprioceptors in muscles and tendons. The fourth is a purely proprioceptive reflex, the last is initiated from tactile receptors. The *hopping reactions* consist of limb movements which serve to maintain the standing position against any force acting upon it in a horizontal plane. When, for example, a cat is held so that its body is supported upon one fore or hindlimb and is then pushed in one or other direction, the supporting limb hops quickly in the direction of the displacement, the foot being kept directly under the corresponding shoulder or hip. The hopping reactions are probably dependent upon myotatic (stretch) reflexes (p. 1162).

The placing and hopping reactions are controlled from the sensorimotor area of the cerebral cortex. Removal of this region from both cerebral hemispheres by Bard and Brooks was found to abolish the placing reactions and to produce an extreme degree of deficiency in the hopping reactions. Deoortication (complete removal of the neocortex) produce no greater deficiency. The control exerted by the cerebral cortex is entirely contralateral, i.e. the component movements of the reactions on one side of the body are governed solely by the opposite side of the brain.

Kinetic, Statokinetic or Accelerator Reflexes

The term kinetic is attached to these labyrinthine

FIG 6410 Diagram showing the semicircular canals and their relation to the planes of the skull. S, median sagittal plane, F, transverse frontal plane (see text).

these reflexes because they are caused by the movement of the head, but since it is not the movement itself, but acceleration above a certain rate, angular (rotary) or linear (progressive) that is the adequate stimulus, *acceleratory reflexes* is a better name.

ANATOMY OF THE LABYRINTH

Before a description of other labyrinthine functions e.g., the statokinetic reflexes can be undertaken, a brief description of the structure of the labyrinth must be given. This structure consists of an auditory (cochlear) and a nonauditory portion. We are concerned here only with the latter which we shall refer to simply as the labyrinth. The *bony labyrinth* comprises a series of cavities tunnelled in the petrous part of the temporal bone. The cavities are the three semicircular canals each of which opens by its two extremities into a ovoid chamber known as the *vestibule*. The bony labyrinth lodges a series of hollow membranous structures—the *membranous labyrinth*. The membranous labyrinth consists of (a) *Three semicircular*

FIG. 64 12 Diagram (not to scale) giving a lateral view of the internal ear within the skull. V, vertical canals, H, horizontal canal, U, utricle, S, saccule, C, cochlea. (Redrawn from Quix.)

FIG. 64 13 Drawing of crista (From Bailey's *Histology* after Schafer.)

canals lying in the corresponding bony canals (b). Two sacs—the utricle and saccule situated in the vestibules (Fig. 64 11).

THE SEMICIRCULAR CANALS. One extremity of each canal shows an expansion known as the *ampulla* wherein is situated the specific sense organ. The membranous labyrinth is filled with fluid—the *endolymph*—a similar fluid—the *perilymph*—lies between its walls and the walls of the bony labyrinth. The canals lie in planes approximately at right angles to one another and are called respectively *external* or *lateral* (horizontal), *anterior* or *superior* (vertical) and *posterior* (vertical) (see Fig. 64 10). It will be noted that the nonexpanded extremities of the vertical canals join to form a common stem through which they communicate with the utricle (Figs. 64 10, 64 11) and 64 12).

The external canal is directed with its convexity outwards and backwards. When the head is in the erect position this canal is only approximately horizontal; it is inclined backwards and downwards at an angle of about 30° to the horizontal plane. The vertical (anterior and posterior) canals both make an angle of about 45° with the frontal and the sagittal planes of the skull. The anterior canal of one ear is therefore nearly in the same plane as the posterior canal of the other ear, whereas the posterior or anterior canal of one ear is at right angles to its fellow of the opposite side as well as to the other two canals of the same ear. The external (horizontal) canals of the two sides lie in the same plane.

THE CRISTA. This is the receptor organ of a semicircular canal. It is situated in the ampulla and consists of a mound of sensory hair cells between which are non-sensory supporting cells. The sen-

* That is their planes cross both the frontal and sagittal planes diagonally.

veyed to the medulla by the vestibular branch of the 8th nerve. The cell bodies of the vestibular fibers lie in Scarpa's ganglion situated at the bottom of the internal auditory meatus. These cells are bipolar. Their afferent processes (dendrites) are distributed to the sense organs of the utricle, saccule and semicircular canals, and terminate in the hair cells. Their axons pass for the most part to the superior, lateral, medial and inferior vestibular nuclei in the medulla (a few go directly to the flocculo-nodular lobe and the fastigial nuclei of the cerebellum) from which relay fibers follow three pathways (fig. 6114). Thus there are:

(1) Ascending fibers from the superior vestibular nucleus which join the medial longitudinal bundle of the same side. From the medial vestibular nucleus impulses are relayed to the medial longitudinal fasciculus of the opposite side, from the inferior vestibular nucleus fibers ascend in the medial longitudinal fasciculus of both sides. The fibers from these nuclei terminate in the nuclei of the 3rd, 4th and 6th cranial nerves and constitute the vestibulo-ocular tract. Through these connections, reflex movements of the eyes are brought about.

(2) Fibers descend from the lateral (Dieter) and the inferior vestibular nuclei. Those from the lateral nucleus constitute the vestibulo-spinal tract (ch. 85), while those from the inferior nucleus descend in the spinal extension of the medial longitudinal fasciculus as far as the upper cervical region of the cord, where they synapse with the anterior horn cells. Through these connections impulses are conveyed to the skeletal muscles.

(3) Fibers pass via the inferior cerebellar peduncle mainly to the flocculo-nodular lobe of the cerebellum on the same side but also to the fastigial nucleus of the same side. These constitute the vestibulo-cerebellar tract.

As a result of his clinical findings I. H. Jones concludes that the fibers from the vertical and from the horizontal canals follow different paths. Those from the vertical canals do not according to this observer, enter the vestibular nuclei but ascend to the pons where they divide into two diverging paths, one arm of the Y so formed joins the medial longitudinal bundle and is distributed to the ocular nuclei, the other passes to the cerebellum via the middle cerebellar peduncle.

EFFECTS FOLLOWING LABYRINTHECTOMY (IN THE DOG)

Unilateral labyrinthectomy (1) *Ocular* Both eyes are turned toward the side of the operation. The eye of this side also shows a downward deviation while the eye of the sound side deviates upwards (skew deviation). *Horizontal nystagmus* (pp. 1179, 1180) with the slow movement toward the operated side.

(2) *Lateral flexion and rotation of the occiput* to the operated side together with flexion of the thorax on the pelvis toward this side.

(3) *The extensor tone of the limb muscles* is greater on the sound side than on the operated side, the limbs of this side being flexed and adducted whereas those of the opposite side are extended and abducted.

(4) *Spontaneous movements*. These are all toward the operated side and consist of (a) circling i.e., turning of the body around a vertical axis (b) rolling i.e., rotation around a horizontal axis in the rabbit the rolling movements are very violent, (c) side to side movements of the head (head nystagmus) (d) falling to operated side (e) stepping gait.

Many of the foregoing features e.g., nystagmus, rolling and circling movements are *irritative* in nature i.e., the result of irritation of nerve endings by the operative trauma. They therefore, improve with time. The others e.g., oscillating movements of the head, head torsion, stepping gait, falling and asymmetrical distribution of tone, are deficiency phenomena.¹⁰ These for the most part also improve since they tend to be compensated by visual and other nonlabyrinthine reflexes especially in higher animals who also learn to exercise cerebral control over the abnormal muscular activity.

Bilateral labyrinthectomy produces irritative effects similar to those described above, the direction of the movements being variable and dependent upon which ear shows the greatest degree of irritation. The labyrinthine static reflexes are, of course, abolished but in the more intelligent animals the defects of orientation are largely compensated for by visual reactions. The normal reactions to rotation (p. 1179) are abolished.

It is surprising that such striking manifestations were seen in the dog following destruction of the labyrinth as section of the eighth cranial nerve in man is not followed by any such symptom complex. In fact such a section is usually followed by no symptoms or signs of any moment. The question must therefore be raised as to whether the manifestations described above might have arisen as the result of some complication of the operation, or as the result of an incomplete destruction of the labyrinth which resulted in stimulation. The different results may

¹⁰ Cocaine injected into the labyrinth produces the deficiency phenomena characteristic of labyrinthectomy but when applied to the nerve stump after removal of the labyrinth it prevents the occurrence of the irritative phenomena.

be dependent upon variations in function and importance of the labyrinths in different animals

LABYRINTHINE FUNCTION

The semicircular canals are organs of dynamic sense, the otolithic organs subserve both dynamic and static senses. The hair cells of the cristae in the canals respond to angular acceleration (rotation), and are therefore called *rotary receptors*. The hair-cells of the macula on the medial wall of the utricle, and probably the macula of the saccule, as well, are stimulated mainly by changes in position of the head, and by linear acceleration. They are called *gravity receptors*.¹¹

The semicircular canals. The rotary receptors of the cristae respond and give rise to a sensation at the commencement and at the cessation of a rapid rotary movement. Though impulses at low frequency are discharged along the nerve fibers while the head is at rest, a sharp increase in impulse frequency occurs at the commencement of the rotary movement, and at its end. The rapid discharge lasts for about 25 seconds. The rotary receptors, therefore, give no information of a continuous rotary motion of unvarying speed, though any alteration in speed of rotation (angular acceleration) arouses a sensation. The reason for this will be evident upon consideration of the stimulating mechanism.

Stimulation of the sensitive hair-cells of the

cristae is brought about through the effect which the movement of the head exerts upon the endolymph within the canal, the particular canal which is stimulated depending upon the plane in which the rotation occurs. The canals are of capillary diameter (0.1 to 0.2 mm. in man), and the endolymph is of relatively high viscosity (2 to 3 times that of water). The membranous labyrinth is a practically closed system and is supported on the outside by perilymph, and the unyielding walls of the osseous labyrinth.

When the head turns quickly from a position of rest, say to the right (see fig. 64 16 and table 64 1), i. e., in a clockwise direction, and in the plane of the horizontal canals (around a vertical axis), the endolymph within the canal, owing to its inertia, does not move at first with the walls of the canal. This lag is equivalent to a movement or flow of endolymph to the left—anticlockwise—in both canals. But owing to the relative positions of the two ampullae such a flow of endolymph causes the cupula—the gelatinous mass surrounding the crista, and in which the hair-cells are embedded—to swing toward the utricle in the right ampulla and away from the utricle in the left ampulla. Deflection of the cupula causes, in turn, deformation of the hair-cells which acts as a stimulus when the swing is toward the utricle (right) but is inhibitory if it is away from the utricle (left). These events are reversed when the rotation is to the left—anticlockwise.

Thus, a clockwise rotary movement of the head (e. g. a quick turn) around a vertical axis stimulates the right horizontal canal, an anticlockwise motion excites the left, or put in another way, the rotary receptors are stimulated only when the narrow part of the canal is leading and the ampulla trailing.

The receptors of the vertical canals, on the other hand are stimulated only when the ampulla is leading and the narrow part of the canal bringing up the rear. There is no explanation for this difference between the horizontal and vertical canals.

The maximal response is given by a canal when it is rotated in its own plane.¹² No response is aroused from a horizontal canal by rotation in a

¹² It will be recalled that the vertical canals are placed diagonally in the head, and that an anterior vertical canal is in the same plane with the posterior canal of the opposite side, therefore, in a manner analogous to that of the horizontal canals, a diagonal rotary movement forward will maximally stimulate an anterior canal and suppress the activity in the opposite posterior canal. A backward rotary movement would act in the opposite way.

¹¹ Breuer (1874 to 1891) was the first to point out the difference in function between the semicircular canals and the utricle.

plane at right angles to this. But a vertical canal though most effectively stimulated by rotation in its own plane (diagonal) also gives a lesser response when rotated in other planes. Thus a quick tilt of the head, forward or backward (rotation around a transverse axis), or laterally toward a shoulder (rotation around an anteroposterior axis) stimulates the vertical canals. The threshold of excitation of a horizontal canal is an angular acceleration between 2° and 3° per sec.

When any rotary movement is continued for longer than a few seconds and the inertia of the endolymph is overcome, the cupula regains its resting (umbent) position, at the cessation of the movement the momentum of the fluid causes bending of the cupula in a direction opposite to that at the commencement of the movement. This is why no sensation occurs, during prolonged rotation but a sensation of turning in the opposite direction is felt when the rotation suddenly ceases.

The mechanism of the semicircular canals is admirably suited to signal rapid turns of the head i.e. a rotary movement in one or other plane. But it is poorly adapted to report continuous rotation at a constant speed (for as Adrian points out this is a movement to which the body throughout its life is rarely if ever subjected and has therefore not developed suitable receptors for recording it). Continuous rotation tends to confuse rather than to inform, and also, because of the swing of the cupula in the reverse direction when the rotary movement ceases an illusion of rotation (in the opposite direction) is created. The ballet dancer avoids the confusion in a *pas de deux* by making a series of alternating acceleration and deceleration.

A brief outline of the experiments on vestibular function. The foregoing account of vestibular mechanisms is based upon the work of many investigators. Some of the more recent experiments will be briefly outlined.

Tait and McNally studied the effect on frogs of tilting and rotation after denervation of one or more canals in various combinations, and after destruction of the utricle or saccule. Steinhausen elucidated especially the movements of the cupula in the canals of the pike whose labyrinth can be visualized in the living fish after the introduction of India ink, the cupula showing up clearly against the darker background. This structure was shown to completely partition the cavity of the ampulla being in contact everywhere around its free circumference with the membranous wall.

It was shown to move during caloric stimulation as well as during angular acceleration, but not during electrical stimulation. Later, similar studies were made by Dohlman which confirmed Steinhausen's findings. Dohlman followed the endolymph movements by means of a drop of oil introduced into a canal. Ross employed the *right half* of a frog's head held in an apparatus whereby the labyrinth could be turned and fixed in any desired plane, and subjected to rotation. The electrical changes were recorded from a filament of the auditory nerve. Clockwise rotation caused a response from the horizontal canal, whereas an anticlockwise movement was ineffective. Steinhausen's conception of a deflected cupula caused by an endolymph movement was verified. Lowenstein and Sand employed the surviving isolated labyrinths of the pike and ray (*Raja clavata*) and recorded the electrical potentials from individual canals and found that the nerve endings of the cristae discharged impulses continuously during rest at a low rate but at increased frequency during angular acceleration and deceleration. Adrian experimenting with cats recorded the potentials from single units by means of a fine wire electrode inserted into the medulla in close proximity to the vestibular nuclei. The main findings of others in cold blood animals were confirmed.

EFFECTS OF STIMULATION OF THE SEMICIRCULAR CANALS

The semicircular canals respond to any one of the following forms of stimulation: (1) *Rotation* (angular acceleration) of the head on a vertical transverse or anteroposterior axis. (2) *Caloric*—synergizing the ear with a hot or cold solution. (3) *Galanic*. (4) *Mechanical*.

Rotation

The effects produced by rotation are (a) *eye movements*, (b) *vertigo*, (c) *reactions of the neck and limb muscles*, (d) *reactions of the autonomic nervous system*.

(a) *Eye movements*. When an animal's head is turned sharply on a vertical axis i.e. in the plane of the horizontal canals the eyes deviate in the opposite direction and then return with a quick jerk to the original forward looking position. The movement causing the slow deviation of the eyes is really a rotary one through a small arc.

If the horizontal rotation is continuous, a *rhythmic* to and fro movement of the eyes occurs when the rotary movement ceases. This is called *nystagmus*. It can be easily demonstrated

FIG 64 15 Positions during rotation Upper horizontal canals in plane of rotation Lower, vertical canals in plane of rotation V vertical canals, H horizontal canals

in man by rotating him with eyes closed in a revolving chair, at a rate of about 10 complete turns in 20 seconds. In order to stimulate the canals maximally, the head should be inclined

FIG 64 16 Diagram of ampullae (A) of horizontal canals and utricle showing deflection of the cupula during rotation. Plus and minus signs indicate increase and decrease respectively, in the impulse frequency from the hair cells, arrows indicate the direction of rotation, C, cupula

FIG 64 17 Postrotary nystagmus

forward about 15° when the rotary movement is almost exactly in the plane of the horizontal canals. When the rotation is suddenly stopped (angular deceleration), and the subject opens his eyes the rapid to and fro motion of the eyes is seen. It consists of a slow deviation to one side, and a quick return to the normal position. This post rotary nystagmus lasts for about 20 sec in a normal person. its quick component is in a direction opposite to that of the rotary movement. By convention the quick movement or jerk to the normal position is taken to designate the direction of nystagmus from whatever cause. Thus a right horizontal post-rotary nystagmus is caused by rotation to the left. At the beginning of the rotation to the left the nystagmus would be in the opposite direction—quick movement to the right (figs 64 15 and 64 17).

There are two other forms of nystagmus—vertical and rotary—in which the eyes oscillate up and down, and round and anteroposterior axis, respectively. These types result from the simultaneous excitation of both vertical canals. Vertical nystagmus is induced when the canals are stimulated with the sagittal plane of the head in the plane of rotation—that is with the head inclined about 90° to one or other shoulder. The rotary type follows when the frontal plane of the head is bent forward 90° or more, or backward 30° to 60° . In each instance the post rotary nystagmus is observed after the head has been brought upright.

Central connections responsible for nystagmus. The slow phase of nystagmus is initiated from the semicircular canals and has its center in the vestibular nuclei from which impulses are discharged, in part at least through the median longitudinal bundle to the eye muscles. The quick movement is entirely central but the nervous pathways upon which it depends are uncertain. However, its neural mechanism must lie in the brain stem between and including the nuclei for the third nerves and the vestibular nuclei for nystagmus occurs after transections of the brain above and below these

levels, respectively. It is not abolished by ablation of the cerebellum. Even the nuclei of the 3rd and 4th nerves may not be necessary for in the rabbit nystagmus can be induced after section just above the abducent nucleus. Lorente de No has located the center for the rapid phase in the formatio reticularis in the region of the abducent nucleus. He also found that nystagmus could still be produced after section of both median longitudinal bundles. There may be a double pathway from the vestibular nucleus to the nuclei of the ocular nerves—through the medial longitudinal bundle and through the formatio reticularis.

(b) *Vertigo*. Vertigo consists of a sensation that the environment is whirling, that objects at which the person is looking are moving or a feeling of unsteadiness and of an actual disturbance of the equilibrium of the individual so that he is unsteady and staggers. He may fall. When the subject is rotated with head erect his vertigo is in the horizontal plane, i.e., in the plane of the external canals but in the direction opposite to that of the previous rotation (sensation of counter-rotation).

If the subject is rotated with the head bowed forward at an angle of about 90° , in order to stimulate the vertical canals and the head maintained in this position after rotation the sensation is the same as if the head position had been upright during rotation, i.e. one of counter rotation in the horizontal plane. If however the head is brought upright after rotation there is then a sensation of falling to one or the other side, i.e. of rotation of the body in the frontal plane. The sensation is of falling to the side away from that toward which the body had been rotated. Rotation with the head bent backwards to an angle of 60° and then brought upright gives a sensation of falling to the same side as that toward which the body had been rotated (see table 64.2). A sensation of falling forward or backward (i.e. rotation in the sagittal plane) results from rotation with the head flexed on one shoulder and then brought upright.

Vertigo arises from other causes than rotation. It is a common symptom in disease constitutional or neurological, and occurs in alcoholic intoxication seasickness, swinging, etc. Also just as the labyrinth influences the movements of the ocular muscles so conversely, labyrinthine function may be disturbed and vertigo produced as a result of some unusual or abnormal action of the eye muscles. Vertigo and its associated phenomena are, therefore, common effects of eye strain or of viewing the landscape from a moving train, an ocular element is also an important contributory factor in the causation of seasickness. For ex-

ample, if one sees a moving picture, which if actually experienced would cause giddiness, a sensation of vertigo is aroused. But with whatever condition vertigo is associated whether cardiovascular, renal, toxic, gastrointestinal or neurological, its immediate cause is excitation of the semicircular canals or of their central connections.

(c) *Reactions of the neck and limb muscles*. In animals stimulation of the horizontal canals by a rotary motion causes alterations in tone and movements on both sides of the body which tend to resist the rotary movement and enable the animal to maintain its balance. When for example, a frog is rotated on a round table say to the left the tone of the neck muscles is increased on the right side and reduced on the left the head turning to the right. The limbs, especially the hindlimbs on the left are extended those on the right are flexed the animal may move around to the right. Cessation of the rotary motion causes a reversal of these effects upon the neck and limbs. In the snake lizard and reptiles with very long necks, the head may deviate to one or other side by as much as 100° or more. Sometimes a quick return to the normal position occurs as in nystagmus.

Dusser de Barenne who first described these reflexes cites a simple means for their demonstration. When a frog is rotated say to the left around its long axis by suspending it by a thread fixed to its jaw and giving the thread a twist between the finger and thumb the animal's right hindlimb is extended and abducted and the toes spread while the left hindlimb is bent at knee and ankle and the toes flexed. As the movement to the left comes to an end and turning to the right begins the limb movements are reversed. Similar movements may occur in the forelimbs.

Corresponding effects follow rotation, e.g., a quick tilt in the plane of a vertical canal. Tat and McNally described the respective vertical canals as affecting the limb muscles on one or other 'corner' of the body. Thus, stimulation of the right anterior vertical canal by a quick tilt diagonally forward and to the right causes contraction of the right forelimb stimulation of the left anterior vertical canal by tilting forward and to the left causes a corresponding movement of the left forelimb. Backward tilting to right or left causes respectively, contraction of the muscles of the right and of the left hindlimbs.

The post pointing test of Barany. Under ordinary circumstances a normal person if he places his finger upon a certain spot has no difficulty in hitting the mark again with his eyes closed. After

TABLE 64.2

Position of Head	Stimulus	Type and Direction of Nystagmus (Rapid Phase)	Sensation of Vertigo Head Upright after Rotation	Fast Pointing	Falling (after Bringing Head Upright)
Upright or forward	Rotation right	Horizontal left	Turning left	To right	To right
Forward 120°	Rotation right	Rotary, left	Falling to left	To right	To right
Backward 30°-60°	Rotation right	Rotary, right	Falling to right	To left	To left
Inclined to right shoulder	Rotation right	Vertical downward	Falling forward	Upward	Backward
Inclined to left shoulder	Rotation right	Vertical upward	Falling backward	Downward	Forward
Backward 30°-60°	Caloric 112°F to ear or 65°F to left	Horizontal right	Falling to right	To left	To left
Forward 90°-120°	Caloric 112°F to left ear or 65°F to left Galvanic	Horizontal left Mixture of horizontal and rotary Direction same as that of current	Falling to left	To right	To right

With stimuli opposite to sign to those given in the table the reactions are reversed

rotation, though able to place his finger upon a mark with his eyes open, he cannot find it again when his eyes are closed. The finger *deviates* or *past-points* to one or other side or above or below the mark, the direction of the miss aim being dependent upon the direction of the previous rotation and upon the position of the head during rotation (see table 64.2). Fast pointing is not reflex in nature but is a voluntary motor act; the error in judgment is the result of the associated subjective phenomenon, a subconscious correction being made in the opposite direction for the false sensation. The deviation of the finger and the vertigo are in opposite directions.

Other post-rotary reactions. If the body is rotated in the plane of the horizontal canals and the movement stopped, the head (eyes closed) then turns in the direction of the rotation. If rotation is carried out with the head in one or other plane of the vertical canals and the head after rotation is brought upright while the eyes are closed, the

body leans to one or other side backward or forward according to the position of the head during rotation. The subject may actually fall in the direction to which the body leans. The phenomenon is virtually a past-pointing of the entire body. The actual fall is therefore, opposite in

FIG 64.18 So-called discobolus position resulting from caloric or galvanic excitation of the labyrinth. (From Camus after Wodak and Fischer.)

direction to the vertiginous sensation of falling. That is, the subject has the illusion that he is leaning to one side (i.e., a sense of being rotated in the frontal plane of the skull), and in order to correct his supposed false position and return his balance leans actually in the *opposite* direction, and therefore falls if he leans too far.

One particularly interesting reaction resulting from excitation of the semicircular canals is that which has been appropriately called the *disc throwing* or *discobolus* attitude (fig. 6418). Though occurring after rotation it is evoked most readily by caloric (especially cold) or galvanic stimulation of the canals. A stimulus applied, say to the left ear, causes a twisting of the thorax upon the pelvis and rotation of the head to the stimulated side. When the arms are raised they are also turned toward this side with the left limb lower than the right. After a short time the attitude is reversed, the body swings round and takes up a position in the *opposite* direction. The attitude may reverse its direction several times. It is due to reflex alterations in tone of the musculature on the two sides of the body.

(d) *Reactions of the autonomic nervous system*. Excitation of the semicircular canals in man is not uncommonly followed by nausea, vomiting and pallor. A fall in blood pressure of 10 mm. or so may occur, together with slowing of the heart by 8 or 10 beats per min. In the rabbit syringing the ear causes vasodilatation and a fall in blood pressure. During rotation the pupil constricts; pupillary dilatation occurs upon cessation of the rotary movement.

Caloric Stimulation

The effects of caloric stimulation are similar to those following rotation but possess an advantage in that one or other ear can be examined separately. The ear to be tested is syringed with hot (112°F.) or with cold (68°F.) water.¹³ (In clinical practice much colder water is often used in examining the labyrinths.) When the head is bent backward through 60° the horizontal canals are brought into a vertical position. The douche causes a greater change in the temperature of the endolymph in the part of the canal lying nearer to the external meatus than in the part more deeply situated. Convection currents are set up which stimulate the receptors of the cristae; horizontal nystagmus and vertigo result. The change in temperature in the canal follows the irrigation of the external meatus by about 3 seconds. The direction of the convection currents, which of course are due to

changes in the specific gravity of the endolymph resulting from heating or cooling is determined by the temperature of the douche fluid. Thus a cold douche causes currents away from the ampulla; a hot douche causes ones toward the ampulla (see table 642). Caloric stimulation of the vertical canals is effected by donching with the head upright.

Galvanic Stimulation

In the employment of this method of stimulating the canals electrodes are placed one upon each mastoid process or more usually one on a mastoid process and the other on some indifferent part of the body. The current required in normal persons is from 2 to 7 ma. Owing to current spread all six canals are excited usually by electrical stimulation. The nystagmus has a rotary movement as well as a horizontal. The horizontal movement is with the current. Thus when the cathode is over the right labyrinth the nystagmus is to the right though the head may turn to the left. The resulting nystagmus is a mixture of the horizontal and rotary forms, its direction being the same as that of the current. Thus when the cathode is over the right labyrinth the nystagmus is to the right and vice versa. The effects occur only during the make and break of the current. In the absence of the labyrinth the galvanic current produces its effects by stimulation of the vestibular nerve. Consequently when as the result of disease labyrinthine function has been destroyed this method affords a means of determining the condition of the nerve. Whereas rotary, caloric and direct mechanical stimulation involve essentially the same mechanism—movement of the cupula—the galvanic current is a direct electrical stimulation of the cristae. Steinhausen observed no movement of the cupula during this form of stimulation.

Galvanic stimulation does not have the reliability of caloric stimulation and has not found wide acceptance in clinical practice.

Direct Mechanical Stimulation of the Canals in Animals

Ewald cemented a metal cylinder over a hole made in the bony wall of the horizontal canal. A piston fitted into the cylinder could be operated by air pressure. During the descent and ascent of the pneumatic hammer the membranous canal was compressed and decompressed respectively. The endolymph during compression and decompression moved respectively toward and away from the ampulla. An endolymph movement toward the ampulla caused a movement of the head and eyes to the opposite side. Decompression caused a weaker movement in the reverse direction.

The otolithic organs: utricle and saccule: gravity receptors. The role played by the utricle in the static reflexes has been dealt with in previous

¹³ Douches much nearer the body temperature than these will stimulate.

FIG. 64-19. Response of gravity receptor (otolith organ) showing the relationship between degree of tilt of head and frequency of impulses in vestibular nerve (After Adrian).

sections (see righting reflexes). But the gravity receptors respond also to linear acceleration—that is to movements in a straight line forward backward up or down, or laterally, as well as to slow tilting of the head on its transverse or its anteroposterior axis. The gravity receptors are also stimulated by a sudden cessation of a linear movement (deceleration), or a sharp change in the speed of such a movement. The receptors are stimulated when the otoliths are hanging down, and thus exerting a gravitational pull upon the sensitive hairs. It is possible that bending the hairs also acts as a stimulus. The utricular organs are also stimulated by centrifugal force and under certain conditions by angular acceleration.

In the cat when the head is level the receptors cause a discharge of impulses at a relatively low frequency (at about 6 per sec). When the head is tilted laterally (on its anteroposterior axis—cheek down) from the level position to an angle of 20°, the impulse frequency increases up to 95 per sec in the nerve on the side to which the head is tilted, but the resting discharge on the opposite side ceases. Thus, in a lateral tilt to the right the otoliths on that side (cheek down) are dependent and presumably exert a gravitational pull, whereas those on the opposite side are *resting* on the maculae, and are inactive. The greater the degree of downward tilt from the level position the higher is the impulse frequency (see fig. 64-19). If the head is held in the tilted position the impulse frequency declines slowly, for the gravity receptors are of the slow-adapting type. Tilting around a transverse axis (snout up or down) also evokes a response, though less readily than does a lateral tilt.

A pull upon the otoliths as a result of their inertia should also be caused by linear acceleration, i.e., a progressive or translatory movement in any of three directions, fore and aft, up or down (vertical linear acceleration),¹⁴ or sideways. Records of the action currents from the labyrinth show that this actually occurs, horizontal or vertical acceleration stimulates the gravity receptors in a lateral movement on the side from which the movement is made. Thus, a quick movement to the left stimulates the receptors on the right owing to the inertia of the otoliths, acceleration laterally and to the left acting like a gravitational pull upon the receptors of the right side. Adrian found that rapid fore or aft or up or down (vertical linear acceleration) also caused responses from the labyrinth. The threshold of excitation of the otolith organs by linear acceleration is around 12 cm. per sec. per sec.

The saccule. The role played by the saccule in the responses just described has not been settled unequivocally. Though anatomically this structure appears to be part of the vestibular mechanism it has been thought by many to have a cochlear rather than a vestibular function. McNally and Tait observed no loss of any known vestibular function after denervation of the saccules. The auditory nerve from a frog's labyrinth which has been denervated except for the saccule does not respond to vestibular stimuli by a discharge of impulses but gives a response when a vibrating tuning fork is brought near it. Lorente de No, on the other hand, traced saccular fibers to the vestibular nucleus but none could be found connecting this organ with the cochlear nucleus. Adrian considers that the saccules rather than the utricles are more likely responsible for the responses caused by lateral tilting and for upward linear acceleration while the utricles are excited by downward and horizontal accelerations and tilting around a transverse axis. A macula is situated on the medial wall of the saccule and faces laterally, a position suitable for stimulation of gravity receptors by a lateral tilt. Another macula lies in the roof of the saccule and faces downward and could be stimulated by upward linear acceleration.

In the guinea pig the otolith membranes can be

¹⁴ In a quick linear movement forward or backward or vertically the gravity receptors would be in the same plane as that of the movement which implies that they can respond to a pull acting in their own plane, though probably less effectively than to one acting at right angles. But in this case bending of the hairs rather than a pull upon them may be the effective stimulus.

detached by centrifuging the animal (at a speed of 1000 m per min) All responses to linear acceleration or to different positions of the head are then lost, but those caused by angular acceleration are retained

VESTIBULAR REACTIONS IN DISEASE

Abnormal vestibular reactions are seen in various diseased conditions involving (a) the labyrinth, (b) the vestibular nerve, or (c) the vestibular centers or central pathways (e.g., Deiter's nucleus, medial longitudinal bundle, cerebellum) Normally, some slight nystagmus may occur upon looking for a time to the right or left, but if nystagmus is present when looking forward or if pronounced when the eyes are turned to one side, it is pathological A spontaneous vertical nystagmus suggests a lesion of the brain-stem, it is not seen in disease of the labyrinth itself or of the vestibular nerve The phenomenon of past-pointing, unless induced artificially, is always pathological and suggests a cerebellar lesion Spontaneous vertigo most commonly occurs as a result of labyrinthine disease but may be seen with disorders of the medulla oblongata Disturbance of equilibration may be seen with diseases of the labyrinth, the brain-stem or the cerebellum On the other hand, a lesion in one or other of these situations may cause a failure of the usual reactions following rotary or caloric stimulation In deaf mutes, the labyrinthine reactions, as a rule, are absent Again, the reactions to artificial stimulation may be abnormal, for example, in a lesion of the brain-stem vertical nystagmus may occur in response to a stimulus which normally causes nystagmus of the horizontal type

MÉNIÈRE'S SYNDROME

The features of this condition are paroxysmal attacks of vertigo, noises in the ears (tinnitus) and a progressive impairment of hearing of the inner ear type (ch 78) The sense organs of the cochlea (organ of Corti) as well as those of the semicircular canals are affected in this disease There are various pathological processes in the inner ear which may give rise to this symptom complex, but labyrinthine hydrops is the most common one Medical therapy directed toward the reduction of the sodium content of the body has been effective in relieving the victims of this condition The surgical treatment of the condition consists of severing the

vestibular portion of the 8th nerve intracranially, leaving the cochlear division intact (McKenzie, Dandy), or of destroying the labyrinth with ultrasonic waves

THE SPINAL CORD AND BRAIN STEM (MEDULLA OBLONGATA, PONS AND MIDBRAIN) AND THE RETICULAR FORMATION

Outline of the Internal Structure of the Spinal Cord

In figure 65 1 the spinal cord is shown in cross-section. The *gray matter*, centrally placed, is in the form roughly of an H or the two wings of a butterfly. It is composed of a mass of nerve cell bodies and nerve fibers (dendrons and axons), mostly unmyelinated, supported by a framework of neuroglia. The ventral and dorsal portions of each lateral half of the gray mass (i.e. each arm of the H) are commonly referred to, respectively, as the ventral (or anterior) and dorsal (or posterior) horns but since the gray matter extends throughout the length of the cord 'column' is a more suitable term than 'horn'. In the ventral columns are situated the large bodies (100μ in diameter) of the motor neurones whose axons leave the cord by the ventral roots. Each axon ends in a group of skeletal muscle fibers—the neuromuscular structure constituting the so-called motor unit. The large multipolar cells are known as α cells and innervate the ordinary striated muscle fibers. The small γ cells innervate the intrafusal fibers of the muscle spindles and thus regulate the threshold of these important proprioceptive end-organs (see ch. 62). In the thoracic and upper lumbar segments, the gray mass lying between the ventral and dorsal columns shows a small lateral projection. This is the lateral column or horn: it contains a cluster of nerve cells (the *intermediate lateral cell column*); they give origin to sympathetic (preganglionic) fibers which leave the cord by the anterior (ventral) nerve roots. The well defined collection of cells occupying the inner part of the base of the posterior horn is known as *Clarke's column*: this group, since it is confined almost entirely to the thoracic region of the cord, is also known as the *dorsal nucleus*. It is homologous with the nucleus cuneatus of the medulla oblongata (p. 1193). To the outer side of

the base of the posterior column is an area where strands of white matter and prolongations from the main mass of gray matter intermingle to form a delicate interlacement. This is known as the *reticular formation* (*formatio reticularis*) and is most prominent in the cervical region. It is continuous with the reticular formation of the medulla oblongata and pons. At the apex of the dorsal horn is a cap of gelatinous material containing groups of small nerve cells possessing many dendrites and named the *substantia gelatinosa of Rolando*. It is believed to receive the finest fibers (myelinated and unmyelinated) of the posterior roots. The remaining part of the substance of the dorsal horns constitutes the *chief sensory nucleus*. A canal pierces the bar or isthmus connecting the two lateral masses of gray matter across the midline; it is known as the *central canal*. The gray isthmus itself is called the *gray commissure*. Sometimes the parts in front and behind the central canal are referred to as the anterior and posterior gray commissures respectively (fig. 65 2).

The *white matter* which completely surrounds the gray matter is composed of bundles of fibers both myelinated and unmyelinated, the former predominating. A deep cleft on the ventral aspect of the spinal cord (the *anterior median fissure*) and a septum on the dorsal aspect (*posterior median septum*) together, incompletely divide the white matter into two lateral halves. The bands of white matter lying in front of the gray commissure are called the *anterior (ventral) white commissure*; a few strands of white matter lying behind or within the posterior part of the gray commissure are sometimes called the *posterior (dorsal) white commissure*. Each half is further marked out, by the fibers of the ventral and dorsal nerve roots, into three white columns or funiculi, ventral (anterior), lateral and dorsal (posterior). The *anterior*

FIG 634 Showing distribution of cutaneous nerves (right halves of figures) and the dermatomes (left halves) (After Wolff) The student must recognize that these are schematic outlines and that the actual areas of innervation vary considerably from person to person

FIG 635 Diagram showing the overlapping of the skin area innervated through the fourth thoracic spinal nerve root by those supplied by the third and fifth. The small circle indicates the position of the nipple (After Sherrington)

area lying between the tip of the posterior horn and the periphery of the spinal cord (fig. 636). It is composed of fibers derived from the lateral division of the posterior nerve roots. These fibers

upon entering the spinal cord connect immediately, or after a very short upward or downward course, with cells occupying the tip of the posterior horn, i.e., in the substantia gelatinosa of Rolando (p. 1186). The fibers of this tract are mostly of small diameter and for the most part unmyelinated, and from both pathological and experimental evidence there is little doubt but that they constitute the primary neurons in the pathway for pain and crude thermal sensations. The axons of the secondary neurons (axons of the cells in the substantia gelatinosa of Rolando just mentioned) go to form the lateral spinothalamic tract of the opposite side, to be immediately

Dorsal (posterior)	Fasciculus gracilis Fasciculus cuneatus		Septomarginal fasciculus Dorsal (posterior) intersegmental fasciculus

2 ANTEROLATERAL AND VENTRAL (ANTERIOR) SPINOTHALAMIC TRACTS These tracts occupy respectively, the lateral and ventral columns of the cord. The fibers of the *lateral tract* arise, as mentioned above, from cells in the substantia gelatinosa of Rolando, of the opposite side of the cord. Those of the *ventral tract* are the axons of cells in the chief sensory nucleus of the opposite dorsal horn of gray matter.

In order to reach the ventral spinothalamic tract of the opposite side the fibers arising from the chief sensory nucleus ascend in the posterior columns for two or three spinal segments, and then cross in the anterior white commissure. This tract is a crossed pathway for the sensations of touch, and probably also for tactile localization. These sensations have therefore a double path to consciousness for they are also conveyed uncrossed in the posterior columns of the cord.

The fibers going to form the lateral spinothalamic tract (secondary neurons from cells of substantia gelatinosa of Rolando of the opposite side) ascend for a short way (within a single segment) and then cross in the anterior white commissure. This tract transmits impulses aroused by all forms of thermal and painful stimuli.

The two tracts—*anterior and lateral*—come together in the medulla oblongata to constitute the spinal lemniscus which joins the medial lemniscus in the upper part of the medulla oblongata to enter the thalamus (ch. 66).

3 SPINOTECTAL TRACT This is placed in the lateral column ventral to the lateral spinothalamic tract. Its fibers arise from cells in the posterior horn of the opposite side and terminate in the superior colliculus. It subserves spinovisual reflexes.

4 SPINO-OLIVARY TRACT The fibers of this tract are the axons of cells in the dorsal horn of gray matter; they run with olivospinal fibers and end in the inferior olivary nucleus of the opposite side. They probably transmit proprioceptive impulses which are relayed from the olivary nucleus to the cerebellum. Some anatomists have expressed doubts as to the existence of an olivospinal tract.

5 SPINOCEREBELLAR TRACTS (a) The *dorsal (posterior) spinocerebellar tract* (direct cerebellar or tract of Flechsig) is situated in the posterior part of the lateral funiculus to the outer side of the lateral corticospinal tract. It is composed of the axons of the cells of Clarke's column (p. 1186) of the same side and possibly, to some extent of the opposite side. The direct cerebellar tract reaches the cerebellum via the inferior cerebellar peduncle; its fibers end mainly in the cortex of the anterior and posterior lobes of the cerebellum (ch. 69). (b) The *ventral (anterior or indirect) spinocerebellar tract* arises from cells in the base of the dorsal horn mainly of the same side, but also of the opposite side of the cord. It ascends in front of the dorsal spinocerebellar tract and is con-

FIG. 656 Diagram showing the course of afferent impulses after their entrance into the cord. *Red* pathway for pain and thermal sensations (ascend in ventrolateral spinothalamic tract of opposite side). *Blue*, pathway for touch, sense of position and movement and spatial discrimination (ascend in posterior columns), external arcuate fibers from posterior column nuclei to cerebellum also shown. *Green*, pathway for touch and tactile localization (after travelling for variable distances in posterior columns fibers cross to ventral spinothalamic tract of opposite side). *Black*, ventral and dorsal spino-cerebellar tracts, some fibers of latter (not shown) also cross to opposite side.

tinued upwards through the brain stem as far as the midbrain where it arches backwards (arciform fibers) to reach the cerebellum via its superior peduncle. Its constituent fibers end in the cortex of the anterior and posterior cerebellar lobes. The spino-cerebellar tracts carry impulses arising in the proprioceptors of the muscles, tendons and joints. The information thus conveyed to the cerebellum is essential for the latter's function in adjusting the tone of the skeletal muscles and synergizing their movements (ch. 69).

6 FASCICULI GRACILIS (TRACT OF GOLL) AND CUNEATUS (TRACT OF BURDACH). These occupy the dorsal (posterior) funiculus of the spinal cord. In the upper part of the spinal cord the former tract lies on the medial side of the latter.

Both tracts are composed of heavily myelinated fibers which are the continuation upwards of the fibers of the medial division of the posterior nerve roots of the same side. The nerve cell bodies from which these fibers arise lie outside of the spinal cord in the posterior root ganglia. The fasciculus

gracilis commences in the lowest level of the spinal cord. After their entrance into the cord, its fibers divide into long ascending and short descending branches. A few of the former fibers and all the latter, after a short course, enter the gray matter. The long divisions become displaced medially as they ascend, with the result that fibers arising at lower levels (e.g., sacral region) come to lie nearer the midline than those entering the spinal cord higher up. The *fasciculus cuneatus* first appears in the midthoracic region. Therefore, from the midthoracic region upwards, the more medially placed tract (*fasciculus gracilis*) is derived from the lower thoracic, and the lumbar and sacral nerve roots, in this order, from the lateral to the medial border of the tract. The ascending fibers of both tracts pass uncrossed to the medulla oblongata, ending, respectively, in the nucleus *gracilis* and the nucleus *cuneatus*. However, this division into two tracts and two nuclei is an artificial one. We are dealing here with only one tract with fibers serving different parts of the body. From the nuclei *gracilis* and *cuneatus* the axons of secondary neurons emerge and, passing medially as the *internal arcuate fibers*, decussate with those of the opposite side (sensory decussation). They ascend through the brain stem as the *medial lemniscus* (see below) to terminate in the posteroventral part of the lateral nucleus of the thalamus. Other fibers (*external arcuate*) from the nuclei *gracilis* and *cuneatus* relay impulses to the cerebellum from these same posterior columns. They are concerned with reflex activity and not with sensory perception.

SUMMARY OF THE PRINCIPAL PATHWAYS ASCENDING THROUGH THE SPINAL CORD

1 **SENSORY** (conveying impulses to consciousness) (a) The fibers mediating thermal and painful sensations enter the cord in the lateral divisions of the posterior nerve roots. According to Ranson they are unmyelinated. Within the spinal cord they constitute Lissauer's tract. Immediately, or after a very short upward or downward course, they enter the dorsal horn and connect with nerve cells in the substantia gelatinosa of Rolando. The axons of the latter secondary neurons cross to the opposite side in the white commissures and ascend as the ventrolateral spinothalamic tract. This tract occupies a position in the brain stem lateral to the medial lemniscus and ends in the posterolateral part of the ventral nucleus of the thalamus (cf. figs. 65.1 and 65.6).

(b) The fibers conveying all other sensory impulses, e.g., from the muscles and joints (sense of movement and position), and those mediating the senses of vibration, touch, pressure, tactile localization and spatial discrimination (compass test), enter the cord in the medial division of the posterior roots and ascend in the *fasciculus gracilis* and *fasciculus cuneatus*. The fibers mediating all these sensations, except some of those concerned with touch and probably with tactile localization, pass without crossing to the nuclei in the medulla oblongata where they connect with secondary neurons. The axons of the latter constitute the *internal arcuate fibers*; they decussate with those of the opposite side and ascend to the thalamus as the *medial lemniscus* (or *fillet*). Tertiary neurons convey the impulses to the cerebral cortex.

In a transverse spinal lesion interrupting solely the posterior fasciculi, vibratory and position senses are lost but the sensation of touch is retained, since the fibers which have entered the gray matter and crossed below the level of the lesion to ascend in the ventral spinothalamic tract have escaped injury. Likewise, although a hemisection of the spinal cord destroys vibratory and position senses on the same side and pain and temperature sensibilities on the opposite side, it does not abolish tactile sensibility as this is conveyed in both crossed and uncrossed pathways (see hemisection of the cord).

2 **NON-SENSORY** impulses from the muscles, tendons and joints as well as nonsensory impulses aroused by a tactile stimulus, are conveyed into the spinal cord by fibers composing the radial divisions of the posterior roots. These fibers connect immediately with the cells of Clarke's column and are continued upwards in the dorsal (direct) and ventral (indirect) cerebellar tracts of the same side, mainly, but also of the opposite side. Some of these impulses, viz., those which enter the cervical cord, are conveyed by fibers of the cuneate fasciculus to the cuneate nucleus to be relayed by secondary neurons (*external arcuate fibers*) via the inferior peduncles to the cerebellum (see fig. 65.6).

Sensory Paths in the Brain Stem (Medulla Oblongata, Pons and Midbrain)

The *medial lemniscus* (or *fillet*) is composed of fibers arising in the nuclei *gracilis* and *cuneatus*. The fibers leave the ventral aspects of these nuclei and arch forward and medially (as *internal arcuate fibers*) to the midline where they cross

FIG. 65. Diagram of the trigeminal, medial and spinal lemnisci: *mn* mesencephalic motor nucleus of trigeminal nerve; *sn* sensory nuc. of trigeminal; *st* spinal tract and nucleus of trigeminal; *md* motor fibers passing into mandibular nerve; *gg* Gasserian ganglion; *nc* nuc. cuneatus; *fp* posterior columns of the cord; *ng* nuc. gracilis; *tl* trigeminal lemniscus; *pvm* posterior ventral nuc. of the thalamus; *st* spinal lemniscus; *ml* medial lemniscus; *lst* lateral spinothalamic tract; *ast* anterior spinothalamic tract; *md* midline. The trigeminal is on the medial side of the medial lemniscus; only in the medulla it comes to lie on the outer side in the pons and in close relation to the spinal lemniscus.

with corresponding fibers of the opposite side (*sensorj decussation*). They then turn upwards as a compact bundle known as the medial lemniscus or fillet. This ascends through the medulla oblongata and pons dorsal to the corticospinal tracts and through the tegmentum of the mid brain.

The *spinal lemniscus* (or fillet) is formed by the fusion of the anterior and lateral spinothalamic tracts and is therefore a crossed path for impulses aroused by light touch, pressure, pain, heat and cold. In the upper part of the medulla oblongata the spinal lemniscus joins the medial lemniscus on its outer side and is joined in the pons by the trigeminal lemniscus.

The *trigeminal lemniscus* (or fillet) conveys impulses from the area of distribution of the trigeminal nerve of the opposite side (p. 1199).

The fibers of the medial spinal and trigeminal lemnisci terminate in the thalamus, from where tertiary neurons pass to the cerebral cortex (see fig. 65.7).

The *lateral lemniscus* constitutes the pathway for auditory impulses from the cochlear nuclei to the inferior colliculus and the medial geniculate body.

The sensory pathways are constituted of three neurons. For example, the pathway traversed by the sensory impulses for touch or kinesthetic sense consists of a primary neuron whose cell body lies in the posterior root ganglion, a secondary neuron originating in a posterior column nucleus (*gracilis* or *cuneatus*) and a tertiary neuron arising in the thalamus which convey impulses to the somesthetic area of the cerebral cortex (ch. 67). The cells of the Gasserian ganglia are the primary neurons of the trigeminal pathway; secondary neurons lie in the sensory nucleus and in the spinal nucleus of the nerve (p. 1198); tertiary neuron fibers ascend to the cortex from the thalamus. In the upper part of the pons and in the midbrain these several sensory pathways become fused together into a compact bundle. But a lesion in the lower part of the brain stem may involve one of the sensory pathways exclusively of the others. Thus an injury localized to the outer part of the lower pons or of the medulla oblongata may, by injuring the spinal lemniscus, cause loss of sensation to pain, heat and cold over the *opposite half* of the body, leaving muscle sense and tactile discrimination intact. Sensory loss of this nature accompanied by ipsilateral cerebellar symptoms occurs as a result of the occlusion (as by thrombosis or embolism) of the posterior inferior cerebellar artery. Usually also as a result of the involvement of the bulbospinal tract of the trigeminal nerve (p. 1198) the face on the *same side* as the occluded vessel shows a loss of pain and temperature sensibilities, whereas tactile sensation which is transmitted by the main sensory nucleus is largely unaffected. A lesion more centrally placed may, by implicating the medial lemniscus alone, cause the converse type of dissociated sensory defect, namely, loss of the sense of position of the limbs and of spatial discrimination, with retention of sensibility to pain, heat and cold. In lesions at higher levels in the brain stem all forms of sensation are likely to be involved more or less equally.

Descending Tracts of the Spinal Cord

1 CORTICO-SPINAL (CEREBRO-SPINAL) TRACTS

From their origins in the cerebral cortex these tracts descend through the cerebrum and brain stem on each side to the lower border of the medulla oblongata. Here each tract divides into two bundles of unequal size, the larger of which crosses to the opposite side and descends in the posterior part of the lateral funiculus of the cord as the *lateral corticospinal tract*. The remaining fibers uncrossed, descend in the anterior funiculus as the *anterior corticospinal tract*. In most instances the direct or anterior cortico-spinal tract is but a small part of the total number of cortico-spinal fibers (usually not over 10 per cent), but the number of fibers in the anterior tract varies and in rare instances most of the corticospinal fibers lie in this position. In most cases these anteriorly placed fibers descend only as far as the cervical spinal cord. Even these fibers cross to the opposite side

before terminating on the ganglion cells of the anterior gray column (cf figs 651 and 658). There are also direct cortico-spinal fibers lying in the lateral columns of the spinal cord which do not cross to the opposite side. Through these the precentral motor cortex sends impulses to ipsilateral skeletal muscles.

All cortico-spinal fibers whether crossed or uncrossed connect with the large motor cells of the ventral gray columns (anterior horn cells). The connections are of two types, (a) direct synapses (20 to 30 per cent) with the motor neurons, (b) in direct connections with these cells through an internuncial neuron whose cell body is also in communication with a posterior root fiber on each side. It has been estimated that from 75 to 90 per cent of the cortico-spinal fibers terminate in the cervical (55 per cent) and thoracic (20 per cent) regions of the spinal cord and about 25 per cent in the lumbar and sacral regions.

FIG. 658 Diagram of the descending tracts of the cord showing corticospinal tracts (black), rubrospinal tracts (red), tectospinal tracts (blue) and vestibulospinal tracts (green). B.C. Betz cell of motor cortex, R.N., red nucleus, S.C. superior colliculus, V.N. vestibular nucleus. The implication of this figure that the corticospinal tract arises exclusively from the Betz cells is erroneous.

For many years an erroneous belief was entertained that all of the fibers in the pyramids on the ventral surface of the medulla oblongata arose from the Betz cells of the precentral gyrus and were responsible for all voluntary activity of the skeletal musculature. It is now known that this concept contains many errors. Only a very small percentage of the corticospinal fibers arise from the gigantic Betz cells of the precentral gyrus, approximately 3 to 4 per cent. The remainder of the corticospinal fibers arise from other cells in the precentral gyrus, from cells in the parietal cortex and perhaps other areas. There is a question as to whether all of the fibers in the medullary pyramids are of cortical origin and some investigators have even questioned as to whether they are all descending fibers. Certainly all voluntary muscular activity is not achieved exclusively by corticospinal fibers or by fibers contained in the medullary pyramids. There are multisynaptic fiber pathways from the cortex down to the anterior horn cells of the spinal cord which are also capable of producing voluntary movement.

2 VESTIBULOSPINAL TRACTS Two tracts, a ventral and a lateral, are commonly designated, although there is no evidence that they serve different functions or that there is any significant difference between them. The *ventral vestibulospinal tract* arises predominantly from the spinal or inferior vestibular nucleus (in the cat) and descends in the forepart of the anterior funiculus of the spinal cord just lateral to the anterior corticospinal tract. It is a downward extension of the medial longitudinal fasciculus of the brain stem. The *lateral vestibulospinal tract* is a prominent descending pathway lying in the anterolateral part of the spinal cord. It arises from the lateral vestibular or Dürer's nucleus and extends throughout the entire length of the spinal cord. Most of its fibers are uncrossed although a few arise from the contralateral lateral vestibular nucleus. The vestibulospinal fibers terminate either upon the anterior horn cells or upon small internuncial neurons which in turn form synapses with the motor cells of the anterior gray horns of the spinal cord.

3 TECTOSPINAL TRACTS of each spinal half arise from the contralateral superior and inferior colliculi and descend at first as a single compact bundle through the reticular formation of the brain stem. Upon reaching the cord the fibers are segregated into two fasciculi, a ventral and a dorsal which descend in the ventral and lateral white columns respectively. The fibers synapse with the spinal motoneurons, either directly or

through internuncial neurons, especially in the cervical region, wherein are situated the centers for the neck muscles. Impulses from the retina are received by the superior colliculus which through such impulses, and its spinal connections serves as a center for the integration of visual impressions with body movement, especially of the head (*visuospatial reflexes*). This center is probably of less importance in man, with his highly developed visual cortex, than in animals. Auditory reflexes may also be mediated by this tract and the inferior colliculus.

4 RUBROSPINAL TRACT arises from the large cells (nucleus magnocellularis) in the posterior part of the red nucleus (p. 1215). The fibers immediately upon leaving the red nucleus cross to the opposite side (*Forl's decussation*) and descend through the reticular formation of the pons and medulla to enter the lateral funiculus of the cord ventral to the lateral corticospinal tract. In carnivorous animals e.g. cat and dog the rubrospinal tract is large and important. In the primates particularly in man, the rubrospinal tract is so small that its existence has been questioned at any rate it has little if any functional significance.

5 OLIVOSPINAL (BULBOSPINAL) TRACT OF HELWEG Its fibers are presumed to arise from cells in the neighborhood of the inferior olivary nucleus and descend in the ventral and lateral part of the lateral funiculus. However, its existence has been seriously questioned. It descends no farther than the cervical region. The fibers synapse with motor neurons. The functions of this tract are unknown. It and the thalamo-olivary tract constitute a possible path whereby impulses from the thalamus may reach the spinal centers.

6 RETICULOSPINAL TRACTS arise from cells scattered through the reticular formation of the brain stem. They are two in number, one in which crossed fibers predominate descends in the anterior funiculus, the other composed mainly of uncrossed fibers in the lateral funiculus. They connect with the motor neurons in the anterior horns and probably with cells in the lateral horn. Impulses conveyed over this complex pathway are concerned with the regulation of the reflex activity of the skeletal musculature, the control of the vegetative nervous system, adjustment of the threshold of peripheral end-organs such as the muscle spindles and of the sensory pathways.

Intersegmental Tracts of the Spinal Cord

There is in each funiculus of the cord lying close to the gray matter an intersegmental fasciculus

or ground bundle. These, as already mentioned, serve to link spinal segments of different levels. Their fibers arise from cells in the gray matter and after an ascending or descending course of variable length end around cells of the same or of the opposite side at a higher or a lower level. A proportion of the fibers constituting the intersegmental fasciculus of the lateral column of the spinal cord (*lateral intersegmental fasciculus* or *lateral ground bundle*) are continuous upwards into the medial longitudinal fasciculus (or bundle) of the brain stem. The ground bundle of the anterior funiculus (*anterior intersegmental* or *subcomarginal fasciculus*) is composed of fibers which connect the anterior horn cells of one side with those of the opposite side both at the same and at different levels. In the cervical region it is composed largely of the spinal fibers of the medial longitudinal fasciculus.

The posterior funiculus contains (a) the septomarginal fasciculus and (b) the posterior intersegmental fasciculus (or posterior ground bundle).

The *septomarginal fasciculus* is composed of (a) intersegmental fibers which arise from cells of the posterior horn and synapse with corresponding cells at lower levels and (b) descending fibers of the medial divisions of the posterior nerve roots. *Septomarginal fasciculus* is a term applicable to these fibers only in the lumbar region where they abut on each side against the posterior median septum. They are also known here as the *otal area* or *bundle of Flechsig*. These fibers form areas of different sizes and shapes on cross section at various spinal levels. In the cervical and upper thoracic regions the fibers appear on section as a

cresecentic area at about the center of the posterior funiculus. Here they are spoken of as the *comma tract of Schultz* or *tractus interfascicularis*. In the lower thoracic region they form a narrow zone bounding the posterior aspect of the cord and are known as the *dorsal peripheral strand*. In the sacral region this tract lies against the posterior part of the median septum and is called the *triangular area of Philippe Gombault*. The descending fibers of the branches of the medial division of the posterior roots as they descend also like the long ascending branches become displaced toward the midline.

The *posterior intersegmental fasciculus* is seen in cross section as a small area lying behind the posterior gray commissure. Its fibers connect the posterior horn cells of different segments (see fig. 65-1).

The Longitudinal Fasciculus (or Bundle)

The medial (posterior) longitudinal fasciculus (or bundle) is a tract of great physiological importance and is present in all vertebrates. It is composed of fibers which connect the 3rd, 4th and 6th cranial nerves with one another and with the vestibular nuclei and makes connections with the motoneurons of the cervical segments of the spinal cord (fig. 65-1b). The tract lies near the midline and extends from the cervical segments of the spinal cord where it is continuous with the anterior intersegmental fasciculus (anterior ground bundle) to the floor of the 3rd ventricle. In the medulla oblongata it lies immediately subjacent to the floor of the 4th ventricle; in the pons it courses through the *formatio reticularis* and in the midbrain lies in relation to the gray matter of the floor of the Sylvian (cerebral) aqueduct. It also receives fibers from the lateral lemniscus (auditory path p. 1194) and from the superior colliculus through which it is in communication with the optic pathway (ch. 75). The essential function of the medial longitudinal bundle is the coordination of reflex movements of the ocular and neck muscles in response to labyrinthine, auditory and visual stimuli.

The Central Connections of the Trigeminal, Facial, Glossopharyngeal, Vagus, Accessory and Hypoglossal Nerves

THE TRIGEMINAL PATHWAY

The trigeminal nerve appears on the lateral surface of the pons. The nerve has three roots (a) a large sensory (b) a small motor, and (c) a mesencephalic (fig. 65-9).

FIG. 65-9. Diagram of the central connections of the trigeminal nerve.

The fibers of the sensory root convey impulses from the anterior part of the scalp from the skin of the forehead and face with the exception of an area over the lower border of the mandible. It also supplies the mucous membrane of the mouth, anterior two thirds of tongue and nose, the cornea and conjunctiva and part of the intracranial dura mater. This root arises from the cells of the gasserian (semilunar) ganglion, which corresponds to a spinal posterior root ganglion. The processes of the ganglion cells divide into peripheral and central branches. The former enter into the composition of the peripheral divisions (ophthalmic, maxillary and mandibular) of the nerve; the central branches (which constitute the sensory root of the nerve) enter the pons in close association with the fibers of the motor root and divide into an ascending and a descending group in a manner homologous with a spinal root fiber. The ascending fibers convey impulses of light touch, tactile discrimination and localization, and of the sense of position and passive movement. They end in a nucleus (main or upper sensory nucleus of the trigeminal nerve) situated in the pons, deep and lateral to the motor nucleus. The axons of cells in this nucleus ascend with those from the spinal nucleus of the trigeminal nerve (see below) to form the *trigeminal lemniscus*. The descending fibers constitute the *bulbospinal tract of the trigeminal nerve*. They subserve sensations of pain and temperature over the entire trigeminal area. They descend through the pons and medulla oblongata and may be traced as far as the 2nd cervical segment. This tract dwindles gradually in its descent, its fibers terminating around cells in the substantia gelatinosa of Rolando which in this situation is referred to as the *spinal nucleus of the trigeminal nerve*. From the spinal nucleus the axons of secondary neurons swing downward in the spinal tract of the trigeminal nerve as far as the upper cervical spinal cord. They then cross the midline and turn upward. In the upper part of the medulla oblongata they join fibers arising from the upper sensory nucleus to form the *trigeminal lemniscus* (or fillet). The trigeminal lemniscus lies in close association with the medial and the spinal lemnisci (spinothalamic tracts) (p. 1191), its fibers terminate in the posteroventral nucleus of the thalamus.

A number of reflexes are mediated through the afferent fibers of the trigeminal nerve, e.g., corneal, winking, sneezing and oculocardiac.

The main sensory nucleus of the trigeminal cor

responds to the nuclei of the posterior columns of the spinal cord (nuclei gracilis and cuneatus) and like the latter sends fibers to the cerebellum through the inferior cerebellar peduncle. The spinal tract of the trigeminal nerve may be looked upon as corresponding to the tract of Lissauer (p. 1189), and the spinal nucleus as an extension upwards of the substantia gelatinosa of Rolando whose cells, as we have seen, give rise to the lateral spinothalamic tract.

The motor root fibers arise from a nucleus in the upper part of the pons underlying the lateral part of the floor of the 4th ventricle. The nucleus receives fibers from the corticobulbar tract of the opposite side and also probably from the same side. The motor root after its emergence from the brain stem, travels peripherally with the sensory root and passing deep to the gasserian ganglion, joins the mandibular (3rd) division of the trigeminal nerve to supply the muscles of mastication (temporal, masseter and pterygoids).

The *mesencephalic root* consists of a small bundle of fibers which run in company with the fibers of the motor root. Entering the pons they ascend to the *mesencephalic nucleus* of the trigeminal, an elongated collection of nerve cells extending from the level of the motor nucleus to the upper region of the midbrain. It was thought at one time that the mesencephalic root and nucleus were motor in function, but it is now generally admitted that they are composed of afferent neurons. The nucleus is looked upon as a group of cells homologous with the gasserian (semilunar) ganglion and the posterior root ganglia of the spinal nerves, but which has migrated or been "drawn" into the brain stem at an early period of phylogenetic development. It is believed to receive proprioceptive impulses from the muscles of mastication and possibly from the ocular muscles.

LESIONS INVOLVING THE TRIGEMINAL PATHWAYS. Either the peripheral portions or the central connections of the nerve may be the seat of disease. A lesion of the nerve peripheral to the ganglion is more likely to involve only one of its three divisions. Pain or loss of sensibility over the distribution of the division affected, may result. If the gasserian ganglion is involved the disturbance of sensation usually involves the area of distribution of more than one division, often of the entire nerve. If as a result the eye is rendered anesthetic the patient may develop an ulceration of the cornea and an inflammation of the cornea and conjunctiva. This has often been referred to as a neuroparalytic keratitis and has been attrib-

uted to the loss of some obscure trophic influence of the nerve. Actually it results from the fact that the eye is anesthetic and can be injured easily by a foreign body or by scratching without any discomfort to the patient. The eye is then likely to be neglected by the patient because it is not painful. As a result he may lose his sight or even his eye.

Herpetic eruptions may result from the involvement of the gasserian ganglion. Spontaneous herpes zoster usually involves the area of distribution of the ophthalmic division and is often serious because the lesions on the cornea may lead to corneal opacity and loss of vision. Such herpes is also commonly followed by a very distressing post herpetic neuralgia which is very difficult to treat satisfactorily.

Paralysis of the muscles of mastication with reduction in the strength of the bite on the affected side and deviation of the mandible toward the paralyzed side when it is opened occurs when the motor division is involved. Such paralysis is commonly seen in association with affections of the mandibular division which the motor root joins or of the gasserian ganglion which lies directly over the motor root.

Loss of sensation of taste (as well as of ordinary sensibility) over the anterior two-thirds of the tongue on the corresponding side is a common accompaniment of degenerative changes affecting the mandibular division of the 5th nerve. The taste fibers to this part of the tongue are derived from the chorda tympani branch of the facial, but travel via the lingual branch of the mandibular division of the trigeminal nerve. Removal of the gasserian ganglion does not result in a loss of taste.

Lesions (e.g., tumors, vascular changes) in the pons, medulla or upper cervical spinal cord may injure the upper sensory nucleus, the motor nucleus, the trigeminal lemniscus (crossed) or the bulbospinal tract of the nerve. When the motor nucleus is involved weakness and wasting of the muscles of mastication result, implication of the ascending sensory fibers, or of the main sensory nucleus in the pons, is followed by loss of the sensation of light touch and the discriminative aspects of cutaneous sensibility over the same side of the face, but the retention of sensibility to pain, heat and cold. The neighboring spinothalamic tract (crossed) may suffer coincidentally with the ascending sensory fibers, when *thermanesthesia* and *analgesia* over the trunk and limbs of the opposite side combined with loss of tactile sensation

over the face of the same side will result (see also p. 1193). Syringomyelia extending into the upper cervical region or into the bulb (syringobulbia) is likely to cause, as a result of pressure upon the spinal tract of the nerve, a loss of the appreciation of pain and changes in temperature with retention of tactile sensibility.

The trigeminal nerve, or one of its divisions, is sometimes the seat of a severe and intractable type of pain which recurs in paroxysms (*trigeminal neuralgia* *tic douloureux*). The cause of the affection is unknown. In treating the condition injections of alcohol into the division of the nerve involved are sometimes employed. The injection is made into the nerve at the infraorbital foramen in the case of involvement of the maxillary division and at the foramen ovale of the sphenoid or at the supraorbital notch, respectively, in disease of the mandibular or ophthalmic division. Injection or section of the peripheral branches result in only temporary remission of the pain whereas the section of the nerve between the gasserian ganglion and the pons provides permanent relief. The motor root can be spared in such an operation.

THE FACIAL NERVE

The facial nerve consists of a large motor and a small sensory portion. The two portions or roots appear at the lower border of the pons and enter the internal auditory meatus in company with the auditory nerve.

The sensory root of the facial which is also known as the *nervus intermedius* of H. Risberg contains not only afferent fibers but secretory and vasodilator (parasympathetic) fibers as well.

The sensory fibers arise from the cells of the geniculate ganglion (fig. 6510). The peripheral processes of these cells are distributed through the chorda tympani branch of the facial nerve to the taste buds and mucous membrane of the anterior two-thirds of the tongue, and through the nerve to the pterygoid canal (formed by the union of the greater superficial petrosal and the deep petrosal nerves), and the sphenopalatine ganglion to the lacrimal gland and the mucosa of the soft palate and posterior part of the nose. The chorda tympani branch joins the trunk of the lingual nerve through which it is conveyed to the floor of the mouth.* The central processes of the gan-

* The *nervus intermedius*, the geniculate ganglion, the chorda tympani and part of the great superficial petrosal nerve are sometimes grouped together under the name *glossopalatine nerve*. The origin and distribution of the secretory and sensory fibers of which this nerve is composed are

FIG. 65.10. Diagram of the facial nerve—afferent and efferent paths including taste (red) and secretory fibers (dotted lines) (After Purves Stewart)

gion cells end in the *sensory nucleus* situated in the upper part of the *tractus solitarius*. Fibers arise from the latter and ascend in the medial fillet of the opposite side to reach the thalamus.

The *parasympathetic fibers* arise from the *superior salivatory nucleus* (p. 558) which lies in close relation to the motor nucleus of the facial. After leaving the brain stem in the sensory root the parasympathetic secretory and vasodilator fibers pass via the *great superficial petrosal nerve* and *nerve to pterygoid canal* (formed by the union of the great superficial and deep petrosal nerves) to the *sphenopalatine ganglion* from where they are relayed to the lacrimal gland, and to the vessels and glands of the palate and posterior part of the nose. The secretory and vasodilator fibers to the submandibular and sublingual glands leave the

closely similar to those of the glossopharyngeal and it is considered by some as an aberrant part of the latter nerve.

A small proportion of taste fibers may take an alternative route, namely via the chorda tympani to the otic ganglion and thence by way of the internal sphenoidal and great superficial petrosal nerves, genicular ganglion and *nervus intermedius* to the brain stem (Schwartz and Weddell).

facial with the taste fibers in the chorda tympani branch.

The *motor part* of the facial is conveyed through the facial canal of the temporal bone to the stylomastoid foramen. After its emergence from the latter it is distributed to muscles of the face, auricle and forehead. The motor fibers arise from a nucleus in the lower part of the pons and pass backwards to the lower end of the nucleus of the abducent nerve. Then ascending to the upper end of the latter they bend and sweep downwards and forward to where they leave the brain. As the facial fibers take this arched course to the point of their emergence from the brain stem they together with the abducent nucleus form a prominence in the floor of the 4th ventricle known as the *facial colliculus*.

Connections—the motor nucleus of the facial nerve receives

1. Fibers from the corticobulbar tract of the same and of the opposite side.

2. Fibers from the lateral, trigeminal and medial lemnisci and from the spinothalamic tracts. Through these connections reflex facial move-

ments in animals may be initiated from various receptive areas of the body

FACIAL PARALYSIS The effects of interruption of the facial pathway vary in certain important features according to the level at which the injury occurs. The nature of the motor loss following a lesion of the supranuclear (corticobulbar) fibers is described on page 1206. In the paralysis resulting from division to the trunk of the facial nerve all the muscles of the affected side of the face are completely paralyzed. The subject is unable to close the eye owing to paralysis of the orbicularis oculi, or to frown, the eyebrow droops. The mouth is drawn over to the sound side by the unparalyzed muscles and the muscles of the affected side do not take part in the facial expression of emotional states, e.g., laughing or crying.

Facial paralysis may result from a lesion involving

1 The motor nucleus or the intra pontine course of the motor fibers (tumors, hemorrhage, etc.)

2 The nerve as it crosses the posterior fossa of the skull to reach the internal auditory meatus, as in fractures of the skull or tumors in this situation, the sensory portion and the auditory nerve are commonly involved as well, when loss of the sensation of taste over the anterior two thirds of the tongue, and deafness on the affected side will result.

3 The nerve in its course through the temporal bone as in fracture of the skull or in otitis media, inflammation of the nerve within the facial canal (aqueduct of Fallopius)—*Bell's palsy*—may occur.

4 The nerve after its emergence from the stylomastoid foramen, as it lies behind the angle of the jaw, inflammation, parotid tumors, or accidental injuries may implicate the nerve in this situation.

THE GLOSSOPHARYNGEAL NERVE

The glossopharyngeal nerve contains motor, secretory, vasodilator and sensory fibers. The nerve emerges from the side of the upper part of the medulla oblongata in the groove between the olive and the restiform body. The motor fibers are distributed almost entirely to the stylopharyngeus muscle, a few terminate in the circular and longitudinal muscle of the upper part of the pharynx. However, division of the glossopharyngeal nerve which is done for glossopharyngeal neuralgia produces no motor disability so far as the patient is concerned. The secretory and vasodilator fibers (via its tympanic branch, the tympanic plexus, the small superficial petrosal

nerve and the otic ganglion) (p. 589) supply the parotid gland. The sensory fibers arise from cells in the superior (jugular) and inferior (petrous) ganglia of the glossopharyngeal nerve. The peripheral processes of the cells of the latter ganglion supply the taste buds of the posterior third of the tongue. Those from cells of the superior ganglion mediate ordinary sensations (touch, thermal, etc.), from this part of the tongue and the mucosa of the pharynx and posterior part of the mouth, the central processes (superior ganglion) terminate in the dorsal nucleus of the vagus and (inferior ganglion) in the lower part of the *tractus solitarius*. Fibers (secondary neurons) pass from the latter nucleus and, crossing to the median fillet of the opposite side, ascend to the thalamus from where axons of tertiary neurons pass to the cortical area for taste. The motor fibers arise from the upper part of the *nucleus ambiguus* situated in the reticular formation of the medulla oblongata. Secretory fibers are the axons of cells lying in the inferior salivatory nucleus which lies below the superior nucleus of the same name. The carotid sinus nerve is another important afferent branch of the glossopharyngeal nerve. It is concerned with the conduction of impulses from the carotid body and the carotid sinus to the medulla oblongata. These impulses and their frequency are determined by chemical changes in the blood which are detected by the carotid body and by changes in the blood pressure which are detected by the carotid sinus. These afferent impulses are concerned in reflex activities which take part in controlling the pulse rate, the respiratory rate and the blood pressure.

THE VAGUS NERVE

The vagus nerve contains motor, secretory, vasodilator and sensory fibers. The secretory and vasodilator fibers and the fibers to the involuntary muscle of the bronchi, heart, esophagus, stomach, small intestine, gall-bladder, etc. (parasympathetic fibers, ch. 71) arise from cells in the dorsal nucleus of the vagus (principal autonomic nucleus). This gray mass extends upwards from the lower, closed part of the medulla oblongata to beneath the floor of the 4th ventricle at the level of the *striae medullares*. The voluntary motor fibers arise in close relationship with the motor fibers of the glossopharyngeal nerve, namely, from the cells of the *nucleus ambiguus* lying below the glossopharyngeal neurons. They supply (through the superior laryngeal branch) the cricothyroid and arytenoid muscles of the larynx, and the in-

fenor constrictor of the pharynx. The pharyngeal and recurrent laryngeal branches of the vagus also convey voluntary motor fibers many of which are derived from the bulbar nucleus of the accessory nerve (see below) to the pharyngeal muscles (with the exception of the stylopharyngeus), and to the muscles of the soft palate (except the tensor palati) and larynx (except the cricothyroid). The cell bodies of the sensory fibers lie in the inferior ganglion of the vagus (ganglion nodosum). The peripheral processes of these cells convey impulses from the lungs, heart, larynx, pharynx, esophagus, stomach, small intestine and gall bladder. They also, through the anterior laryngeal branch, innervate the taste buds of the epiglottis and valleculae (the depressions lying at the sides of the fold running from the epiglottis to the base of the tongue). The taste fibers end centrally by synapsing with cells in the gustatory nucleus lying in the upper and medial part of the tractus solitarius. These impulses are relayed upwards along the same paths as those conveying other taste impulses. Afferent vagal fibers from visceral structures terminate in the dorsal nucleus. This latter is, therefore, both motor and sensory in function and constitutes an important visceral reflex center. It contains the cardio-inhibitory and vomiting centers.

Vagal afferent filaments travelling in Arnold's nerve mediate the general sensations of the skin lining the external auditory meatus and a small area behind the auricle. Irritation of these fibers may cause reflex coughing (p. 477). These sensory fibers have their cell stations in the jugular ganglion.

THE SPINAL ACCESSORY NERVE

The spinal accessory nerve is entirely motor and is made up of a bulbar and a spinal root. The bulbar root arises from the lower (caudal) end of the nucleus ambiguus from cells situated below those which give origin to the motor fibers of the vagus. The bulbar fibers join the vagus within and below the jugular foramen and are distributed, as already mentioned in the pharyngeal and recurrent branches of the latter nerve, these fibers of the spinal accessory nerve innervate the muscles of the larynx, with the exception of the cricothyroid, the muscles of the pharynx and those of the soft palate, with the exception of the tensor palati (which is supplied by the 5th cranial nerve). The spinal root is composed of the axons of a group of cells in the anterior gray column of the spinal cord extending

from the 1st to the 4th or 5th cervical segment inclusive. These fibers supply the sternocleidomastoid and trapezius muscles. The spinal part of the nerve exchanges fibers with the bulbar part in the jugular foramen.

THE HYPOGLOSSAL NERVE

The hypoglossal nerve is also purely motor. Its fibers are derived from a nucleus situated near the midline in the floor of the posterior part of the 4th ventricle and medial to the nucleus ambiguus. It supplies the thyrohyoid, styloglossus, hyoglossus and genioglossus muscles and the intrinsic muscles of the tongue.

THE PATHWAY FOR THE CONTROL OF MUSCULAR ACTIVITY

The neural mechanism controlling the activity of the skeletal musculature is extremely complex and as yet incompletely understood. Voluntary movements are dependent in primates (monkeys, apes and man) upon the precentral motor cortex. The same is not true for lower animals. Birds and reptiles have practically no cerebral cortex and their well organized movements are controlled by nuclear masses more or less comparable to the basal ganglia of the primate brain. In higher animal forms such as rodents the cerebral cortex is present but of relatively little importance so far as muscular activity is concerned. In the carnivores, e.g., cat and dog, a specialized portion of the cerebral cortex (the sigmoid gyrus) has developed into a motor cortex. If it is stimulated electrically, movements can be produced in the contralateral extremities and if the sigmoid gyrus is removed a transitory contralateral paralysis ensues. However, the cerebral cortex is not essential for useful movement of the skeletal musculature. The sigmoid gyrus can be removed from both sides with only a temporary paralysis. In fact the entire cortex can be removed and the animal still be able to sit, stand, walk or run. In primates the situation is quite different. Here the cerebral cortex is much more important but there still exists a considerable difference between the various animals. If one removes the precentral motor cortex or even the entire cortex from one cerebral hemisphere in a monkey, a complete paralysis of the opposite side of the face and of the opposite arm and leg will result. Useful movement will soon begin to return and in a few weeks the animal will be running about, climbing the walls of his cage and hopping about on his trapeze in an agile fashion, although a partial paralysis of the in-

volved arm and leg will be obvious. The ape, too, will recover, though not as completely as the monkey, whereas removal of the precentral motor cortex in man will result in a contralateral paralysis which, though it will improve, will always be severely disabling. After such an operation a man will become able to walk, although with a limping gait dragging and circumducting his leg. He will never recover useful movement in his upper extremity and will probably have no movement at all in his hand and fingers.

The recovery in primates following removal of the precentral motor cortex is due almost entirely to ipsilateral innervation from the intact cerebral hemisphere, for if the remaining precentral motor cortex is removed a severe and enduring paralysis in all four extremities is the immediate result. It is true that if the cortex is removed piecemeal in several operations over months of time and if the animal is given very special care occasionally it is possible to produce a bilaterally decorticate monkey that has a few awkward but very limited voluntary movements. At best such an animal is almost completely disabled. In most instances he is totally paralyzed except for a few useless stereotyped grasping movements. In view of the demonstrably greater importance of the precentral motor cortex in man as compared with the motor cortex of cats it is obvious that in the human being the production of useful voluntary movements is dependent upon this important area of the cerebral cortex. It is evident that the subcortical centers (basal ganglia, red nucleus, substantia nigra, reticular formation, cerebellum and spinal cord) are important in the production of well coordinated, useful muscular activity, but in man these centers cannot function adequately in the absence of the precentral motor cortex.

The precentral motor cortex gives rise to corticospinal fibers which arise from the precentral gyrus and descend to the anterior gray horns of the spinal cord. These fibers are concerned with voluntary muscular activity and primarily with delicate, precise, well coordinated movements of the distal parts of the extremities, particularly the digits. The relationship of the corticospinal fibers which arise in the parietal cortex to voluntary muscular activity is unknown. It is certain, however, that this parietal component of the corticospinal system is not capable of producing useful coordinated movements independent of the precentral motor cortex.

The precentral motor cortex gives rise to many more descending fibers with motor functions than

just the corticospinal fibers. There are fibers to the basal ganglia, the red nucleus, the substantia nigra, the reticular formation and the pontine nuclei (and through them impulses pass to the cerebellum). These, too, are concerned with the production of voluntary muscular activity. In the absence of the corticospinal tract such movement is apt to be cruder and less delicate but still useful. Exactly which of these many fiber systems—corticocaudate, corticopallidal, corticonigral, corticopontine, etc.—is concerned in the production of voluntary muscular activity is unknown.

This neural mechanism is also concerned with other functions of great concern in the organization of muscular activity. These include (1) the control by inhibition and facilitation of the various postural reflexes (see ch. 64) (2) the control of various automatic and associated movements, such as swinging of the arms when walking (3) various visceral and vasomotor activities such as respiratory movements, blood pressure, pulse rate, the vascular bed, gastrointestinal motility, etc.

CORTICOBULBAR FIBERS

The fibers passing from the lower part of the motor area of the cortex to the cranial nuclei constitute an important part of the *corticobulbar tract*. These bear precisely the same relationship to the cells of the cranial motor nuclei as does the corticospinal tract to the anterior horn cells of the cord. The corticobulbar fibers, however, cross at various levels throughout the brain stem.

THE INTERNAL CAPSULE

In a horizontal section of the cerebrum, the internal capsule is seen as a compact band of white matter lying between the thalamus and caudate nucleus on its inner aspect and the lenticular nucleus on its lateral aspect (cf. fig. 65.11). It is the broad highway of communication in both directions between the cerebral cortex and subcortical and spinal centers. In addition to the corticospinal and corticobulbar tracts the following are the principal tracts which compose it:

I Descending

- a *Corticopontine tracts* consisting of three bundles of fibers: *frontopontine*, *parietopontine* and *occipitopontine* from the corresponding areas of the cerebral cortex to the nuclei of the pons.
- b *Corticocerebral tract*, from the frontal lobe to the red nucleus.

FIG 6-11 Horizontal section of right hemisphere showing corticoulbar and corticospinal fibers and the location of the visual and sensory fibers A anterior limb of capsule B posterior limb G genu

- c *Corticothalamic* from almost all areas of the cortex to various nuclei of the thalamus
- d *Corticostriatal* fibers from the precentral area of the cortex to the caudate nucleus and the globus pallidus
- e *Occipitotectal* fibers from the parietal and parietal cortex to the tectum of the mid brain
- f *Corticospinal* fibers from the precentral and temporal areas to the substantia nigra

II Ascending

- a *Thalamic radiations* consist of four bundles ascending from the thalamus: *anterior superior posterior and inferior* which connect the thalamus with various parts of the cerebral cortex. The anterior group terminate in prefrontal areas and the superior group in the somesthetic area (postcentral gyrus)
- b *Auditory radiations* fibers ascending from the medial geniculate body to the temporal cortex (geniculate temporal fibers)
- c *Optic radiation* fibers ascending from the lateral geniculate body to the visual area in the occipital cortex (geniculocalcarine) fibers
- d *Rubrothalamic* fibers from the red nucleus to the cortex

The internal capsule is bent in the horizontal plane to form a convexity directed medially. The region of the angle so produced is called the *knee* (*genu*) the portions in front and behind this are known respectively, as the *anterior* and *posterior limbs*. The shorter anterior limb lies between the

caudate nucleus and the lenticular nucleus the posterior limb between the lenticular nucleus and the thalamus. The extension backwards of the posterior limb is known as the *retrolenticular part*.

The anterior limb is occupied by the *fronto-pontine* fibers and the *anterior thalamic radiation* (thalamofrontal fibers) the *frontothalamic tract* *corticostriatal* and *corticorubral tracts*. In the anterior three fifths of the posterior limb are transmitted the *corticobulbar* and *corticospinal* fibers. The fibers of these two tracts are organized in accordance with the portions of the body which they innervate, those carrying impulses for the eye muscles, the muscles of the tongue and face and upper and lower extremities arranged in this order from before backwards and those transmitting impulses destined for the proximal part of an extremity are placed in front of those for the more distal muscles. The remaining part of the posterior limb and the retrolenticular part carry in anteroposterior order the *superior and posterior thalamic radiations* the *auditory* (geniculotemporal), and the *inferior thalamic radiations* *corticothalamic*, and *parietopontine* fibers and the *optic* (geniculo-occipital) radiations.

The internal capsule is supplied with blood through the lateral striate branches of the middle cerebral artery, by the recurrent artery of Hubner from the anterior cerebral artery, and the anterior choroidal artery from the internal carotid artery.

A Comparison of the Effects Produced by Injury of Supraspinal Paths with Those of the Spinal Centers or Peripheral Nerves (Motoneurons)

It is obvious that lesions at various points in the nervous system are likely to produce different manifestations. This is particularly true in the field of muscular activity. In view of the intricacy of the neural mechanism responsible for muscular activity which has been briefly outlined above, it must be obvious that the patterns of muscular disturbances which may develop can vary through a wide range. There are no simple syndromes upon which the student may rely. Rather he must familiarize himself, as completely as is possible in our present state of knowledge and ignorance, with the neural mechanisms responsible for muscular activity and then must attempt to understand and interpret what he finds in the patient in the light of that knowledge.

Destruction of the peripheral nerves supplying a skeletal muscle produces an easily understood clinical picture. The muscle is (1) totally paralyzed, it is beyond the patient's control and he can not move it, (2) no reflex activity of any sort is possible, although in the early stages the muscle may still contract in response to direct percussion or direct stimulation with a galvanic current, and (3) the muscle wastes away to a useless fibrous cord because it is devoid of innervation and completely without use. Involvement of this sort is often spoken of as a "lower motor neuron" paralysis and it may develop following destruction of the anterior horn cells in the spinal cord, or following division of the anterior spinal roots or of the muscular nerve. One must never forget, however, that not all paralyses are complete. Some innervation may remain and then the muscle is weakened but not completely paralyzed, the reflexes are diminished but not abolished and the wasting is incomplete.

Although the term "lower motor neuron" paralysis is accurate for the condition described above, it has the disadvantage that it implies that there is a counterpart, an "upper motor neuron" paralysis. This is misleading for there is no constant reliable entity which can be so designated. The manifestations of involvement of the many neurons which lie above the anterior horn cell which are responsible in one way or another for some phase of muscular activity vary widely depending upon which such neurons or groups of neurons are involved. Thus we may have a severe paralysis with spasticity and hyperactivity of the

stretch reflexes if the descending motor pathways in the internal capsule are involved. If on the other hand the lesion is limited to the corticospinal fibers in the central portion of the cerebral peduncle one sees a loss of some fineness and delicacy of movement with little or no spasticity and little increase in tendon reflexes. Lesions of the globus pallidus combined with destruction of the substantia nigra are, on the other hand, characterized by increased resistance to passive manipulation of the extremities, with a generalized rigidity of the body and a loss of the facial movements of expression and of many automatic associated muscular movements but with little or no true paralysis and little if any change in the tendon reflexes. As we have noted before a paralysis arising from a lesion in the internal capsule is commonly associated with a flexor spasticity in the upper extremity and an extensor spasticity in the lower extremity, whereas a severe lesion in the mesencephalon is likely to produce a paralysis with extensor spasticity in all four extremities. In contrast with this a paralysis due to a transverse lesion of the spinal cord will produce a complete paralysis of the skeletal musculature below the level of the lesion with a variable reflex pattern. In some cases, or even only at some times in a given case, the paralyzed extremities may show a severe extensor spasm while at other times a severe flexor pattern may develop. In contrast with "lower motor neuron" lesions, paralysis due to involvement of motor neurons above the anterior horn cells are almost always associated with some type of reflex activity. Often this reflex activity is exaggerated beyond that which one would expect in normal muscles. However, the nature and pattern of the reflex activity will vary depending upon the location of the lesion and the pathways which are involved. One reflex seems to have its own specific significance—the sign of Babinski. This reflex is elicited by stroking the outer margin of the sole of the foot from the heel toward the little toe. Normally, such stimulation is associated with a flexion of all of the toes. However, if the corticospinal fibers from the "foot" area of the upper part of the precentral gyrus are interrupted the great toe will extend or dorsiflex. The other toes may or may not "fan" outward laterally. It must be remembered that such a "positive" response is dependent upon an intact peripheral mechanism. Regardless of the nature or location of the central lesion the sign of Babinski will not be elicited if the great toe is ankylosed, if the extensor tendon is severed or

FIG 65 12 Diagram illustrating the effects of lesions at various levels 1, lesion of cerebral cortex causing monoplegia or hemiplegia depending upon its extent 2 lesion of internal capsule hemiplegia 3 lesion of midbrain involving descending motor fibers and nucleus of tract of the third nerve (Weber's paralysis), 4 lesion in pons destroying descending motor fibers and nucleus of facial nerve crossed hemiplegia with homolateral facial paralysis, 5 lesion in medulla oblongata involving descending motor fibers and the hypoglossal nucleus crossed hemiplegia and homolateral paralysis of lingual muscles 6 transection of spinal cord, paraplegia (In part from Villiger and from Ran son)

the extensor hallucis muscle destroyed, or the muscular nerve to this muscle interrupted or the related anterior spinal root or anterior horn cells seriously damaged. It must also be remembered that this is a sign only of interruption of the corticospinal fibers which innervate the musculature of the great toe. It is not a sign of damage to any other corticospinal fibers.

Both "upper" and "lower" motor neuron paralyses may be associated with atrophy or wasting of the involved muscles. Muscular wasting is in general proportionate to the degree of loss of use of the muscle rather than to loss of innervation. Because the paralysis resulting from a complete "lower" motor neuron lesion is complete both as

to voluntary and reflex activity the atrophy is likewise complete. Wasting from "upper motor neuron" lesions is never that severe because even with a complete paralysis of voluntary activity some reflex activity persists.

Lesions at various levels are likely to involve other structures and thus indicate their location by the nature of the other clinical manifestations which the patient develops (fig 65 12). Thus a massive lesion of the internal capsule will produce a contralateral hemihypesthesia and possibly a homonymous hemianopia as well as a hemiplegia. A unilateral lesion in the midbrain often will produce a third cranial nerve palsy (with a ptosis of the upper eyelid, a paralysis of several ocular muscles, a dilatation of the pupil and a loss of the pupillary light reflex) on the side of involvement in addition to a contralateral spastic hemiplegia. Lesions involving one half of the lower brain stem may be associated with a paralysis of one or more cranial nerves (e.g., facial, vagus or hypoglossal) on that side of the body and a hemiplegia and hemianesthesia on the opposite side of the body. In contrast with this unilateral lesions of the spinal cord produce what is known as a Brown-Sequard syndrome—a paralysis of the skeletal muscles of the trunk and extremities and a loss of position and vibratory sensibilities below the level of the lesion and on the same side with a loss of pain and thermal sensibilities on the opposite side (fig 65 13). Obviously the possible combinations of symptoms and signs are numerous and cannot all be discussed in detail here. Their recognition and proper interpretation are dependent

FIG 65 13 Diagram showing effects following hemisection of the spinal cord in the lower thoracic region. Narrow white band at level of lesion indicates total anesthesia and analgesia.

upon a thorough understanding of the structure and function of the nervous system

It is evident that the paralysis is more likely to be bilateral if the lesion is situated in a region where, as in the brain stem or spinal cord the descending motor tracts of the two sides are approximated, than if it is located at a level where these tracts are widely separated, as in the corona radiata or internal capsule, then unilateral effects are usual. Complete interruption of the spinal cord will of course result in paralysis on both sides of the body below the level of the lesion—*paraplegia* (p 1210)

FUNCTIONAL, MORPHOLOGICAL AND CHEMICAL CHANGES IN DENERVATED MUSCLE

A lesion which involves any part of the lower motor neuron—anterior horn cell—such as may result from anterior poliomyelitis or peripheral nerve injury is followed by degenerative changes which extend to and include the nerve terminals within the muscle. A muscle thus completely denervated exhibits constant, fine, rapid, rhythmic contractions. This so called fibrillation of the denervated muscle does not appear until several days after the abnormal electrical reactions (reaction of degeneration ch 61) have already developed and complete degeneration of the nerve has occurred. The muscle fibers contract asynchronously, the contractions involve only a part of the length (0.5 to 1 mm) of the fiber and give rise to small irregular action potentials. The fibrillation can sometimes though not commonly, be seen through the skin. Having once appeared fibrillation persists for a year or more and until the contractile elements have undergone complete atrophy. According to Denny Brown a reduction in tension developed by the muscle when stimulated maximally can be detected within 2 minutes after section of the nerve but other investigators have been unable to observe any loss of contractile force until after a much longer interval (30 to 40 hours). An outstanding functional effect of denervation is the great increase in the sensitivity of the muscle to the intravenous or intra arterial injection of acetylcholine. Normal muscle is excited by the intra arterial injection of from 0.2 to 2.0 mg of acetylcholine whereas denervated muscle responds to a dose of from 0.002 to 0.02 γ . It is generally believed that this hypersensitivity to acetylcholine is responsible for the Vulpian and Sherrington effects and most probably also for the fright reaction described by Bender. The denervated muscle is also hyperexcitable though to a less pronounced degree to potassium chloride.

The denervated muscle soon commences to atrophy, reduction in its bulk becoming apparent

within a few days after section of the nerve. Atrophy progresses rapidly and is followed by degeneration of the contractile elements. Microscopic changes in the muscle fibers consist of swelling and vesiculation of the nuclei; a reduction in sarcoplasm and fading followed by disappearance of the striations of the myofibrillae. Ultimately all contractile tissue disappears and is replaced by fibrous tissue and fat. As these morphological changes are occurring the muscle gradually loses its plastic or ductile quality, flexors and adductors shorten and become more or less set in their new position. The antagonistic muscles lengthen adaptively. This state of the muscles is called contracture. This disappearance of the denervated muscle fibers and their replacement by fibrous tissue is important in considering when a divided muscular nerve should be sutured or replaced by transplantation of another nerve. Obviously if such operations are delayed until only fibrous tissue remains they will be unsuccessful. If they are to succeed they should be performed within a year after the muscular nerve has been damaged.

The chemical changes in denervated muscle comprise a reduction in glycogen, phosphocreatine and adenosine triphosphate but they do not become pronounced until the onset of fibrillation. The breakdown and subsequent re-synthesis of glycogen by the denervated muscle during a work period is normal for a time following nerve section but when fibrillation supervenes the ability of the muscle to restore its glycogen after contraction is greatly impaired. The atrophying muscle shows a large increase in calcium, a smaller increase in chloride and a decrease in potassium. The changes in chloride and potassium can be accounted for by the reduction in muscle mass and its replacement by interstitial tissue and fluid. The increase in calcium is too great however to be explained entirely in this way.

The cause of fibrillation in denervated muscle is unknown, but it is not improbable that it is a manifestation of its hypersensitivity to acetylcholine. The observation of Magladery and Solandt that quindine which abolishes acetylcholine hypersensitivity also suppresses fibrillation is highly suggestive yet as Dale and his associates have shown direct stimulation of denervated muscle does not cause the release of acetylcholine. It follows therefore, that if the stimulating effect of this agent is responsible for fibrillation it must be carried in the muscle in the blood stream. The increased sensitivity to acetylcholine may be due to a lack of cholinesterase for, according to Naray and Nachmansohn, this enzyme, which normally is concentrated in the neighborhood of the nerve endings in skeletal muscle, disappears after denervation. The lack of cholinesterase might also explain the failure of eserine to cause anything

more than a transient augmentation of fibrilla tion

SYRINGOMYELIA

This condition is characterized by a cavitation of the spinal cord surrounded by an area of gliosis. The disease process involves the central gray matter primarily and the surrounding white matter to a variable degree. The process may extend for considerable distances up and down the spinal cord. The lower cervical and upper thoracic regions are most commonly affected. The disease may extend into the bulb (syringobulbia) when signs of implication of the nuclei of the cranial nerves appear.

A loss of pain and temperature sensibilities, muscular weakness and changes due to involvement of the central sympathetic fibers are among the characteristic features of the disease. Owing to the site of the changes, the fibers mediating pain, heat and cold, where they make connections with the cells of the posterior horns, are first destroyed. If the lesion is unilateral, thermoanesthesia and analgesia of the skin supplied by, and on the same side as the diseased segments result. Other sensations, e.g. touch, muscle sense, are unaffected until later in the disease. Involvement of the spinal nucleus of the trigeminal results in the characteristic sensory loss over the face. When the disease involves both dorsal horns or the anterior gray commissure where the fibers subserving pain and temperature sensibilities cross the thermoanesthesia and analgesia are bilateral. The muscles innervated by the anterior horn cells of the diseased segments become weak and wasted, these effects often appear first in the small muscles of the hand. So long as the disease does not cause injury to the white matter, the sensory and motor effects are limited and have a segmental distribution. Involvement of the descending motor pathways will result in a *spastic paralysis* below the level of the lesion, while pressure upon the spinothalamic tracts and dorsal columns will be followed by sensory loss below the level of the lesion. The degree of sensory loss, its type and distribution and whether homolateral or contralateral vary according to the extent to which the individual tracts are affected by the disease. As a result of the loss of the protective sensations (pain and temperature), patients with syringomyelia are prone to suffer injuries which, not being perceived at the time, are neglected and ultimately lead to serious lesions, e.g. painless burns or the disorganization of a joint (arthropathy, Charcot's joint). Involvement of the sympathetic centers in the lateral columns leads to vasomotor disturbances, excessive sweating or absence of sweating, cyanosis, etc. So called trophic disturbances, e.g. ulcers, whitlows, gangrene, etc., are largely the result of vasomotor abnormalities and the loss of

sensation which, as just mentioned, permits an injury, trivial perhaps at first, to be disregarded.

SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD

This condition involves the white matter of the cord and is almost always associated sooner or later with pernicious anemia. The degenerative process consists of a breakdown of the myelin sheaths, subsequent destruction of the axons and their replacement by newly formed glial tissue. The changes are most pronounced in the corticospinal and cerebellar tracts and in the posterior columns. The chief clinical features are, therefore: (a) muscular weakness and spasticity, (b) impairment of the sense of position and of passive movement of the limbs with consequent ataxia and a positive Romberg sign, (c) loss or impairment of spatial discrimination, and vibratory sensibility. The relative extent to which these sensations are lost is variable. Paresthesias (tingling, pricking and burning sensations) frequently precede the sensory loss, and are usually the result of an associated peripheral neuropathy. The reflexes vary. The tendon jerks are frequently exaggerated as a result of involvement of the descending motor pathways, but they may disappear as the disease progresses if the peripheral neuropathy becomes sufficiently severe. The plantar response is usually of the "extensor" type.

The severity of the nervous manifestations do not always run parallel with that of the blood picture, the neurological features may be pronounced though the anemia is of mild degree, or vice versa. Subacute combined degeneration of the cord, though associated with pernicious anemia, is not due to the anemia itself. This is shown by the well recognized fact that the blood picture may be restored to normal by the administration of folic acid, but the neurological condition progresses unchecked, whereas the latter is arrested by the hematine principle (vitamin B₁₂). See also p. 931.

TABES DORSALIS, LOCOMOTOR ATAXIA

In this condition, which is the result of syphilis, the fibers of the dorsal roots at their point of entry into the spinal cord (i.e., the central processes of the primary sensory neurons) are attacked. The ganglion cell bodies of the dorsal roots, as a rule, are not affected. The essential lesion within the spinal cord, therefore, involves the entrance zone of the lateral division of the dorsal roots (dorso-lateral fasciculus of Lissauer), and the dorsal fasciculi (gracilis and cuneatus). The endogenous fibers of the spinal cord escape, but although it is these tracts composed of exogenous fibers which are specifically attacked by the disease, the functions of the cerebellar and spinothalamic tracts

are also seriously disturbed as a result of degeneration of the primary neurons leading to them. The descending tracts remain as a rule practically unaffected. The reason for the selective destruction of the exogenous fibers of the cord is unknown, possibly it is compression of the fibers by proliferation or inflammatory swelling of the meninges at the point of entrance of the posterior root.

The sensory changes are those which might be expected to result from a gradual degeneration of dorsal root fibers. Somewhat similar effects are produced in monkeys by section of the posterior nerve roots.

The chief manifestations are as follows: (a) During the degenerative process paresthesias of various types, hyperesthesia and stabbing pains are common. (b) Impairment, or loss to a variable degree, of all forms of sensation follows. Loss of the rapid conduction component of deep pain occurs early. Loss of the sense of position and of passive movement, and blockage of afferent cerebellar impulses result in marked incoordination of the muscles—ataxia. Movements are jerky, exaggerated and imperfectly controlled, the subject being unable to move his feet in the desired direction or to assume a given position at will, e.g., placing the heel of one foot upon the toes of the other. The gait is ataxic, the feet are kept wide apart, raised unnecessarily high and brought down in a stamping fashion, the patient may learn to overcome this tendency by shuffling.

The loss of sense of position is in large measure responsible for the patient's difficulties. When standing with the eyes closed the patient, being thus deprived of an important aid in maintaining his equilibrium, tends to sway and may fall (Romberg's sign). (c) The interruption of the pathways for proprioceptive impulses from the skeletal muscles (p. 1446) results in extreme hypotonia, but there is no true paralysis. (d) The tendon reflexes are abolished as a result of the destruction of the afferent limb of the proprioceptive reflex arc. The abdominal reflexes may or may not be present. (e) 'Lightning pains and trophic disturbances'. The former are severe stabbing paroxysmal pains usually localized to an area supplied by one or more spinal segments. They are commonly in the abdomen or in the lower extremities. Vasodilatation, small hemorrhages or herpes zoster may occur in the painful area. These vascular and cutaneous effects have been attributed to antidromic impulses reaching the periphery via sensory fibers. The skin of the affected area may break down with the formation of so-called trophic ulcers. Painless destruction of joints (Charcot's joint) is not uncommon in tabes. The loss of the sense of pain which causes the patient to suffer injuries of which he is unaware, the extreme hypotonia of the muscles which normally support the joint, and the vascular disturbances resulting

from damage to autonomic fibers combine to produce such joint conditions. They are usually classed among the trophic disturbances, the term implying that the interruption of trophic impulses is responsible. However, the existence of true trophic fibers, i.e., specific fibers which preside over the nutrition of the peripheral tissues, is questionable. (f) *Tabetic crises*. These are apparently the result of the involvement of afferent autonomic fibers which enter the spinal cord by the dorsal roots. They consist of paroxysmal attacks of pain and functional disturbances in one or other of the viscera. *Gastric crises* are the commonest. They consist of severe epigastric pain and vomiting. *Rectal crises* consisting of pain in and increased activity of the rectum, *renal crises* with bladder pain and difficult urination or *laryngeal crises*, in which spasm of the adductors of the larynx with dyspnea may occur. (g) *Ocular signs*. The pupils are as a rule constricted and often unequal. The Argyll Robertson pupil (p. 1412) in which the reflex to accommodation is retained but the reaction to light is lost, is a characteristic ocular feature of tabes dorsalis. The pupil also frequently fails to respond by dilatation to stimulation of the skin of the neck (ilio-spinal reflex). The loss of this reflex is usually attributed to degeneration of the central sympathetic pathway through which the dilator pupillae muscle is innervated. Some drooping of the upper lid (ptosis) may also result from the blockage of sympathetic pathways which normally transmit impulses to the smooth muscle in this situation, compensatory contraction of the frontalis muscle with wrinkling of the skin of the forehead results. Damage to the fibers of the 3rd, 4th or 6th nerves results in paralysis of the ocular muscles: the external rectus most commonly. Squint and double vision (diplopia (p. 1418)) are consequences. Primary optic atrophy often occurs.

DISSEMINATED (MULTIPLE) SCLEROSIS

This is a chronic disease of the nervous system characterized anatomically by the occurrence of small patches of demyelination followed by overgrowth of glial tissue throughout the white substance of the brain (especially in the regions beneath the lateral ventricles), and spinal cord. The lesions in the cord are most numerous in the cortico-spinal tracts and in the posterior columns. Clinically, the disease is marked by an insidious onset, irregular course with remissions and relapses of unpredictable duration, and a great variability of signs and symptoms between individual cases. Progressive spastic weakness of the muscles of the legs with increased tendon jerks, 'extensor' plantar response (Babinski) and loss of abdominal reflexes, is a common manifestation of this disease. Many patients also complain of paresthesias and have a loss of vibration and muscle senses from

lesions in the posterior columns. The loss of tactile and pain and thermal sensibilities are seldom striking and rarely of an enduring nature. Impairment of vision or even blindness, may result from involvement of the optic nerve, chiasma or tract. Nystagmus, slurring of speech and intention tremor, once regarded as diagnostic of the disease, appear late if at all and are manifestations of involvement of cerebellar pathways.

COMPLETE TRANSVERSE DIVISION OF THE SPINAL CORD

A sudden or rapidly progressive, complete interruption of the continuity of the cord may result from injury (e.g. gunshot wound, fracture-dislocation of the spine, etc.) or from acute inflammation (e.g., transverse myelitis). Immediate and complete loss of voluntary power below the level of the lesion results. Paralysis of both lower limbs resulting from this or any other nervous lesion is spoken of as *paraplegia*. Complete division of the cord in the lower cervical region will result in paralysis of all four limbs *quadriplegia*. A lesion of this nature in the upper cervical region is of course rapidly fatal since the diaphragm and other respiratory muscles are isolated from the respiratory center.

Stage of spinal shock. Immediately following the injury there are complete loss of visceral and somatic sensations, and flaccid paralysis below the level of the lesion. The skeletal muscles are quite toneless. The tendon jerks, plantar response and abdominal reflexes are abolished. The cremasteric and bulbocavernosus reflexes, though absent as a rule, may at times be elicited. The anal reflex is present. A zone of heightened sensitivity (hyperesthesia) immediately above the level of the lesion may be present and spontaneous pains in this region, or a feeling of tightness encircling the body may be experienced by the patient. There is retention of urine and feces. This stage is analogous to the state of spinal shock in lower animals but is much more severe and prolonged (ch. 67). In man spinal shock lasts for from one to three weeks.

Stage of reflex activity. After a variable period of time, depending largely upon the general health of the patient, reflex activity begins to return to the isolated spinal cord below the level of the lesion. The first reflex to appear is usually the sign of Babinski, the extensor response of the great toe to stimulation of the sole of the foot. This reflex is actually a part of the flexor reflex pattern of the lower extremities. Both exaggerated extensor and flexor reflex patterns are usually present with lesions of the descending motor pathways. They

vary in intensity and in relation to each other. If the lesion lies above the pons the extensor reflexes usually predominate. If the lesion is in the spinal cord the flexor reflexes are usually more prominent than when the lesion lies at higher levels and they may exceed the extensor reflexes in intensity. Then a paraplegia in flexion is present. However, this balance between extensor and flexor reflexes fluctuates from time to time in the same patient and is quite variable from one patient to another. After the sign of Babinski has become elicitable other flexor reflexes, dorsiflexion of the foot, flexion of the knee and hip gradually become more marked and more easily elicited. At first they are usually seen only with stimuli which except for the interruption of the pain pathways in the spinal cord would be painful, i.e., nociceptive stimuli. Later less intense stimuli such as passive flexion of the toes or mere touching of the foot or leg may be sufficient to provoke a violent flexion of the leg. When this stage is reached the patient usually has a paraplegia in flexion. The extensor reflexes begin to return after variable periods. At first the only demonstrable reflex of this type may be the patellar tendon reflex (knee jerk). Later the Achilles tendon reflex (ankle jerk) will return, ankle and patellar clonus may be elicited. At times the patient may develop severe extensor spasms and the muscles may be involved by severe clonic contractions with little or no external stimulation. At other times the extremities may lie quietly without either extensor or flexor reflexes causing any striking disturbances. Elicitation of the flexor reflexes will immediately result in a subsidence of ankle clonus or other manifestations of the extensor reflexes, and *vice versa*. This inhibition of the one when the other is produced is due to reciprocal innervation. On occasion elicitation of the flexor reflexes will be associated with evacuation of the bowel and bladder. This Head and Riddock termed the "mass reflex." However, reflex or automatic evacuation of the bowel and bladder need not be associated with a violent flexion of both lower extremities. Such reflex evacuation may result from distention of the bladder or rectum as the case may be, or may be induced by the patient. He may produce emptying of the bladder by stimulating the skin on the inner aspect of the upper thigh or reflex defecation by stimulating the rectal mucosa at and just above the anal ring. These reflexes are often used to great advantage by the paraplegic patient. The time of development of these various reflexes and their vigor depend in large measure upon the condition of the

patient and his paralyzed extremities. A poor state of nutrition or the presence of infection in the urinary tract or in decubitus ulcers, the development of severe muscular wasting or of fibrous changes in the muscles or about the joints will all mitigate against the development of active reflex activity.

INCOMPLETE INTERRUPTION OF THE CORD

A bilateral lesion of gradual onset which impairs the activity of the descending motor pathways usually causes *paraplegia in extension*. The muscles are spastic and extensor activity predominates. The tendon jerks are exaggerated and patellar and ankle clonus can be readily elicited. Paraplegia in extension is more or less comparable to decerebrate extensor rigidity. The 'extensor' plantar response, which is in reality a part of the flexor reflex pattern, is present, but much less intense than in paraplegia in flexion. It is associated with much less contraction in other flexor muscles and may be accompanied by a crossed extensor reflex. The mass reflex is absent. The abdominal reflexes are lost.

THE PLANTAR REFLEXES

This is the most appropriate place to consider these and other superficial reflexes.

The normal plantar response to a light scratch applied to the skin of the sole is plantar flexion of the four outer toes with no movement, or, more usually, plantar flexion of the great toe. The center for the reflex lies in the first sacral segment, its physiological significance is unknown. With a lesion of the cortico-spinal fibers from the precentral region to the foot (see also p 1205) at any level above the first sacral segment, the normal response is replaced by one in which dorsiflexion of the great toe and often spreading or fanning of the outer toes occurs. It is elicited best from the outer border of the sole. This response is called after its discoverer the *sign of Babinski* (fig 65 14). From the dorsiflexion of the great toe which is due to the contraction of the extensor longus hallucis, this reflex is also frequently referred to as the extensor response*. This term, however, is incorrect since the upward movement of the great toe is part of a general

FIG 65 14 Upper drawing normal plantar response, lower drawing Babinski response

flexor response homologous with the flexor reflex elicitable from the hind limb of a lower animal (p 1156) (see Walshe). The dorsiflexors of the toes, although classed anatomically as extensors must, when compared physiologically with similar muscles in the limb of an animal such as the dog be included among the flexors. In lesions of descending spinal tracts in which extensor reflex activity overshadows the flexor reactions, the so-called extensor plantar response is less active and less readily elicited than when flexor patterns predominate. Nevertheless the flexor nature of the reflex is shown by the associated contraction of the hamstrings, i.e., semitendinosus, semumembranosus and biceps femoris, which usually occurs (see also p 1210). Its flexor nature is also indicated by the fact that an undoubted extensor reflex such as ankle clonus is readily inhibited by evoking the Babinski reaction (reciprocal inhibition).

In the restricted forms of the extensor response as seen in hemiplegia, the receptive field of the reflex is also strictly circumscribed being elicitable only from the sole—the outer border especially.

In paraplegia in flexion in which flexor activity predominates the so-called 'extensor' response is maximal and, as we have seen, is simply part of a widespread flexor reaction. The receptive field of the reflex is extensive and the application of a stimulus is followed by contraction not only of the extensor longus hallucis (with dorsiflexion of the hallux) and hamstrings but by an associated contraction of the true flexors of the lower limb—the extensor longus digitorum, tibialis anticus, gracilis, sartorius, rectus femoris and iliopsoas.

OTHER SUPERFICIAL REFLEXES

1 *Oppenheim's reflex* is simply a modified Babinski response: it is associated with the same

* An 'extensor' plantar response is present normally in infants up to the first year or so i.e. to the age of walking and is then probably due to the undeveloped state of the corticospinal tracts. It is also present in normal adults during deep sleep (p 1200) and in the apneic stage of Cheyne Stokes respiration being apparently due in the latter instance to anoxemia of the motor cortex.

conditions as the latter and has a similar significance. It consists in dorsiflexion of the hallux which results when a firm downward sliding pressure is applied to the skin over the anterior border of the tibia. The Gordon, Chaddock and Gonda reflexes are other modifications of the Babinski response.

2 Abdominal reflexes. Lightly scratching the skin of the abdomen of a normal person causes a reflex contraction of the abdominal muscles. They do not appear until between the 6th and 8th months of age when the infant can sit up unsupported. These reflexes are, of course, abolished by any lesion which interrupts afferent conduction from the skin of the abdomen or destroys the anterior horn cells or the motor pathways concerned with the abdominal musculature. These reflexes also are often abolished by a lesion which interrupts the cortico-spinal pathways above the 7th thoracic segment, but they are not permanently abolished by extirpation of the precentral gyrus. These confusing facts have thrown serious doubt on all current physiological explanations of the abdominal reflexes.

3 Cremasteric reflex consists of contraction of the cremaster muscle and elevation of testicle which results from a light stroke applied to the skin on the inner aspect of the upper part of the thigh. It is often abolished by cortico-spinal lesions or as a result of destruction of the center in the 1st or 2nd lumbar segment.

4 Bulbocavernosus reflex has its center in the 3rd and 4th sacral segments. It consists of contraction of the bulbocavernosus muscle (detected by palpation) in response to stimulation of the glans penis. It is absent in a lesion involving any part of its reflex arc, motor or sensory limb, or center.

5 Anal reflex is the contraction of the external anal sphincter in response to scratching the neighboring skin. Its center is situated in the 4th and 5th sacral segments and the coccygeal segment; it is lost after interruption of its reflex arc.

6 Gluteal reflex. Scratching the skin of the buttock causes contraction of the gluteal muscles. It depends upon the integrity of the 4th and 5th lumbar and upper sacral segments.

The deep or tendon reflexes, such as the knee jerk, ankle jerk, etc., have been discussed in chapters 63 and 64.

THE RETICULAR FORMATION

The central portion of the brain stem is occupied by a diffuse ill defined mass of nerve cells and fibers known as the *reticular formation*. It extends downward into the spinal cord and upward into the thalamus and subthalamus. In the following discussion we shall not be concerned with the spinal reticular formation. The reticular forma-

tion in the brain stem can be subdivided into numerous nuclei or cell masses. However, as these have not been shown to have functional significance no cognizance of these cellular groups will be taken here. The reticular formation has been defined (see Segundo, 1956) as including all areas within the brain stem (excepting primary afferent pathways) which when stimulated will produce "arousal." This includes the bulbar reticular formation, the pontomesencephalic tegmentum, the hypothalamus, the subthalamus, and the ventromedial portion (including the intralaminar nuclei) and the reticular nucleus of the thalamus. There appears to be little doubt but that the reticular formation constitutes one, if not the most important regulatory mechanism within the central nervous system. As will be discussed below it is concerned with such general effects as the arousal of the entire organism, alerting the animal, maintaining attention, or, on the other hand, with the production of sleep or in cases of injury to the reticular formation the development of stupor or coma. It is also concerned with such specific effects as the control of muscular activity, the regulation of the receptivity of peripheral sensory end-organs, the control of the threshold of central sensory pathways, the regulation of vegetative visceral and vasomotor responses and of emotional expression. (The reader who is interested in the extensive literature concerning the reticular formation, and in more detailed information is referred to the summarizing articles by Segundo (1956) and French (1953) and to the Henry Ford Hospital symposium on the reticular formation of the brain (1953)).

The reticular formation is subject to a wide variety of afferent impulses. Every afferent pathway bearing information to the brain concerning the outside world, its relation to the organism itself and activities within the organism also sends afferents into the reticular formation. These connections are by means of both direct afferent fibers and collaterals from the main afferent pathways to the cerebellum and thalamus. Thus the reticular formation receives afferent impulses from the optic, the olfactory, the auditory and the gustatory systems as well as from the spinal and trigeminal pathways which bear impulses concerned with tactile, painful thermal and vibratory sensibilities and sensations from the muscles, joints and tendons, and afferent impulses from the viscera and other internal structures of the body. In addition afferent fibers converge on the reticular formation from the cerebellum, the basal ganglia,

the thalamus, the rhinencephalon and the cerebral cortex. Particularly, only certain specific portions of the cerebral neocortex seem to send afferent impulses to the reticular formation. These are the orbital, oculomotor, sensorimotor and posterior parietal cortices, the superior temporal and cingulate gyri and the temporal pole. In addition the activity of the reticular formation is influenced by certain hormonal and chemical changes (adrenalin, acetylcholine, carbon dioxide, etc.) and by many drugs (barbiturates, anesthetics, tranquilizing compounds, etc.).

In turn, efferent impulses from the reticular formation are conducted cephalad into the brain, particularly to all parts of the cerebral cortex, and caudad into the spinal cord. Because of the multisynaptic character of the pathways to and from the reticular formation and the small caliber of many of the fibers connected with it, reticulocortical conduction is much slower than in the primary sensory system. The reticulospinal fibers run bilaterally in the lateral and ventral white columns of the spinal cord and transmission in this system is thought to be quite rapid.

One of the first effects shown to result from excitation of the reticular formation was that of arousal. This may be demonstrated in two ways, electroencephalographically and by the animal's behavior. In general these two parallel one another but that is not invariably true. There are circumstances under which the electroencephalographic pattern may be changed from that characteristic of the waking state (desynchronized, irregular waves of low amplitude), to that characteristic of sleep (slow, regular waves of high amplitude) without the animal's actually going to sleep, e.g., in the atropinized animal. The changes characteristic of arousal which are induced by stimulation of the reticular formation are the same as those brought about by physiological stimuli. In addition to actual arousal from sleep, stimulation of the reticular formation also has a very definite effect upon the awake animal in that it appears to "alert" him for possible changes in his environment, or serves to make him more attentive to such changes. Thus it may be said that the reticular formation is indispensable for the initiation and maintenance of wakefulness. On the other hand, lesions of the reticular formation impair the wakefulness of the organism. Experimental lesions in the cephalic end of the reticular formation in the mesencephalic tegmentum and basal portion of the diencephalon of the cat produces sleep while destructive lesions in this same portion of the human brain result in coma. Like-

wise, small lesions in this same portion of the reticular formation of the cat are associated with a state which Ingram, Barris and Ranson referred to as "catalepsy."

The reticular formation is also concerned with more specific activities. Early Magoun and Rhines showed that the bulbar reticular formation is capable of inhibiting the spinal mechanism responsible for the stretch reflex of the skeletal muscles. It is through this mechanism in the brain stem that the cortical inhibitory mechanism finds expression. In addition the reticular formation is also capable of facilitation of the more peripheral motor mechanism. These effects are produced through the large motor cells of the anterior gray column of the spinal cord, the alpha cells, which innervate the ordinary striated muscle fibers, and also by controlling the receptivity of the muscle spindle (the sensory end-organ within skeletal muscle which responds to stretching) through the small gamma cells of the anterior horn.

In addition to controlling the receptivity of the stretch receptors in skeletal muscles, it also appears that the reticular formation is able to control the sensitivity of certain other sensory receptors such as those in the retina and the cochlea, and of tactile receptors, and is capable of modifying conduction along various sensory pathways, in the thalamus and in the sensory cortex. In this way the reticular formation is able to regulate the threshold of sensory perception and to control the level of attention to sensory stimuli. In all likelihood the reticular formation is not the only neural mechanism concerned in such control but it appears to be an important one.

The reticular formation is also capable of exerting extensive influence over many autonomic, or viscerovascular vegetative functions, such as cardiac, vascular, respiratory, gastrointestinal, metabolic and the control of the temperature of the body.

THE BASAL GANGLIA. THE THALAMUS AND HYPOTHALAMUS

The Basal Ganglia

The basal ganglia form a large and prominent part of the human brain, and in lower animal forms are a very important part of the nervous mechanism controlling muscular activity. Destructive lesions in the human basal ganglia are associated with several well known, common, severe motor disorders which are fairly constant in their clinical pattern, yet our knowledge of the nervous connections and of the functional activity of the human basal ganglia is grossly deficient. At one time it was denied (erroneously) that the basal ganglia had any connections with the cerebral cortex or that there was any functional or somatotopic localization within them. The thalamic connections are imperfectly understood. There is no known direct connection by which afferent impulses from the various sense organs can send information regarding the outside world or the body itself to the basal ganglia. Experimental stimulation or destruction of the basal ganglia in laboratory animals produces very little effect. Then what is the function of the basal ganglia in the human brain? What do they do and how? Are they merely vestigial remnants from earlier animal forms? That seems most unlikely. They form a large part of the brain and they have grown proportionately from the lower primates to man, so that whereas the globus pallidus, putamen and caudate nucleus occupy 980 cu mm in the rhesus monkey, they measure 2775 cu mm in the chimpanzee and have a volume of 14 912 cu mm in man (Harman and Carpenter, 1930). There have been some discussions of the possibility that the basal ganglia may be related to perceptual functions (Mettler, 1935) but the evidence in support of such a possibility is most tenuous. There also is some reason to believe that the basal ganglia may be related to vegetative or autonomic functions but the evidence is inadequate to establish such a relationship or to permit us to understand it if it exists. At this time we have reliable

evidence only that the basal ganglia are intimately concerned in the activity of the skeletal musculature. At present no one can answer the question as to what the basal ganglia do or how they do it in man. It may prove profitable, however, to summarize what we do know.

The term 'basal ganglia' is a loose one which defies accurate definition. There certainly is no uniformity of opinion even as to what the term includes. Perhaps the term is meaningless in modern neurology and will be discarded shortly, but for the moment it is so deeply embedded in our literature and in our thinking that it cannot be discarded. For the purpose of this discussion the term will include the *caudate nucleus*, the *putamen*, the *globus pallidus*, the *subthalamic body of Luys*, the *red nucleus* and the *substantia nigra*. (The caudate nucleus and putamen are often referred to as the *striatum* and the globus pallidus as the *pallidum*. The putamen and globus pallidus are sometimes referred to as the *lenticular nucleus*.) The *claustrum* should also be included in the basal ganglia but as practically nothing is known of its connections or functions it need not be considered further. It might be argued that the subthalamic body, the red nucleus and the substantia nigra should not be included, but their anatomical relationships, their numerous connections and their apparent close functional relationships with the other nuclei of the basal ganglia make their inclusion natural and reasonable. One might also include the substantia reticularis of the brain stem, the pontine nuclei, the inferior olive, the cerebellum and the amygdala. They certainly form part of this subcortical motor mechanism. But the reticular formation is related not only to muscular activities as are the basal ganglia (Magoun and Rhines 1947) but it also has what are perhaps even more important functions concerned with the alerting reaction, the control of spinal reflexes, of sensory threshold and of visceral regulation (Magoun and his coworkers). The pontine

nuclei, inferior olive, and cerebellum, although related in an important fashion to muscular activity (Bailey, 1949) are too far removed to be included in the term "basal ganglia." The amygdala has no known connections with the functions of the skeletal muscular system and seems more likely to be related to vegetative activities.

The cytology of the various nuclei under discussion offers little assistance in understanding their functional activity. For the most part the nuclei seem to be divided into two groups—the small celled and the large-celled parts. As is true of the cerebral cortex the small-celled parts appear to be the receptive divisions of the basal ganglia, whereas the large celled parts have a predominantly motor function. The caudate nucleus and the putamen constitute the receptive portion and so far as is known at this time receive their afferent innervation from the precentral motor cortex (areas 4, 4s, and 6), the

FIG 66.1 The connections from the cerebral cortex to the caudate nucleus and putamen

FIG 66.2 Some of the intrinsic connections within the basal ganglia

suppressor strips of Dusser de Barenne and his coworkers (areas 4s, 8, 2, and 24), (Fig 66.1) and in a small way from the thalamus. In turn the caudate nucleus and putamen send their efferent fibers mainly to the large-celled or "motor" portion of the lenticular nucleus, the globus pallidus, (Fig 66.2) with a much smaller group of efferent fibers going to the substantia nigra. Similarly the substantia nigra is divided into a large celled (pigmented) dorsal portion and a small celled (unpigmented) ventral portion which lies just above the cerebral peduncle. And the red nucleus is divided into a small-celled anterior portion and a large-celled posterior portion which gives rise to the rubrospinal tract. Here we must call attention to the fact that a material change has occurred in the red nucleus in primates as compared with that in the carnivora. In the dog and cat the magnocellular portion of the red nucleus and the rubrospinal tract are large and presumably important structures, whereas in the primates this portion of the red nucleus and the rubrospinal tract which arises from it are small and apparently insignificant (Stern, 1936). It is obvious that the experimental evidence which has indicated a place of great importance for the magnocellular portion of the red nucleus and the rubrospinal tract in the neural mechanism controlling muscular tone in the carnivora (Rademaker, 1926) is not applicable to the monkey, the ape or man. Another structure, the reticular formation of the brain stem, has apparently taken over that function. In fact, the reticular formation and the inferior olive are probably the principal effector or efferent structures of the subcortical motor system in primates.

Within the basal ganglia almost all parts are connected with all other parts (Fig 66.2), i.e., the globus pallidus sends fibers to the red nucleus, the substantia nigra and the subthalamic nucleus, the substantia nigra sends fibers to the red nucleus, the globus pallidus and the subthalamic nucleus, the subthalamic nucleus sends fibers to the globus pallidus, red nucleus and the substantia nigra. Within the basal ganglia there are also circular systems, such as the projection from the caudate nucleus to the globus pallidus, the globus pallidus to the ventral anterior nucleus of the thalamus, and from this thalamic nucleus back to the caudate nucleus (Fig 66.2). Two parts of the basal ganglia, however, remain more or less aloof from this intranuclear activity. They are the caudate nucleus and putamen, and the red nucleus. The caudate nucleus and puta

FIG 66 3 Connections of the red nucleus

FIG 66 4 Some connections of the substantia nigra with other parts of the basal ganglia

men on the one hand receive their afferent innervation largely from the cerebral cortex (with additional afferent connections from the substantia nigra (Ranson and Ranson 1939) and from the ventral anterior nucleus of the thalamus) and they distribute their efferents to the globus pallidus and the substantia nigra. The red nucleus receives from all of the other nuclei of the basal ganglia (and from the precentral motor cortex and the cerebellum) but sends all of its efferent fibers to structures outside of the basal

ganglia, to the spinal cord, the reticular substance of the brain stem, the ventrolateral nucleus of the thalamus, the inferior olive and the oculomotor nuclei (Fig 66 3). Thus the caudate nucleus and the putamen appear to be acting as the primary receiving station of the basal ganglia whereas the red nucleus and the globus pallidus are acting as the principal sending stations. In addition to their efferent fibers there are fibers from the substantia nigra and the subthalamic nucleus to the substantia reticularis and the center median nucleus of the thalamus (Ranson, Ranson and Ranson 1941, Glee 1945, Brodal, 1943) (Fig 66 4).

FUNCTION

What do the basal ganglia do with this complicated neural mechanism? Here again our knowledge is very incomplete. The location of the basal ganglia in the interior of the cerebral hemisphere, covered with the cerebral cortex and white matter, in very intimate relationship with the Island of Reil, the internal capsule, the thalamus and the hypothalamus has made discrete stimulation or destruction difficult. In any event the many experiments carried out on the

basal ganglia have shed surprisingly little light on their activity. Furthermore, in man the functional activity of the basal ganglia is apparently quite different from the lower animal forms, even monkeys. Whether this or some other factors are the reason, it is a fact that it has been almost impossible to duplicate in animals the clinical pictures associated with diseases of the basal ganglia in man. The only exception is the intention tremor produced in both man and monkey by section of the superior cerebellar peduncle (Walker and Botterell, 1937). It is true that Richter (1945) produced a parkinsonianlike state in monkeys by destruction of the globus pallidus and substantia nigra by chronic intoxication with carbon disulfide. But as Richter noted, the experimentally produced state was not the same as that seen in man because, "The characteristic tremor, in particular, is lacking." As a result we must turn to the experiments conducted in man by nature herself for what limited knowledge we have of the functions of the human basal ganglia.

It has been repeatedly said that there is no localization of function, somatotopic or other wise, in the basal ganglia. Clinical experience leaves no doubt that this statement is untrue. Disease in different parts of the basal ganglia give rise to vastly different clinical pictures. Destruction at any point in the dentato rubro-thalamic projection (Fig. 66.5) causes an intention tremor. Lesions of the substantia nigra and globus pallidus are associated with parkinsonism and a tremor at rest. Destruction of the caudate nucleus and putamen is seen in patients with choreoathetosis. Obviously there must be some functional differences between these various nuclei. Every clinical neurologist is aware of how the tremor of parkinsonism may begin in the head and neck, or in the foot, or in a finger, and then later gradually spread to other parts of the body on the same or opposite side. Obviously there is somatotopic localization in the basal ganglia in man, otherwise such localized manifestations of disease would not be possible.

What are the specific manifestations of disease

FIG. 66.5 A circular pathway involving the cerebral cortex and the cerebellum. Interruption of this pathway between the dentate nucleus, red nucleus and thalamus results in the appearance of an intention tremor. This probably is the result of the loss of controlling impulses from the cerebellum to the precentral motor cortex.

of the basal ganglia and what do they signify in terms of normal physiological activity? Diseases of the basal ganglia and experimental studies indicate at least four principal functions of the basal ganglia: (a) the production of useful voluntary muscular activity, (b) the control of reflex muscular activity, (c) the production of automatic associated movements, and (d) the control of the precentral motor cortex in its function of producing muscular activity.

Voluntary muscular activity For years it was thought that the production of voluntary muscular activity occurred exclusively as the result of the activity of the corticospinal tract. It is now obvious that that is incorrect. In the birds and reptiles there is no "motor cortex" (Arens Kappers 1929). The basal ganglia function as the 'head ganglia' of the neural mechanism controlling movement, it is a detailed and exquisite control, as one can see by studying a bird in the air. In the dog and cat there is a "motor" cortex but if it (or even the entire cerebral cortex) is removed the animal still sits, stands and walks. It appears that the animal does this largely with its basal ganglia but even if the basal ganglia and the diencephalon are removed useful movements are not completely abolished in cats. Bard and Macht (1938) decerebrated a small series of cats. In some animals the transection was immediately above the pons, in others it was through the mesencephalon producing a "low mesencephalic cat," whereas in the remainder it was through the upper mid brain producing a "high mesencephalic cat." The 'pontile cats' never stood or walked. The 'low mesencephalic cats' never walked spontaneously but unsteady walking could be induced by "strong" stimulation. The "high mesencephalic cats" spontaneously assumed a crouching or sitting position and walked in response to such stimuli as a light slap, a whistle or a tweak of the tail. One such animal 'frequently' walked spontaneously. Unfortunately we are not supplied with detailed information regarding the character of the walking and other muscular activities, nor do we know how the activity of these animals compared with that of a decorticate cat with the basal ganglia intact. That there was a considerable difference seems obvious.

In primates the situation is quite different from what it is in the carnivora and other lower animal forms. If the precentral motor cortex (areas 4 and 6) is removed from both cerebral hemispheres the animal becomes almost totally paralyzed. Such voluntary movement as an occa-

sional animal may reacquire is possible only if the cortex is removed piecemeal over months of time and if the animal is given painstaking care in retraining and repeated manipulation of its extremities. Even under the most optimum circumstances the movement which is recovered is very limited and stereotyped (Bucy and Fulton, 1933; Woolsey and Bard, 1943; Travis and Woolsey, 1956). Does this mean that in primates the basal ganglia and other subcortical centers have lost their ability to produce useful voluntary movements? This seems unlikely but it does appear that they have lost their ability to produce such movements in the absence of the precentral motor cortex. Area 4 of the precentral cortex gives rise to corticospinal fibers whereas area 6 does not (Verhaart and Kennard, 1940). If we remove area 4 from the precentral motor cortex of monkeys bilaterally, leaving area 6 on one or both sides the animal is still able to walk, sit, climb and feed himself but the movements are limited and awkward and reside more about the proximal joints than in the digits (Bucy and Fulton, 1933). Similarly, if the medullary pyramids on the under surface of the medulla oblongata are sectioned in the monkey, the fine, delicate, precise movements of the digits are lost but crude awkward movements of the extremities, particularly those which are more stereotyped and which are related to standing to progression, etc., are retained (Tower 1940). Likewise, and somewhat surprisingly, destruction of the corticospinal fibers in the cerebral peduncle in man does not completely paralyze the contralateral extremities nor is such an operation necessarily associated with the severely incapacitating hemiplegia of a destructive lesion in the motor cortex or in the internal capsule (Walker, 1949 and 1952; White Swanson Bucy, 1957). These patients are able to walk and to use their upper extremities for many useful purposes. Although final decisive proof is lacking it seems probable that these voluntary movements present in the absence of the corticospinal fibers are produced over the multisynaptic system of the precentral motor cortex and the basal ganglia and other subcortical centers functioning together.

Reflex muscular activity Rigidity is one of the characteristics of disease of the basal ganglia, notably Parkinson's paralysis agitans. Clinicians frequently attempt to make a sharp distinction between the rigidity of diseases of the basal ganglia and the spasticity associated with decerebration and capsular hemiplegia. However,

the differences appear to be rather superficial. As Fulton and his coworkers were the first to emphasize, both result from the loss of supraspinal inhibition which is not concerned with the corticospinal fibers. Furthermore, as Foerster (1921), Walshe (1924), and Pollock and Davis (1930) have shown, the rigidity of paralysis agitans, like the spasticity of decerebration, is abolished by interrupting afferent impulses from the involved muscle to the spinal cord. This demonstrates that both rigidity and spasticity result primarily from activity of the local, spinal reflex arc which is released to hyperactivity by removal of descending inhibitory influences. Thus it appears likely that the basal ganglia as well as the precentral motor cortex, area 4s and the bulbar reticular formation, exert an inhibitory influence over the spinal reflexes which control the muscular activity responsible for posture and reflex standing. Recent clinical observations reported by Narabayashi (1956), Guot (1957), and Cooper (1956) that lesions in the globus pallidus produced surgically in the treatment of various diseases result in the reduction of rigidity indicate the possibility that the basal ganglia exert an excitatory as well as an inhibitory influence upon the spinal reflex mechanism responsible for rigidity. However, the physiological explanation of these clinical observations are as yet unknown and anatomical controls are meager. This serves further to emphasize our ignorance in this field.

Automatic associated movements. One thing that characterizes parkinsonism perhaps even more than tremor or rigidity is the loss of automatic associated movements. Commonly this term is regarded as indicating only the swinging of the arms in walking—a type of movement which is abolished by various destructive lesions in the precentral motor cortex, in the cerebellum as well as in the substantia nigra and globus pallidus in parkinsonism. However, in parkinsonism far more is lost than automatic swinging of the arms. There is a general poverty of movement. The loss of expressional movements of the face results in the familiar masklike face. There is also a generalized loss of movements throughout the body so that the victim is described as being "statuesque." It thus appears that the basal ganglia are responsible for a wide variety of automatic and associated movements.

Abnormal involuntary movements. Lesions of the basal ganglia are commonly associated with various abnormal involuntary movements, the

nature of which vary depending upon the part of the basal ganglia which is involved. It is generally agreed that these movements develop because some inhibitory influence is removed allowing some part of the remaining intact neural mechanism concerned with the control of muscular activity to develop increased and abnormal activity. It seems likely that the corticospinal tract is probably the mechanism responsible for tremor and that some other motor neural mechanism stemming from the precentral motor cortex is responsible for the abnormal movements of choreoathetosis (Bucy, 1949, 1957). Possible inhibitory circuits involving different subcortical nuclei, including the basal ganglia which probably are concerned in the development of these abnormal movements have been described and discussed (Figs 66 5, 66 6 and 66 7) (Bucy, 1942). The connections and pathways outlined in these figures exist but whether their destruction is responsible for the appearance of these diseases is hypothetical.

It is known that destruction of the cerebello-dentato rubro thalamic system results in intention tremor (Walker and Botterell 1937). This system ends in the ventrolateral nucleus of the thalamus which in turn sends its efferent fibers to the precentral motor cortex. This system may well exert a controlling influence over the precentral motor cortex which when removed releases the corticospinal tract to the abnormal activity which results in intention tremor (Fig 66 5).

Destruction of the substantia nigra and globus pallidus is associated with the tremor at rest of parkinsonism. These nuclei are intimately related. The substantia nigra projects onto the globus pallidus directly and via the center median of the thalamus (Fig 66 4). The globus pallidus projects onto the anterior part of the ventrolateral nucleus of the thalamus which in turn sends its fibers to the precentral motor cortex. Again it is thought that this mechanism may exert control over the corticospinal fibers (Fig 66 6).

Choreoathetosis is associated with destruction of the caudate nucleus and putamen. These project directly to the globus pallidus, which again sends impulses to the precentral motor cortex via the thalamus. It is thought that this mechanism probably exerts control over that part of the precentral motor cortex which sends its efferent impulses to the skeletal musculature over one or more synapses in the various subcortical

FIG. 666 A circular pathway involving the basal ganglia. Lesions of the globus pallidus and substantia nigra in man may be associated with parkinsonian tremor at rest. This diagram shows how impulse from these areas may reach and exert a controlling influence on the precentral motor cortex. The loss of such influence may permit tremor at rest to appear.

FIG. 667 Another circular pathway involving the basal ganglia. Lesions of the caudate nucleus and putamen in man may be associated with choreoathetosis. Such lesions might so distort or disorganize the impulses from the basal ganglia to the precentral motor cortex as to cause the abnormal movements of choreo athetosis to appear.

nuclei. When this controlling influence is removed from the precentral motor cortex choreoathetoid movements may develop (Fig. 667).

CONCLUSIONS

What is known of the basal ganglia, their fiber connections and their functions, has been briefly summarized here. Much of this is unconfirmed and not a little has been arrived at by inference. The result is very imperfect knowledge regarding this large and obviously important part of the brain. The basal ganglia merit intensive study in man and in animals by various methods. Until better understanding is achieved our knowledge of the central nervous mechanism responsible for the control of muscular activity will continue to be imperfect.

Clinical Manifestations of Disease of the Basal Ganglia

The chief clinical features of disease of the basal ganglia are (a) muscular rigidity resulting in disturbances of posture and movement, (b) in voluntary movements e.g., tremor, athetosis, chorea, (c) a loss of automatic and associated movements such as those of emotional expression, the swinging of the arms in walking, etc., and (d) absence of a paralysis of voluntary movement, although it may be distinctly impaired by one or all of the other manifestations. The basal ganglia are particularly susceptible to certain toxins (e.g., carbon disulfide), to anoxia and to certain encephalitic processes. The following are some of the syndromes met with: (a) *Progressive hepatolenticular degeneration*, (b) *parkinsonism*—paralysis agitans, etc., (c) *chorea*, (d) *hemiballismus*, (e) *athetosis*, (f) *torsion spasm*.

Progressive hepatolenticular degeneration (Wilson's disease). This was described by Wilson in 1912. It invariably terminates fatally but its duration varies from a few months to several years. The following are its chief features:

1. *Muscular rigidity* is widespread and progressive, it involves face, trunk and limbs. Flexors as well as extensors are affected, but the former more conspicuously than the latter. The hyper-tonus offers a "lead pipe like" resistance to passive movement and results in slowness and difficulty of movement. Eventually, contractures occur and the patient is rendered almost immobile as though carved from stone, he can be lifted or moved *en bloc*. The rigidity of the facial muscles gives a fixed, blank expression. The mouth is sometimes held widely open, the smile or laugh is peculiarly stiff and vacuous. The hypertonus

of the muscles of articulation and deglutition leads to dysarthria (p. 1253) and dysphagia. The rigidity is temporarily abolished by the injection of novocaine into the muscles.

2. *Involuntary movements*. These consist chiefly of tremor (about 6 oscillations per second) which is increased by excitement or any attempt at voluntary movement, sometimes athetoid movements (p. 1224) occur.

3. *The reflexes are normal*. There are no sensory changes and although the muscles often show some weakness and are easily fatigued there is no actual paralysis.

4. *Cirrhosis (multilobular) of the liver* is found at autopsy, but during life there may be no signs of liver disease. In some instances, however, symptoms pointing to the liver precede the nervous manifestations. There is evidence that the changes in the liver and possibly in the brain are associated with disturbances in the metabolism of copper.

5. *Emotionalism*. Involuntary laughing or crying, and some mental deterioration.

6. *Greenish brown pigmentation of the cornea* (in Descemet's membrane) occurs in most cases.

Degeneration of the cells of the putamen and globus pallidus, sometimes with cavitation is found at autopsy. The caudate nucleus is affected to a much less degree.

THE PARKINSONIAN SYNDROME. The principal features of this syndrome are the following: (a) A *coarse tremor* involving head and limbs. The hand may show "pill rolling" movements, i.e., rhythmical movements of thumb upon the first two fingers. Alternating movements of flexion and extension at the wrist, or of supination and pronation of the forearm, are frequently present. When the limb is engaged in some voluntary act the movements often temporarily disappear in that limb. The tremor becomes more pronounced during emotional excitement or when the patient is under a nervous strain. It disappears during sleep. The tremor also disappears on the paralyzed side if hemiplegia supervenes. Ablation of the motor area of the cortex or section of the lateral corticospinal tracts also abolishes it in the related extremities. It therefore seems to be dependent upon an intact pyramidal tract. However, this has been denied by some surgeons who believe they have abolished the tremor by producing lesions in the globus pallidus, the thalamus or the midbrain. The final solution of the problem must await the accumulation of more accurate anatomical and physiological information. (b) *Muscular rigidity* which leads to slowness

and stiffness of movement. The rigidity is different both in its quality and distribution from that characteristic of the decerebrate animal (p 1165) or of the hemiplegic patient. Flexors and extensor muscles are affected about equally, and the resistance of a limb to passive movements has been described as resembling cogwheels moving slowly upon one another, as though groups of muscles gave way in succession to the stretching force. This cogwheel phenomenon is undoubtedly merely a manifestation of the rhythmical innervation of the involved muscles which also gives rise to the tremor. The upper limbs are held in characteristic attitudes of adduction at the shoulders, flexion at the elbows, flexion or slight extension at the wrists, flexion at the metacarpophalangeal joints and slight flexion at the interphalangeal joints. (c) The gait is slow and shuffling with short steps, or it may be 'festinating' in character, i.e., the patient is bent forward and hastens along with short quick steps as though trying to 'catch up to his center of gravity' and prevent his falling. When pushed forward or backward he cannot stop quickly but moves by a series of small rapidly repeated steps in the direction in which he is pushed. *Propulsion* and *retropulsion* are the respective terms applied to these forward and backward movements. There is no true paralysis: the reflexes and sensation are unaffected. (d) One of the most constant manifestations of parkinsonism is the loss of certain automatic and associated movements. As a result the patient does not swing his arms as he walks, the typical facial expressions of various emotions are decreased or absent and the face is said to be masklike. Because the many little movements of the body which characterize normal human activity are absent the patient stands rigidly and without moving, like a statue.

Parkinsonism appears to be the result of destructive lesions in the globus pallidus or the substantia nigra or both. These lesions may appear as the result of a primary idiopathic degeneration of toxic processes, of anaemia, of arteriosclerosis or of encephalitis.

All of the manifestations of parkinsonism are not necessarily present in all cases, or if present they are not of the same intensity. Some patients have the parkinsonian rigidity and lack of automatic and associated movements with little or no tremor. Some have tremor with relatively little rigidity. Some patients, particularly the post-encephalitic group, have associated disturbances of ocular movements known as oculogyric crises,

and of vegetative functions such as salorrhoea and excessive oiliness of the skin. Others, particularly those in the arteriosclerotic group, may have exaggerated tendon reflexes, the sign of Babinski and impairment of psychological processes. These disturbances are, of course, due to involvement of other structures and pathways in the internal capsule, the cerebral cortex, the hypothalamus, the midbrain, etc.

Chorea. There are two principal forms of this condition.

1 SYDENHAM'S CHOREA (or St. Vitus's dance) is one of the manifestations of rheumatic fever. Its chief feature is involuntary jerky movements, semipurposeful in character, involving the muscles of the limbs and face. Facial grimacing, an inability to remain quiet, the frequent dropping of objects from the hands, and the inability to maintain sustained muscular contractions characterize the disease.

Sydenham's chorea may be bilateral or unilateral. Death is rare and there is consequently uncertainty concerning its neuropathology. In those few cases where examinations have been made the lesions have been multiple and diffuse, involving both cerebral cortex and subcortical structures.

2 HUNTINGTON'S CHOREA is a rare familial disease which results in severe disability and ultimately terminates fatally. It is transmitted as a dominant characteristic but the onset is usually late in the fourth decade of life. Pathologically one finds severe degeneration and atrophy of the caudate and lenticular nuclei. The small cells of the caudate nucleus and putamen are particularly affected. However, the large cells are not entirely spared and changes are seen in the globus pallidus and cerebral cortex. The disease is characterized by facial grimacing, jerky gesticulating movements of the upper extremities and a lurching, uncertain gait. Speech is dysarthric. The motor disturbances steadily increase until the patient is incapacitated. There is mental deterioration with irritability and occasional homicidal and suicidal tendencies.

3 HEMIBALLISMUS or HEMI-CHOREA usually results from vascular lesions in the subthalamic nucleus of Luys. It is therefore, seen most often in older people with cerebral arteriosclerosis. It is characterized by wild flinging movements of the extremities on one side of the body. In some cases the condition subsides spontaneously (Hylland and Forman), in others the violent movements continue unremitting during the patient's every waking moment but subside during sleep.

In such cases the patient may injure his extremities and may die of exhaustion. The movements can be abolished by dividing the corticospinal fibers which arise in the precentral gyrus. This can be accomplished at the cortical level, in the cerebral peduncle or in the spinal cord. Pedunculotomy is the simplest of these procedures and should be considered in any case in which the movements show no evidence of subsiding spontaneously and are violent enough to warrant surgical intervention. It has been reported that these movements have been abolished by section of the anterior white column of the spinal cord but this observation needs confirmation. Physiologically it is difficult to understand why section of the corticospinal tract and an anterior cordotomy should both be effective.

ATHETOSIS is a form of abnormal involuntary movements beginning most often in childhood. It is associated with damage to the basal ganglia, particularly the caudate nucleus and the putamen. This damage may result from asphyxia or injury at birth, or from injury or encephalitis subsequently. Pure athetosis consists of slow, writhing, twisting movements of the involved extremities and the face. In many cases there are also quicker, jerky involuntary movements and the condition is then termed *choreoathetosis*. As with most other abnormal involuntary movements these are present during all waking hours and are absent during sleep. They are aggravated by nervous tension and are diminished or abolished by the ingestion of alcohol. In many patients choreoathetoid movements are unilateral and are associated with a hemiparesis on the same side. In some cases with bilateral involvement, or *athetose double*, examination of the brain

will reveal congenital changes in the basal ganglia known as *status marmoratus*. Unilateral choreoathetosis can be abolished by removal of the contralateral precentral motor cortex (areas 4 and 6). They can also be diminished by section of the central portion of the contralateral cerebral peduncle which contains the corticospinal fibers from the precentral gyrus. A few cases have been reported in which the movements have been decreased after surgical lesions have been placed in the region of the internal segment of the globus pallidus or the ansa lenticularis. However, these observations lack anatomical confirmation. It appears likely that both corticospinal fibers and multisynaptic neuron chains from the precentral motor cortex which pass downward through subcortical centers to the spinal cord mediate the impulses which are responsible for the abnormal involuntary movements of choreoathetosis.

TORSION SPASM is a very rare condition and need only be defined. It consists of abnormal involuntary turning, twisting movements of the neck, trunk, and extremities which distort the body into bizarre postures. Pathological changes in various parts of the basal ganglia have been described.

The Thalamus

This large gray mass is related medially to the third ventricle which lies between the thalami of the two sides. The thalami are joined across the midline by an isthmus, the *massa intermedia*. The posterior limb of the internal capsule lies up on the outer side of the thalamus and separates it from the lentiform nucleus. Above the thalamus is the lateral ventricle, a part of whose floor it forms. In front is the head of the caudate nucleus, the arched body of the latter is related to the upper part of the lateral surface of the thalamus. Below the thalamus are the corpus of Luys (subthalamic nucleus) and the forepart of the red nucleus.

There are five main nuclear masses in the thalamus.

A vertical septum of fibers known as the *internal medullary lamina* divides the principal part of the thalamus into A, a medial and B, a lateral mass, each of which contains two main nuclear groups. C, in the *massa intermedia* and the adjacent part of the medial mass are discrete groups of nerve cells known as the *nuclei of the midline*. D, Clusters of nerve cells are present in the internal medullary lamina itself—the *intralaminar nuclei*. E, *Pulvinar*.

FIG 66 S. Showing the anterior nucleus and the divisions of the lateral nuclear mass of the thalamus. DL, dorsal lateral nucleus, PL, posterior lateral nucleus, PV, posterior ventral nucleus, LV, lateral nucleus, AV, anterior ventral nucleus. (Courtesy of Dr. Murray Barr.)

connections of these nuclei are imperfectly known but they are thought to receive both trigeminal fibers and fibers of the medial lemniscus, they project to the globus pallidus and have many connections with neighboring thalamic nuclei. A well defined nucleus in the middle of the thalamus, and usually classed with this group is known as the *central or centromedian nucleus*. It is especially well marked in primates, as is possibly an intrathalamic integrating center.

E The pulvinar is the expanded continuation posteriorly of the lateral nuclear mass. It overhangs the superior colliculus. It projects to the cortex; its inferior part to an area comprising part of the temporal lobe, and the anterior part of the occipital lobe. The rest of the pulvinar projects mainly to the parietal and temporal lobes.

The *medial and lateral geniculate bodies* are usually included as part of the thalamus or referred to as the *metathalamus*; they are dealt with in chapters 75 and 76.

It will be seen from the foregoing account that the nuclei of the thalamus can be divided upon a functional basis into three categories, namely, (a) those which serve as relay stations of afferent impulses from the periphery to the cortex, (b) those which are connected mainly with other subcortical centers and (c) those whose chief function is associative.

FUNCTIONS

We have seen that the corpus striatum is a part of an old or primitive motor system. The thalamus, on the other hand, is a primitive receptive center wherein sensory impulses give rise to a *crude uncritical form of consciousness*, a consciousness which is greatly elaborated upon especially in man by the cerebral cortex (see ch. 67). Sensory localization in the thalamus has been demonstrated by Dussier de Barenne and Sager by means of local strychninization. The injection of a minute quantity of the drug into the thalamus in cats is followed by hyperesthesia and hyperalgesia to cutaneous and deep (muscle, tendon and periosteum) stimuli. The cutaneous hypersensitivity is most pronounced on the contralateral side of the body; increased sensitivity to deep stimuli occurs only on the contralateral side. By this method, and other methods of investigation it has been shown that there is a definite somatotopic organization in the posterior ventral nucleus of the thalamus, which serves the conscious perception of sensory stimuli. The leg is represented most laterally, the face most medially, and the trunk and upper extremity in between.

The thalamus is not, however, entirely sensory in function. In animals possessed of little or no cortex, or in higher mammals (e.g., cat or dog) after decortication it and the corpus striatum serve for the execution of complex movements of an automatic or reflex nature. Furthermore, the reticular nucleus and the ventromedial portion of the thalamus (including the intralaminar nuclei) form part of the reticular formation of the brain stem and take part in the arousal and alerting reactions produced by that mechanism as well as other functions referred to on pages 1224 to 1226.

THALAMIC LESIONS

The effects resulting from a lesion involving the lateral thalamic nuclei will resemble those following an interruption of ascending pathways in the brain stem above their decussation. That is, all types of sensation on the opposite side of the body tend to be lost or grossly affected, or there may be severe pain as a result of destruction of inhibitory mechanisms or possibly of the direct stimulation (irritation) of pain fibers. In addition to the loss or diminution of sensation lesions of the thalamus are not infrequently associated with spontaneous pain and with marked hypersensitivity which has a very unpleasant quality. These manifestations are part of the thalamic syndrome described below and are not well understood.

✓ THE THALAMIC SYNDROME OF DEJERINE AND ROUSSY. This is a characteristic picture occasionally seen in thalamic disease. The following are its chief features:

(1) *Asterognosis and sensory ataxia*, due to the impairment of cutaneous and kinesthetic senses. These and the other effects given below are mainly on the contralateral side of the body.

(2) *Some loss of tactile and thermal sensations* over the body and face. The threshold for these sensations, and for pain is frequently raised. Sometimes the patient with a thalamic lesion is unable with closed eyes to localize the position of a limb and must grope in the air in order to find it (*thalamic phantom limb*), or he may have the illusion that the limb is not there at all (*amelognosis*). He also is commonly unable to localize a point which has been stimulated even though he recognizes the stimulus.

(3) *Spontaneous pain* occurring in paroxysms and often excruciating. The pain may be so intense as to resist the action of powerful sedatives, e.g., morphine. A painful stimulus is felt much more acutely than is normal (hyperalgesia) and

although, as mentioned above, the threshold for pain is often raised, the sensation when once aroused (by increasing the strength of stimulus) is excessively severe. Other stimuli are often associated with an unpleasant sensation. Cold in particular may be most disagreeable but light touch may also be unpleasant. These spontaneous discomforts and unusual reactions to various stimuli are usually referred to as *thalamic over reaction*.

(4) Lesions in the thalamus are frequently associated with various abnormal involuntary movements. Choreoathetosis and intention tremor are the more common. It is believed that choreoathetosis results from the involvement of the projection system from the basal ganglia to the anterior part of the ventrolateral nucleus of the thalamus and that intention tremor arises when the pathway from the dentate nucleus of the cerebellum and the red nucleus is damaged at its point of termination in the posterior part of the ventrolateral nucleus. This nucleus in turn projects to the precentral motor cortex and it is thought possible that these abnormal involuntary movements arise because regulating impulses from the thalamus to the motor cortex have been destroyed (Bucy, 1942). Furthermore such lesions commonly give rise to an abnormal posture of the extended hand known as the '*thalamic hand*'. This is characterized by a moderate flexion of the wrist and a hyperextension of the fingers. The same posture of the outstretched hand is also referred to by some as the '*athetoid hand*'.

(5) Hemiparesis and defects in the visual fields which may be seen in some patients exhibiting the thalamic syndrome are not the result of thalamic involvement but are due to damage to the neighboring internal capsule.

The thalamic syndrome may also be associated with disturbances of sensation which are associated with certain emotional reactions. Thus one of Head's patients was so affected by music that he "could not stand the hymns on his affected side," another said that when the choir sang "a horrid feeling came on the affected side and the leg started to shake." In another patient pleasant feelings of a psychic nature were referred to the abnormal side. He said "I seem to crave for sympathy on my right side," and "My right hand seems to be more artistic."

The Hypothalamus

The hypothalamus is the basal part of the diencephalon (interbrain). It forms the floor and

lower parts of the walls of the 3rd ventricle (fig 66 10).

Of the nuclei of the hypothalamus the greatest interest from the physiological point of view centers around the following:

The *supraoptic nucleus* lies anteriorly, lateral to the optic chiasma and above the commencement of the corresponding optic tract. The *preoptic nucleus* is situated most anteriorly above and in front of the supraoptic nucleus, and immediately behind the lamina terminalis. The *paraventricular nucleus* is found above the supraoptic nucleus and is in close relationship medially to the wall of the 3rd ventricle. It is richly vascular, and its large vacuolated cells contain numerous granules, possibly the mother substance of a secretory product. The *posterior hypothalamic group of nuclei* lie in the posterior part of the hypothalamus in relation to the wall of the 3rd ventricle, and include the mammillary nuclei. Cells of this group send fibers to the medulla oblongata and the lateral horns of the spinal cord, which constitute the spinal sympathetic center. The *tuber cinereum* (*nucleus tuber*) is a small eminence of gray matter situated at the base of the brain between the optic chiasma and the mammillary bodies, i.e., in the midregion of the hypothal-

FIG 66 10 Diagram of the nuclei and connections of the hypothalamus. *cc*, cortico-hypothalamic fiber, *pv*, paraventricular nucl, *po*, preoptic nucl, *so*, supraoptic nucl, *oc*, optic chiasma, *tc*, tuber cinereum, *hy*, hypophysis, *mb*, mammillary body, *pn*, posterior nucl, *ms*, fiber to midbrain and brain stem, *3V*, third ventricle, *th*, thalamus.

amus, from its vicinity grows the pituitary stalk. Two groups of cells can be clearly defined within it, they are known as the *dorsomedial* and *ventromedial hypothalamic nuclei*. The slight swelling caused by these nuclei and covered by the pars tuberalis of the adenohypophysis (ch 56), is called the "median eminence." The tuber cinereum is a center of the parasympathetic nervous system.

Fiber connections. The hypothalamus receives fibers from the globus pallidus (pallidohypothalamic tract), from the amygdaloid nucleus and through the *medial forebrain bundle*, from the olfactory lobe and the parolfactory area. The medial forebrain bundle sweeps through the hypothalamus and in its course gives off fibers to several of the hypothalamic nuclei. The hypothalamus, especially the supraoptic and paraventricular nuclei, also receives fibers from prefrontal areas and the precentral motor area (6) of the cerebral cortex (ch 67) both directly and indirectly through the thalamus. There are probably afferent fibers from the spinal cord doubtless similar to the direct and collateral ascending afferents which go to the reticular formation. It also projects through the anterior and the dorsomedial nuclei of the thalamus to prefrontal areas. The most prominent tract from the hypothalamus to the thalamus is the mammillo-thalamic tract (of Vicq d'Azyr) from the medial mammillary nucleus to the anterior nuclei of the thalamus. Other efferent tracts (sympathetic and parasympathetic) pass backwards in close relation to the ependyma of the third ventricle, and descend in the gray substance of the midbrain (surrounding the cerebral aqueduct), pons, medulla (beneath the floor of the fourth ventricle) and spinal cord (sympathetic).

The various hypothalamic nuclei are in communication with one another through fiber tracts, the best known of these is the paraventricular supraoptic tract, but others undoubtedly exist.

The supraoptic, and tuberal nuclei, and probably the paraventricular nuclei as well, are linked with the hypophysis by efferent fibers which descend the infundibular stalk (hypothalamohypophyseal tract). The majority of these fibers terminate around the pituicytes of the pars nervosa but some can be traced into the pars intermedia.

Thus, there exists a pathway, through the hypothalamus, from the cerebral cortex to the cells (pituicytes) of the neural lobe of the hypophysis.

THE PHYSIOLOGY OF THE HYPOTHALAMIC NUCLEI

Modern experimental and clinical investigations have revealed the hypothalamus as a re-

gion of great physiological importance. Our knowledge of the functions of this part of the cerebrum is still, nevertheless, very incomplete. Much of the evidence is suggestive rather than conclusive and permits only tentative views to be held concerning many of its activities. It is the general opinion, however, that in this part of the diencephalon are contained the mechanisms for the control of certain primitive reactions (visceral and somatic) associated in animals with defense or attack, and in man with emotional states (fear, anger, etc.). This region is also believed to contain centers for the regulation of certain fundamental and vital processes, e.g., fat, carbohydrate and water metabolism, and to exert a governing influence upon the body temperature, the gastric movements, the genital functions and the sleep rhythm (ch 68) hunger and thirst (ch 43).

It is now generally conceded that important centers governing the activities of the autonomic nervous system are situated in the hypothalamus. Those cell groups in the anterior part of the hypothalamus and in the tuberal region were at one time believed to constitute a parasympathetic center, whereas the posterior part was thought to be concerned with sympathetic functions. It is now recognized that our knowledge concerning the localization of function in the hypothalamus is still defective.

The pituitary and the nervous structures of the hypothalamus are intimately associated in function, indeed, they should be considered together as constituting a closely integrated neuroglandular mechanism rather than as possessing distinct and independent functions. It will be recalled that the pars nervosa of the pituitary is developed as a downgrowth from the floor of the third ventricle and that the pituicytes are modified neuroglial cells. On the other hand, the cells of the supraoptic and paraventricular nuclei of the hypothalamus show evidence of possible secretory activity.

A brief summary of the experimental evidence relating to hypothalamic functions will be given in the following paragraphs.

(1) Karplus and Kreidl were the first to furnish evidence of a sympathetic center in the hypothalamus. Upon electrical stimulation of this region they obtained pupillary dilation, sweating and a rise in blood pressure. Inhibition of intestinal movements also results. Liberation of adrenaline has also been reported to follow stimulation of the hypothalamus. By means of needle electrodes inserted into the region of the lateral nucleus Bronk and his colleagues have recorded im-

pulses from sympathetic efferent nerves during stimulation of the hypothalamus. On the other hand, rhythmical variations in potential were produced in the hypothalamus by the stimulation of certain afferent nerves through which reflex sympathetic responses may be elicited.

(2) Beattie, Brow and Long found that extrasystoles produced in the cat by means of chloroform anesthesia, and which had been shown by Levy to be dependent upon sympathetic impulses (ch 71), were abolished by a destructive lesion placed in the posterior hypothalamic nuclei or by a section of the brain behind this region. Stimulation of the posterior hypothalamic region, on the other hand, caused extrasystoles to appear in an animal which previously had been free from these cardiac irregularities. Animals subjected to such lesions also showed hyperglycemia and glycosuria. Drowsiness for two or three days following the operation was a noticeable feature in some animals, they also showed a change in behavior, being more docile and "tamer" after the operation (see "sham rage" below). The nervous system of animals examined histologically some time after the lesions in the posterior hypothalamic nuclei had been made showed degenerating fibers which entered the midbrain and descended through the brain stem and cord. Those in the latter situation entered the lateral column of gray matter at different levels down to the third or fourth lumbar segment.

(3) Decerebration by a section through the midbrain causes a profound fall in body temperature. No such loss of temperature control follows the removal of the cerebral cortex and thalamus provided the hypothalamus is left intact. It is significant that sympathetic effects e.g., adrenaline liberation, ruffling of feathers or hairs, constriction of vessels and goose flesh result from exposure to cold. Moreover, Cushing has called attention to the high temperature which frequently follows operations upon tumors in the region of the third ventricle of the brain.

(4) Hess fixed electrodes in the hypothalamus of cats. After the animals had recovered from the operation a weak electric current passed through the hypothalamus induced a state indistinguishable from normal sleep. More recently Alert, Koella and R. Hess Jr. were all able to produce sleep in cats by stimulation of the intralaminar thalamic nuclei. Both of these observations are difficult to reconcile with the fact that stimulation of the reticular formation arouses the animal from sleep.

(5) Kabat and associates by means of an electrode fixed in the hypothalamus stimulated this

region in the unanesthetized animal. Pupillary dilation, erection of hair, inhibition of gastrointestinal peristalsis, clawing and urination resulted. Stimulation of other parts of the brain produced none of these effects.

(6) Gastric lesions associated with hypothalamic damage have been reported, and ovulation following stimulation of the hypothalamus has been mentioned (p 620). Evidence for hypothalamic control of gastric secretion has been cited on p 975. There is also some evidence of a hypothalamic center for gastric motility.

Quasi emotional State—"Sham Rage"

It was first demonstrated by Goltz that the reactions which usually accompany displeasure and anger are more readily evoked in an animal deprived of its cerebral cortex (decorticated) than in the normal animal. In Goltz's classical experiment the hemispheres and a large part of the thalamus were removed from a dog. The disposition of the animal was greatly altered by the operation, it being very readily aroused to anger. Barking, growling, baring the teeth or snapping occurred upon the least provocation. Cannon and Britton produced a similar state in cats by removal of the cortex, the decortication being performed by means of a pointed stilet inserted through the orbital cavities. Immediately following recovery from the anesthetic the animals showed the following remarkable phenomena which these observers termed "sham rage"—lashing of the tail, erection of the hairs, protrusion of the claws, dilatation of the pupils, sweating, struggling and biting, greatly increased rate of respiration and a rise in blood pressure. Most of these manifestations will be recognized as being of sympathetic origin. In many instances the picture is a combination of fear and anger. Liberation of adrenaline, as indicated by an increase in the rate of the denervated heart (p 1032) also occurred. The mildest stimulus such as jarring the table or lightly touching the animal was sufficient to evoke a paroxysm of rage.¹ In his decortication experiments Bard found that the posterior and ventral portion of the diencephalon was essentially responsible for the development of "sham rage". The typical quasi-emotional behavior occurred after decortication and section through the hypothalamus at about the middle of the tuber cinereum. It also resulted from an operation which

¹ Pseudoaffective states—displeasure, anger or rage can be evoked in animals after a section caudal to the hypothalamus, but much less readily than after decortication, and they do not constitute the fully integrated response of the animal with hypothalamus intact.

removed the basal ganglia and the dorsal half of the diencephalon, i.e., the thalamus, but left the hypothalamus connected with the midbrain. The condition failed to appear if the section separated the caudal part of the hypothalamus.

In view of the excessive display of emotional reactions which can so easily be induced in the cat (or dog) from which the forebrain has been removed, leaving the posterior part of the hypothalamus intact, it was only natural to conclude that the cerebral cortex exerted a regulatory influence over this hypothalamic mechanism. However, Bard and Mountcastle have shown in cats that the restraining influence of higher levels of the cerebrum upon hypothalamic activity is not exerted by the neocortex, but by certain parts of the rhinencephalon (cortex of the pyriform lobe, amygdaloid nucleus and hippocampal formation) and an area of cortex on the medial aspect of the hemisphere lying ventral to the cingular sulcus in front and below the rostrum of the corpus callosum. This latter area of cortex is believed to be a transitional zone between the rhinencephalon and the neocortex. An operation which removed the neocortex alone, leaving the rhinencephalon and the area of transitional cortex uninjured, was performed upon cats whose behavior and temperament had been studied for some time previously. The manifestations of animals prepared in this way were the reverse of those which had been subjected to complete decortication. They showed extraordinary placidity. Responses expressive of pleasure were predominant and often exaggerated. Procedures, which in a normal animal provoke resentment, anger or even rage, such as, pinching the tail strongly with surgical forceps, tying the animal down on its back, strong electric shocks applied to the skin, etc., evoked no sign of anger or even of resentment. The animals responded to mild noceptive stimulation by purring or with other expressions of pleasure. An animal which before operation resented handling or petting, became affectionate, purred when stroked and submitted to being tied to the animal board "as though it enjoyed the maneuver." Removal of those parts of the rhinencephalon mentioned above or of the transitional area of cortex, transformed animals deprived of their neocortex, i.e., abnormally placid animals, into ones which, upon the slightest provocation, exhibited all the signs of rage.

It is apparent from these experiments that some part of the rhinencephalon and the transitional area of cortex exerts a restraining influ-

ence upon those hypothalamic mechanisms governing the expressions displeasure, resentment and anger in carnivores (e.g., cats and dogs).

Repeatedly attention has been called to the danger in transferring information found to be true for one animal to another species of animal without carefully controlled investigations. Nowhere could this precaution be more appropriate than in connection with the amygdala. Although removal of this nucleus bilaterally renders the dog and cat savage and aggressive, it converts the normally intractable Norway wild rat into a gentle animal, bilateral temporal lobectomy, including removal of both amygdaloid nuclei, converts vicious and aggressive rhesus monkeys into relatively tame animals. There are obviously wide species differences and we cannot conclude that what is true for the hypothalamus or the amygdala or the neocortex of the cat is necessarily true for man unless the fact is established.

Emotion. This is an appropriate place to consider the mental state with its accompanying reactions which is generally referred to as emotion. The word emotion is derived from the Latin meaning a "moving out." But there is an inward as well as an outward component of the emotional state. It can be analyzed into subjective and objective elements—emotional feeling or experience, and certain visceral and somatic manifestations, e.g., pallor, blushing, cardiac acceleration, facial expression, etc.

According to the James Lange theory, the emotional feeling is not aroused primarily in consciousness but is the result of the bodily reactions. Briefly, for example, we are frightened because the heart accelerates, the vessels constrict, the respiration quickens and the skeletal muscles increase their tone, or contract for purposes of defense, or in order that one may run away, the afferent impulses initiated by these various activities impinging upon consciousness arouse the feeling of fear. Sherrington showed, however, that the emotional state of a dog remained unaltered after a high spinal transection and section of the vagus nerves, afferent impulses from the viscera and skeletal muscles being thus largely removed.

The modern view, which was advanced by Cannon and by Dana, proposes that emotional feeling and the associated bodily reactions are the result of interaction between the cerebral cortex and the diencephalon—hypothalamus and thalamus (anterior nucleus)—visceral and somatic responses being secondary to the feeling of rage, delight, grief, etc., rather than the cause, which

is dependent upon the cortex, probably of the orbital and cingular gyri and the hippocampus,² but the emotional manifestations are initiated in subcortical levels. As we have seen, there is much experimental support for such a view. Also, clinically, outbursts of uncontrollable laughter or crying are sometimes associated with lesions of the diencephalon.

DISORDERS OF THE HYPOTHALAMUS

The effects which may result from lesions (e.g., tumors, encephalitis, etc.) involving the hypothalamic region fall into the following groups: (a) disturbances in fat in carbohydrate or in water metabolism and (b) disorders of sleep, drowsiness, somnolence and, less commonly, abnormal wakefulness, or reversal of the sleep rhythm.³ (c) emotional manifestations laughing, crying or a state resembling sham rage⁴ in animals, may result, (d) phenomena attributable to sympathetic or parasympathetic stimulation, (e) disorders of the sexual functions.

Any one of the foregoing groups of effects may dominate the clinical condition to give rise to one or other of the following syndromes: (a) diabetes insipidus, (b) dystrophia adiposogenitalis, (c) the Laurence Biedl Moon syndrome and (d) narcolepsy.

These several conditions, with the exception of the last (d), have been considered in chapter 56.

Narcolepsy (see also p. 1272). This is the term applied to a disturbance in the sleep mechanism in which sudden attacks of an irresistible desire for sleep occur during the daytime. The duration of the attacks, which resemble normal sleep, is quite brief—from a few seconds to 20 minutes or so. It is only to such sudden and brief naps, and not to persistent drowsiness or to prolonged periods of pathological sleep that the term is applicable. Nocturnal sleep may be normal but it is often disturbed or there may be insomnia. Sleep may overcome the subject of narcolepsy while he is going about his usual occupation while walking in the middle of a conversation during a meal driving a car, etc. But commonly they occur at times when anyone would be inclined to sleep. There may be many attacks during the day. A few cases were discovered during the war in sol-

diers under trial by court martial for falling asleep on sentry duty. The condition may be a sequel to influenza or to epidemic encephalitis involving the hypothalamus or may result from a tumor or injury in this region. In other instances the condition appears without known cause (idiopathic narcolepsy). Although evidence is not conclusive it is very likely that in these latter, also, disordered hypothalamic function is responsible, for other features, e.g., obesity, polyuria or impairment of the sexual functions, pointing to an abnormality of this region are frequently present. *Ritalin*, *ephedrine sulfate* and *amphetamine* (benzedrine) have been used with benefit in idiopathic narcolepsy. *Cataplexy*⁵ is the term given to a condition allied to and very frequently associated with narcolepsy, in which the patient as a result of some emotion—amusement, anger, fear, embarrassment or surprise—is seized with complete muscular relaxation and weakness. The attack is brief, lasting for a few seconds, or for a minute or two at the most. Consciousness is not lost but the muscles are completely toneless and powerless for the time, and if the attack supervenes while the subject is standing his knees fail him and he sinks to the ground. The deep reflexes are lost. A somewhat similar situation may develop in a normal person who may become "weak with laughter, be struck all of a heap" or transfix when surprised or shocked. Or his jaw may "drop" when confronted with some unexpected occurrence. *Cataplexy* is regarded as an exaggeration of this normal tendency, just as narcolepsy is an intensification of the desire of many normal persons to drop into a doze under certain circumstances. Mirth is especially likely to precipitate a cataplectic attack. One victim reported by Adie remarked, "At the scout camp the boys used to accuse themselves by making me laugh and then running away leaving me helpless on the ground." Though narcolepsy occurs without cataplexy the converse is extremely rare. This association of the two conditions at once suggests a common pathogenesis, but the muscular atonicity characterizing the cataplectic attack cannot be explained upon any physiological basis. An interesting speculation has been made by Wilson, who compares the attacks to the defense reaction of certain animals whereby they fall into immobility when frightened, and suggests for them a certain biological significance, namely, that they are the relic of a primitive reaction uncovered by disease.

⁵ This should not be confused with cataplexy, an entirely different condition.

² von Bonin speaks of a reverberating circuit—hypothalamus (mammillary body) to anterior thalamic nuclei via mammillo-thalamic tract, thence to anterior part of cingular gyrus thence to cornu Ammonis and finally back to the mammillary body through the fornix and fimbria.

THE CEREBRAL CORTEX. THE PHYSIOLOGY OF SPEECH AND SOME OF ITS DISORDERS. APRAXIA AND AGNOSIA. EPILEPSY. HEADACHE

Minute Structure of the Cortex

The human cerebral cortex (or *pallium*) has a total area of about 220 000 sq mm, not more than a third of this lies upon the free surface or crown of the convolutions. The remaining two-thirds of the gray mantle of the cerebrum occupy the walls of the sulci. The total number of nerve cells in the human cerebral cortex has been estimated at around 10^{10} . The number of fibers received from and projected to lower levels of the nervous system is in the neighborhood of 200 million. Added to these are fibers, many times more, which connect cells within the cortex (association fibers). On the basis of cellular structure the major part of the cortical gray matter is divisible into six layers or laminae. But these layers do not show identical histological appearances throughout the extent of the cortex. Characteristic differences in the depth of the individual layers and in their cellular components are found in the various regions. The six layers from the surface inwards with a general description of their cellular features as given by Economo¹ follows (see fig 67 1).

I MOLECULAR (OR PLEXIFORM LAYER) In this, the most superficial layer, the terminal filaments of numerous dendrites from cells of deeper layers, as well as from the axons of Martinotti cells form a dense felted network. Its cells are sparse they are small (4 to 6μ) and pear-shaped or fusiform.

II EXTERNAL GRANULAR LAYER consists of large numbers of small round, polygonal or triangular cells closely packed together. Their afferent processes pass into the overlying layer, their axons end mainly in deeper layers, but some enter the white substance of the hemispheres.

III PYRAMIDAL CELL LAYER Medium-sized pyramidal cells are contained in the outer part of

this layer, pyramidal cells of larger size and more sparsely distributed are present in the deeper part. It is customary, therefore, to subdivide this layer into an outer and an inner portion, Campbell refers to them as separate layers.

IV INTERNAL GRANULAR LAYER resembles the external granular layer in being composed of closely packed masses of small stellate cells, but unlike the outer granular layer it is rich in nerve fibers. This layer contains many horizontal fibers which show as a white stripe, or band known as the outer stripe or line of Baillarger, which is especially well marked in the calcarine cortex, but in this situation it is more usually referred to as the line of Vieq d'Azyr or of Gennari.

V GANGLIONIC LAYER (or internal pyramidal layer) consists of pyramidal cells of graded sizes. This layer is particularly well-developed in the precentral (motor) cortex where giant pyramidal cells (Betz) are conspicuous. It contains, also cells of Martinotti, these cells are peculiar in that their axons pass outwards toward the surface of the cortex and arborize in their own layer, or in overlying layers. Some of these cells can be found in nearly all layers of the cortex. Its deeper strata contain a dense network of fibers which forms the inner line of Baillarger.

VI FUSIFORM CELL LAYER, in contact with the white matter, is composed of closely packed small spindle-shaped cells with their long diameters perpendicular. Cells of Martinotti and small stellate cells are present also in this layer but fewer in number.

It should be emphasized that the foregoing is no more than a general description of the histological structure of the cortex and that marked regional differences exist. Even the lamination itself is not a feature common to the entire cortex. In man one-twelfth of the cortical area shows little or no lamination, this portion, which is called the *allocortex* or *archipallium* comprises the

¹ For a detailed description this author, or the earlier works of Campbell and of Bolton should be consulted.

FIG 671 Showing layers of area 4 of human cerebral cortex (agranular) left cell bodies Nissl stain right nerve fibers Weigert stain a outer band of Baillarger b inner band of Baillarger Note the large cells of Betz in the fifth layer (After Brodmann)

cortex of the olfactory lobe (i.e., the pyriform area and the hippocampal, supracallosal and olfactory gyr, etc.) The laminated cortex, which in man constitutes the remaining eleven twelfths, but which in lower mammals is a much smaller fraction of the whole, is called the *isocortex* or *neopallium*

The greater part of the human laminated cortex shows the cytoarchitectural features described above, and is therefore sometimes referred to as the *homotypical* cortex. In other more restricted areas the cortex departs from the typical cytological appearance, chiefly in the preponderances of the small granular cells or of the pyramidal elements and is called *heterotypical*. In areas in which the internal granular layer is absent or practically so and in which pyramidal cells predominate the cortex is called *agranular*, and when the small granulelike cells form a prominent internal granular layer with few pyramidal cells, it is called the *granular* cortex. The agranular cortex is thicker than the granular which is particularly thin at the frontal and occipital poles of the hemispheres

The cortex of the precentral region (areas 4 and 6) is of the agranular type. The granular layers (II and IV) are shallow, being encroached upon by the expansion of the pyramidal layers III and

V. In the deep part of layer V of area 4 (the area *gigantopyramidalis*) are situated the characteristic giant cells of Betz (60 to 80 microns in their greatest diameters) (see below). These cells contribute fibers to the corticospinal tracts (ch 65). In area 6 in front of area 4 the granular layers are also inconspicuous but the large cells of Betz are absent.

In the cortex of the walls of, and surrounding the calcarine fissure—the *area striata* or *visual area*—the outer and inner granular layers (II and IV) are expanded at the expense of the pyramidal layers (III and V). This very finely granular type of cortex, also called from its ‘dusty’ appearance under the microscope the *koniocortex*, is characteristic of sensory areas. It is present though to a less fully specialized degree than in the visual cortex, in the postcentral gyrus (somesthetic area) and in Heschl’s gyrus (auditory cortex, p 1445).

Upon gross examination of a section of the brain two lighter bands can be seen in the cortex against the darker gray matter. These are produced by nerve fibers running parallel to the surface of the convolutions. They are known respectively as the outer (already mentioned) and inner bands of Baillarger. In the visual area the outer band is broad and prominent and is usually referred to in this part of the cortex as the band of Vicq d’Azyr or of Gennari, who had described it previously. The inner band is less dense than the outer, particularly in this area.

✓ Localization of Function in the Cerebral Cortex

Campbell mapped the cortex into 20 areas which could be differentiated on the basis of their cytoarchitectural characters. This number was raised to 47 by Brodmann and subsequent workers (Vogts) have subdivided these again to make a total of 200. Bailey and von Bonin (1951) in a careful reappraisal of the matter of the subdivision of the cerebral cortex on the basis of cytoarchitectonic studies concluded that most of the divisions of the cortex which had been devised previously were unsupportable. They were able to divide the cerebral cortex into the allocortex of the hippocampal region and the pyriform lobe, the agranular cortex of the precentral region and the anterior limbic area, the *koniocortex* of the primary sensory areas (the somesthetic areas of

* The macroscopical study of the cortex and mapping it into areas according to the cytological characteristics is called *cytoarchitectonics*

the postcentral gyrus, the visual cortex of the calcarine area, and the auditory cortex of Heschl's convolution on the superior surface of the first temporal gyrus), and the culminate cortex of most of the remainder of the mantle of the cerebral hemisphere.

Differences, most of them minor, within this broad outline were demonstrable. Thus in the precentral agranular cortex there are two areas—the area gigantopyramidalis (area 4) which lies just in front of the central fissure and contains the large cells of Betz, and the other which Brodmann designated area 6 and which lies immediately in front of area 4 and is devoid of gigantic pyramidal cells. The agranular cortex of the anterior limbic area partakes of some of the characteristics of the allocortex. The koniocortex of the visual area is more complex than that of the somesthetic and auditory areas and there are minor variations in different parts of the culminate cortex which need not concern us here. In the following discussion we shall refer to the numerically designated areas described by Brodmann as they are well established in neurological literature and teaching, but his finer subdivisions will not be dwelt upon.

THE FRONTAL LOBE

The Precentral Cortex, Areas 4, 4s, 6, 8 and 44

Area 4 is a tapering strip of agranular cortex lying with its wider end at the upper border of the hemisphere, in front of the central fissure (Rolandic), and occupying the posterior part of

the precentral convolution. A good part of this area is buried, for it covers the anterior wall of the central fissure. It also turns over the upper border of the hemisphere and extends down the mesial aspect as far as the cingulate sulcus. Area 4 is a center for voluntary movement. It gives origin to an important part of the corticospinal tracts, and also projects to the pons (frontopontine tract), corpus striatum, red nucleus, and the subthalamus. Areas 4 and 6 are also connected by intracortical fibers. The muscles of the various parts of the body are represented in this area on the mesial and the lateral surfaces, in an order which is, in general, the inverse of that in the body itself, namely, toes, ankle, knee, hip, trunk, shoulder, arm, elbow, wrist, hand, fingers, brow, eyes, face, larynx, jaw and tongue (fig. 67-2). The parts of the face are not inverted. By suitable electrical stimulation of different parts of this area, movements of muscles on the opposite side of the body can be evoked.

The careful studies of Woolsey (on the monkey) have demonstrated that the distal parts of the extremities, i.e., the hands and feet, are represented near the central fissure while the more proximal joints, i.e., shoulders and hips, and the trunk, are represented somewhat more anteriorly. With suitably controlled stimuli discrete movements limited to a small part of the extremity or even to a single muscle may be elicited. Although most of the control of the precentral cortex over the muscular activities of the body are exerted contralaterally, there is also some control over muscles on the same side of the body. This ipsi-

FIG. 67-2. Coronal section through the hemispheres to show the motor and sensory representations in the cerebral cortex. (From Rasmussen and Penfield.)

lateral innervation is greater in the proximal joints of the extremities than in the distal parts and is greater in the lower than in the upper extremity. Furthermore, this ipsilateral innervation by the precentral motor cortex is greater in monkeys than in man. Electrical stimulation of the cerebral cortex, although a valuable tool for the study of cortical activity, is a poor substitute for normal physiological activity. The range and extent of movement produced by such stimulation represents but a small fraction of the motor activity which the intact cerebral cortex is able to produce under normal circumstances. Furthermore, the movements which are induced by electrical stimulation are crude and limited compared with the well coordinated, smoothly executed movements of the normal animal. One must never fall into the error of concluding that the results of electrical stimulation are a measure of the extent or nature of the normal activity of the areas stimulated.

Penfield and Welch, and Woolsey and his associates have demonstrated a *supplementary motor area* lying on the medial surface of the hemisphere in both man and monkey. This area lies anteriorly and ventrally to the primary motor area described above. In it the entire body is again represented. The head and upper extremity are represented farther forward and closer to the edge of the hemisphere while the lower extremity is represented more posteriorly and nearer to the corpus callosum. The threshold of this supplementary motor area is somewhat higher than that of the primary motor area which lies immediately anterior to the central fissure. The function of this supplementary area has not yet been well defined.

A large percentage of the corticospinal fibers arise from the precentral gyrus (area 4 in the monkey), whereas it is questionable if any corticospinal fibers arise from area 6. However, as both of these areas give rise to fibers which descend to subcortical centers (e.g., basal ganglia, thalamus, reticular formation, pontine nuclei, etc.) destructive lesions of neither area 4 nor area 6 is comparable to an isolated lesion of either the corticospinal or the multynaptic motor pathways which pass through the subcortical nuclei. Thus any idea that a lesion of area 4 which gives rise to both types of motor fibers is comparable to a section of the corticospinal fibers in the cerebral peduncle or the medullary pyramid is false, as is the thought that a lesion of area 6, which gives rise to much fewer fibers to the subcortical nuclei

than does area 4, will give rise to a clinical picture typical of destruction of the motor pathways through the basal ganglia, etc.

Destructive lesions of the various parts of the precentral motor cortex do have certain important characteristics. First, it is obvious that the precentral motor cortex is essential to normal activity of the skeletal musculature in primates. If one removes the excitable motor cortex (the sigmoid gyrus) from both cerebral hemispheres of a dog or cat, or even if all of the cerebral cortex is removed, there is some interference with motor activity, especially with certain stereotyped reactions, such as the placing and hopping reactions but the animal is not paralyzed. He can still sit, stand, walk, or run in a very creditable manner. If the precentral motor cortex is removed from both hemispheres of a monkey he is permanently and severely incapacitated and only a few stereotyped movements are possible. It is true that if the precentral motor cortex is removed piece meal over months of time and if the animal is given intensive care with massage, manipulation and re-education he can in a few instances become able to stand in a very uncertain fashion and take a few halting awkward steps. These observations indicate clearly that in dogs and cats some subcortical mechanism (the basal ganglia?) is capable of producing useful well coordinated movements, but that in the monkey the motor cortex has assumed much greater importance and the subcortical mechanism is almost totally unable to function in the absence of the cortex. Naturally the precentral motor cortex has rarely been removed bilaterally in man, and in one case observed by Walker the patient's condition and short postoperative survival did not permit of any study of value. The evidence available indicates that the precentral motor cortex in man is of even greater importance and that functions are even more localized and even more contralaterally represented than in the monkey.

In the cat and dog the unilateral removal of the motor cortex (sigmoid gyrus) or even the removal of all of the cortex from one cerebral hemisphere causes little motor disturbance. Even in the monkey the motor deficiency resulting from such an operation is not profound. The animal still uses all four extremities. He sits, stands, runs and hops about in his cage from one wall to another and back and forth on his trapeze. The extremities contralateral to the hemidecortication are more awkward than the normal ones. In jump-

ing the animal misses the bars of his cage occasionally with the involved digits, and often rests on the backs of the fingers or toes rather than on the palmar and volar surfaces as the normal animal does. So long as his normal extremities are available he seldom uses the involved ones to pick up food, but he can do so in case of necessity. In other words, although the contralateral extremities are not normal, they are far from being paralyzed. Naturally one asks what is the source of the innervation of these extremities. There can be little doubt that it is from the intact ipsilateral cerebral hemisphere, for if it is removed, the animal not only becomes paralyzed in the extremities contralateral to it but in those affected by the original decortication as well. In other words, removal of the cortex from the remaining hemisphere results in a severe paralysis of all four extremities. There are other evidences that the precentral motor cortex is capable of ipsilateral innervation. Holmes and May, and later Bucy and Fulton presented definite evidence that ipsilateral movements, particularly in the lower extremity and particularly in the more proximal joints could be produced by electrical stimulation of the precentral motor cortex.

In man the situation is similar but not identical. If the precentral motor cortex is removed from one hemisphere the contralateral extremities are severely incapacitated but not completely paralyzed. Movements at the distal joints—the wrist, hand and fingers, the ankle, foot and toes—are entirely or nearly completely abolished. In some cases a slow and rather weak simultaneous flexion of all the digits of the hand can be produced voluntarily. Movements at the shoulder and elbow and at the hip and knee are much fuller and stronger. In the upper extremity the flexor movements tend to be better, whereas in the lower extremity extension at both the hip and knee is more extensive and stronger than flexion. Such movements in the upper extremity are less than in the lower, but this does not account for all of the differences from the standpoint of usefulness. The upper extremity is primarily a prehensile one, designed to bring things to the individual or to pull him to them. Thus a condition in which the fingers, hand and wrist are paralyzed and only movements at the elbow and shoulder are possible does not result in a useful extremity. On the other hand, the lower extremity is used for standing and walking. It is primarily a supporting pillar. The fact that the toes and foot can not be moved is of relatively little importance while the ability

to move the extremity at the knee and hip, especially at the latter, enables the patient with his precentral motor cortex destroyed or its pathways severed to walk in a very useful fashion, even though he limps and has to circumduct the involved foot with each step. Evidence is not available to prove the source of the innervation which accounts for the remaining muscular activity in the involved extremities in man, but reasoning by analogy from the monkey it would seem most likely that it is from the ipsilateral cerebral hemisphere. The few bits of evidence available to us support this view. For instance, in a few human cases in which the upper part of the precentral motor cortex has been destroyed bilaterally by a tumor or by injury, both legs have been paralyzed. If the movement in the lower extremities seen in hemiplegics were produced by the subcortical centers, then such a paraplegia would not be expected as the result of purely cortical lesions. Furthermore, Bates has been able to produce ipsilateral movements by electrical stimulation of the medial surface of the cerebral hemisphere in man.

As noted above there are differences in function between the various parts of the precentral motor cortex. Lesions of area 4 produce more severe motor deficiencies than do lesions of area 6. While lesions of both together produce the most severe deficiency. However, either area 4 or area 6 alone in one hemisphere of the monkey, all other parts of the precentral motor cortices having been removed, is able to produce useful movements in all four extremities. This is evidence of the presence of ipsilateral as well as contralateral motor innervation from both area 4 and area 6, and is also evidence that useful movements can be produced over the multisynaptic neuronal pathways from the precentral motor cortex through the various subcortical centers (the so-called extrapyramidal pathways) as well as over the corticospinal tract direct from the precentral gyrus to the spinal cord. Other evidence in confirmation of this fact is the demonstration that useful voluntary movement is still possible in the monkey after the medullary pyramids have been divided (Tower, 1940) and in man after the central portion of the cerebral peduncle has been cut (Bucy, 1957). There is one interesting and as yet enigmatic fact concerned with these two observations, the one on the monkey and the other in man. When the medullary pyramid is divided in the monkey, the greatest defect in movement is seen in the distal parts of the extremities, that is, in

the fingers, hand, toes and foot. This is similar to the deficiency which develops when the precentral motor cortex is destroyed. Surprisingly when the cerebral peduncle is cut in man movements of the digits and the distal part of the extremity remain good and in a recent case were the first movements to recover and the strongest.

Alteration in only one reflex can be attributed to destruction of the corticospinal tract from the precentral gyrus. If the "foot" area in the upper most part of area 4 on the medial surface of the hemisphere is destroyed or if the corticospinal fibers to the muscles of the great toe are divided it will become possible to elicit the sign of Babinski. Destruction of other parts of the precentral region or section of other corticospinal fibers, of course, does not have such an effect. Furthermore, this reflex can only appear if the peripheral mechanism is intact. Thus the necessary anterior horn cells, anterior spinal roots, peripheral nerves, and muscles must be present and functioning and the great toe and its joints must be in condition to respond properly if the reflex is to appear.

Destruction of area 4 results in a weakness of the contralateral extremities which is relatively flaccid as compared with that resulting from a lesion of both areas 4 and 6. This led Fulton and his associates to conclude correctly that destruction of the corticospinal tract which arises from the precentral gyrus is not the cause of the spasticity so commonly seen in animals or men with capsular hemiplegias. Hines demonstrated that spasticity tended to appear most prominently when a narrow strip lying just in front of area 4 was removed. This area which has been called "the strip" of Marion Hines or area 4s appears to be the part of the precentral motor cortex particularly concerned with the control of the postural and the stretch reflexes. Its destruction causes these reflexes to become exaggerated and spasticity with hyperactive tendon reflexes to appear. McCulloch, Graf and Magoun showed that area 4s projects to the bulbar reticular formation and exerts its controlling influence on these reflexes through that important mechanism. In addition Dusser de Barenne and his coworkers have demonstrated that area 4s is capable of inhibiting other forms of peripheral motor activity in addition to these reflexes. They have also shown that under certain special circumstances the area 4s (and certain other "strip" areas, areas 8, 2, 19 and 24) is capable by means of connections which pass through the caudate nucleus to suppress the electrical activity of the remainder

of the cerebral cortex. Various other investigators have questioned the accuracy of these observations, but peculiarly no one of them has ever repeated the experiments of Dusser de Barenne and his coworkers. It is recognized that this suppressor function can be demonstrated only under certain special conditions as to anesthesia, stimulation of the suppressor strips, and that we do not know what, if any, function these suppressor strips and their effect upon other cortical areas play in the normal physiological activity of the animal.

Lesions of area 6, in contrast with those of area 4, give rise to an awkwardness in the performance of skilled acts with little loss of strength, spasticity and increase in the tendon reflexes (possibly due to involvement of area 4s which lies so close), forced grasping and groping and in some cases disturbances in autonomic functions. These effects are all contralateral to the lesion. Woolsey would view these facts somewhat differently. It is his opinion that lesions in area 4 near the central fissure would affect the distal parts of the extremities (hand and fingers, foot and toes) whereas those lesions farther forward in area 6 would produce changes in movements of the trunk and proximal joints.

Irritative lesions involving area 4 give rise to localized clonic convulsive seizures. The convulsive movement usually begins focally in some part of the body depending upon which part of area 4 is irritated. There may be a localized twitching of the face, or of one or more fingers, or of the foot or of the leg. This convulsive movement may remain localized or it may spread to neighboring parts of the body or even become generalized. This "march" of the convulsive involvement is typical of what is known as a Jacksonian epileptic seizure and is dependent upon a spread of the irritation in the motor cortex. A convulsive seizure produced by irritation of area 6 is characterized by what Foerster termed an adversive seizure. These begin with a turning of the head and eyes and often of the body toward the side opposite the involved cerebral cortex. Bucy and Pribram described a case in which a tumor in the "face" area of the precentral motor cortex was associated with localized convulsions of the contralateral side of the face and with localized sweating of that side of the face and to a lesser extent of the upper extremity. Such paroxysmal outbursts of autonomic activity are far from common but indicate the relationship of this part of the cerebral cortex to vegetative functions.

There is other definite evidence that the precentral motor cortex also exerts some control over various visceral and vascular activities, such as heart rate, vasomotor activities, gastrointestinal motility, perspiration. There is also evidence, at least in the cat, that these activities are also controlled in some measure by the cortex on the mesial surface of the hemisphere, and that of the orbital surface of the frontal lobe.

It has been noted above that destruction of the precentral motor cortex (areas 4 and 6) results in a spastic hemiplegia. However, it is not to be assumed that this condition is identical with the spastic paralysis which results from lesions at lower levels. The spasticity resulting from lesions of the internal capsule is in general greater than that seen with cortical lesions. In all probability this is due at least in part to the fact that in the internal capsule the fibers are drawn close together in a compact bundle and the damage is, therefore, greater than with the usual cortical lesion. There is also the possibility that the greater spasticity commonly seen with hemiplegias of capsular origin is the result of some destruction in the basal ganglia, which is common with such lesions, as well as the destruction of the fibers descending from the precentral motor cortex. In any event the pattern of the increased tone is similar with hemiplegias of both cortical and capsular origin, i.e., the increase in tone in the upper extremity is in the flexor muscles. With severe lesions at the mesencephalic level it is common to see spasticity even greater than is commonly seen with capsular or cortical lesions but the pattern in both the upper and lower extremities is an extensor one. If the lesion is in the spinal cord, one may see either a paralysis with very severe extensor rigidity or a paraplegia in flexion, as has been discussed elsewhere.

Grasping Movements and Tonic Innervation

Involvement of the anterior part of the precentral motor cortex, i.e., of area 6, is not uncommonly associated with a group of phenomena to which various terms have been applied, e.g., 'forced grasping and groping', 'grasp reflex', 'tonic innervation' and so forth. A description of these phenomena follows.

(1) Merely touching the skin between the finger and thumb with a pencil results in slow flexion of the fingers. If the stimulating agent is withdrawn gently without disturbing the position of the patient's fingers no tightening of the grasp results but his hand and arm sometimes move

through space (grobe) in the direction of the moving object, as if drawn by a magnet.

(2) *Grasp reflex*. When an object is placed in the involved hand of the patient the fingers close slowly and gently around it, but any attempt made by the observer to withdraw the object often results in its being grasped more firmly. Nevertheless, when the patient clenches his empty fist he can relax the fingers again without difficulty.

(3) Any attempt to bend the arm or leg is met by an active resistance exerted by the antagonistic (stretched) muscles; this differs from the resistance offered by the ordinary spastic limb in that there is no sudden giving way with a "clasp-knife effect".

Walsh and Robertson have made a critical study of these phenomena and find that they are separable into two distinct components: (a) the *grasp movement* and (b) *tonic innervation*.

The *gentle grasp* and the *groping movements* just described (see (1) above) are voluntary and not reflex acts. That is to say, though they are automatic in nature and are taken to indicate deterioration of the psychomotor functions, the patient can prevent their occurrence if asked to do so. They disappear in stupor or in coma. The *gentle grasping movement* follows tactile stimuli alone or visual and tactile stimuli acting together. The *groping movements* can be elicited by visual stimuli alone but not by tactile stimuli alone.

Tonic innervation (see (3) above) is a 'stretch reflex' (ch. 64). The *strong grasp* (2) which results when an attempt is made to remove an object from the hand is simply one phase—an incident—of this reflex. It is quite distinct from the *gentle grasp movement*. It results from the passive stretching of the flexor muscles of the fingers caused by the observer's attempt to extricate the object. The patient cannot relax the grasp and release the grasped object. It occurs in the unconscious patient. The grasp reflex is most pronounced when the patient is on his side and the affected arm uppermost (Fulton).

Richter and Hines produced the "tonic grasp reflex" in adult monkeys by removal of area 6. Excision of the motor areas or the prefrontal areas from both hemispheres did not cause the effect. A similar reflex is present in normal infants, Robinson showing that in these it is sufficiently strong to suspend the body from a bar for 2 minutes. A grasping reflex has also been described for the foot in lesions of area 6, it occurs in the normal infant up to the end of the first

year and is said to occur in 50 per cent of Mongolian idiots. It is elicited by stroking the sole.

Area 8 is called the *frontal eye field*. It lies in front of *area 6*. Stimulation of the cortex here causes a conjugate movement of the eyes to the opposite side, opening and closing of the eyelids, and sometimes dilation of the pupils and lachrymation. No visual hallucinations occur in man but an epileptiform seizure may be provoked which spreads to the *adversive field* (*area 6*).³ Ablation of *area 8* of one side in monkeys or involvement of this area or its projection fibers in man causes the eyes to be turned up toward the side of the lesion, and paralysis of the conjugate eye movement. These effects are temporary. The animal in walking circles toward the side of the lesion. No abnormalities are observed in the pupils or in the movements of the lids. *Area 8* is one of the "suppressor" areas. This area receives fibers from the dorsomedial nucleus of the thalamus, through which it is connected with the hypothalamus. It also connects by long association tracts, both afferent and efferent, with the occipital lobe (*visual area, 18*) and with the tegmentum of the midbrain (probably with the oculomotor nuclei).⁴

Area 44 in the region of the posterior part of the frontal operculum in the *dominant hemisphere* (which is the left in right-handed persons) is the motor area for speech (Broca's area). Stimulation of this area in conscious patients causes their speech to be abruptly arrested.

PREFRONTAL OR ORBITOFRONTAL REGION

The prefrontal region embraces the part of the frontal lobe in front of *areas 8 and 44* but it includes the orbital as well as the lateral aspect of the lobe, and for this reason is also known as the orbitofrontal region. It was divided by Brodmann into several different areas (9, 10, 11, 12, 13 and 14) but Bailey and von Bonin do not believe that

³ Stimulation of *area 8* in man also causes conjugate deviation of the eyes and turning of the head to the opposite side.

⁴ Unilateral ablation of this area in monkeys is followed by a visual defect in the form of failure to recognize objects in the opposite homonymous halves of the visual fields—a *pseudohemianopia*—results. When *area 8* is destroyed on both sides the animal does not react in a normal manner to visual stimuli. It may appear to be blind for it walks into or stumbles over obstructions in its path and tends to stare straight ahead with an immobile, wooden expression (see Kennard and Letors). Yet an animal will follow an object with its eyes and will seize anything offered to it though failing, apparently, to recognize it or to understand what to do with it.

such subdivision of this area is supportable by a careful study of the cytoarchitecture. These areas until recent years have been thought to be inexcitable, and were therefore referred to as "silent" or association areas. But upon stimulation by a suitable electric current having pulses of low frequency, autonomic, respiratory, circulatory, renal, and gastrointestinal responses can be elicited. After bilateral removal of these areas the blood pressure is reduced, gastric secretion suppressed, and gastrointestinal movements increased. In man, suffering from intractable pain is relieved. These areas receive important fibers from the dorsomedial nucleus of the thalamus which in turn receives impulses from the hypothalamus. These orbitofrontal areas, especially those of the orbital surface, are thought also to be closely associated with emotional feeling. Their part in the scheme of cortical representation of sensation is uncertain, but they are probably concerned with visceral rather than with somatic sensations through the hypothalamus and dorsomedial thalamic nucleus.

Area 24, anterior part of the cingular gyrus on the mesial aspect of the hemisphere, is a powerful suppressor area. Various autonomic responses follow stimulation of this area including pupillary dilation, pilo-erection, acceleration of the heart, and a fall in blood pressure. Arrest of respiration in expiration also results.

The prefrontal areas have extensive subcortical and cortical connections. Areas from 9 to 12 in the monkey receive fibers from the dorsomedial nucleus of the thalamus. Fibers ascending to the orbital areas 11 and 12 from this nucleus have also been demonstrated in man from a study of retrograde degeneration in the nucleus following section of white matter. The anterior nucleus of the thalamus also sends fibers to the prefrontal area (*area 23*), and both dorsomedial and anterior thalamic nuclei receive fibers from the hypothalamus. The pathway from hypothalamus to the cortex through the dorsomedial nucleus was established by stimulation of the posterior hypothalamic region and observing the action potentials in the thalamic nucleus and the cortex. The greater part of the prefrontal cortex is considered by Le Gros Clark as a projection area for the hypothalamus just as the occipital cortex and auditory cortex are projection areas respectively for the retina and the cochlea (fig. 674).

The prefrontal areas are connected by efferent fibers with (a) the hypothalamus through the dorsomedial nucleus of the thalamus, (b) there is also good evidence for the existence of a direct efferent connection with the hypothalamus both

in animals and in man, (c) with the caudate nucleus, (d) nuclei of the pons (from area 10), (e) tegmentum of the midbrain

Unilateral or bilateral removal of the *prefrontal area* does not cause paralysis either in the monkey or in man. Unilateral removal of the human prefrontal area produces a definite if rather subtle alteration in mental processes. Some loss of initiative and mental alertness are the most outstanding results of the operation. Memory, judgment and intellect often show little or no deterioration. Removal of the prefrontal area of the dominant hemisphere (i.e., the left in right handed and the right in left handed persons) is sometimes thought to produce somewhat greater alterations in character or intellect than does a similar operation upon the nondominant side. Even the bilateral excision of prefrontal areas is followed by a sur-

prisingly moderate mental defect so far as superficial observation and examinations are concerned. However, we must not be misled by such inadequate observations. The fact that the patient following a unilateral or even a bilateral prefrontal lobectomy appears normal functions as a normal individual during casual associations or passes the usual psychometric tests with flying colors does not mean that the frontal lobes are without important functions so far as mental activity and behavior are concerned. Halstead has discussed this matter in detail and has developed tests which indicate with amazing accuracy the damage to the frontal lobes. These tests have been elaborated into a battery of very objective tests the results of which give an impairment index of the functions of the frontal lobes. Damage to other parts of the brain does not give rise to comparable changes in these tests. Subcortical lesions involving the white matter of the frontal lobes do not disturb these functions as do lesions of the frontal cortex. Many of these tests are based upon the ability of the patient to classify and categorize a large number of familiar objects and to recall them once they have been taken from him. In an operation

for the eradication of a tumor, Dandy excised the frontal lobes on both sides in front of the motor areas (reported by Brickner). The subject of this extensive extirpation appeared of normal intelligence upon a casual acquaintance. It is reported that for an hour he toured the hospital with two visiting neurologists who failed to notice in him any mental abnormality. A more intimate knowledge of the patient, however, revealed very definite defects of character and mentality. His mental age was about thirteen years, his intelligence quotient eighty. The main features shown by this subject and which may be taken generally as representative of the effects of extensive prefrontal destruction are listed below. They constitute what has been called the *frontal lobe syndrome**.

(1) *Lack of restraint* leading to boasting, self aggrandizement, hostility, aggressiveness

(2) *Distractibility and restlessness*—difficulty in fixing attention

(3) *Hypermotility* which appears to be due to the loss especially of area 13

(4) *Flight of ideas*, puerile fantasies, emotional instability, facetiousness, punning

(5) *Lack of initiative*, and difficulty in planning any course of action

(6) *Impairment of memory* for recent events but not for remote events

(7) *Impairment of moral and social sense*—loss of love for family

(8) *Failure to realize*, or indifference to, the seriousness of his condition, and a sense of well-being (euphoria)

Among some of the other manifestations which may follow a prefrontal defect are (a) increased appetite, (b) impaired control of the sphincter

* The classical example of a severe prefrontal injury which resulted in surprisingly little mental defect is the case of the American Phineas Gage (1848) who suffered extensive damage of his frontal lobes by an iron tamping bar driven through his head by an explosion. The bar penetrated the left orbit and emerged from the midline of the head just anterior to the coronal suture. He was stunned for only an hour and was able with assistance to walk to a surgeon's office. He lived for 12 years after the accident and showed in general these mental changes. A case has also been reported in which the prefrontal cortex on both sides were absent or degenerated. The condition existed from early childhood yet, at adult age the subject of this defect, after a careful psychologic and psychiatric examination, was reported to be of normal intelligence, though some defect in planning capacity and in the ability 'to organize his behavior toward a relatively remote goal' were revealed.

of the bladder or rectum, (c) disturbances of orientation in time and space, and (d) tremor.

Chimpanzees which have had both prefrontal areas removed show restlessness and are easily distracted, though they remain alert and evince a keen interest in things around them. Fulton and Jacobson reported in 1935 that after this operation chimpanzees failed to show temper tantrums and other neurotic effects of frustration (experimental neurosis (p 1266)). This observation formed the basis for the surgical treatment of certain psychoneuroses in man, first employed by the Portuguese neurologist, Egaz Moniz in 1936. The operation called *frontal lobotomy* consists in severing the fibers connecting prefrontal areas with subcortical centers (probably the thalamus and hypothalamus). With the introduction of the various drugs which are capable of reducing nervous tension and rendering the aggressive, agitated patient more tractable the need for this type of operation has been greatly diminished.

The frontal lobes and intelligence. The development of the frontal lobes bears in general a direct relationship to the level of an animal in the phylogenetic scale and to its intelligence. This has led to the belief that this part of the cerebrum is the seat of the intelligence of animals and the 'center or organ of the mind of man'. Within this region those processes underlying intellectual as well as moral and emotional attributes were supposedly carried out. The absence of any overt effect from stimulation of these so-called silent areas seemed to confirm this belief. Extirpation experiments and lobectomy or injury in man, however, show decisively that the prefrontal area cannot be looked upon as a region where these higher mental qualities reside exclusively or even predominantly. Intelligence depends upon a knowledge of the external world received through various channels. Visual, auditory, somesthetic perceptions, etc. are received and stored as memories in cortical areas situated in the occipital, temporal and parietal lobes. Tracts of association fibers in turn link together these several primary areas, sensations of various types are thereby brought into relationship, and synthesized into more complex memories. Thus, as time passes, the fabric of our experience is woven in patterns of greater and greater intricacy.

The progressive increase in size of the frontal lobes through the upper levels of the phylogenetic scale is not as great as that of the parietal lobe, which supports the conclusion derived from extirpation experiments that intelligence, mem-

ory, control of behavior, etc are not solely or even predominantly dependent upon the prefrontal areas

It is probable that the prefrontal area merely represents a region of relatively high associative or synthetic capabilities. The subcortical connections of this area, as well as the effects upon behavior resulting from its injury, strongly suggest that it is concerned with emotional feeling. After its bilateral removal the cerebrum deprived of the synthesizing faculty of this region is incapable of the more elaborate association of those experiences required for the formulation of abstract ideas and more accurate judgment, and for the guidance of conduct in conformity with social customs. Here also are mainly located those mental processes relating to "prediction," forecasting, or to any planned action. A person deprived of these areas would have little ability as a strategist, even a housewife after the loss of these parts of the cortex experiences some difficulty in planning a meal. Nevertheless, synthesis at somewhat lower levels is still possible of achievement through the remaining cerebral tissue. Mental capacity according to this concep-

tion is a function of the cerebral cortex as a whole rather than of any particular region

THE PARIETAL LOBE

The Somesthetic (Somatesthetic) Area

The postcentral gyrus, i.e., the band of cortex lying behind and including the posterior lip and wall of the fissure of Rolando (areas 3, 1 and 2) is sensory in function and is known as the *somesthetic area*. This band of sensory cortex turns over the upper border of the hemisphere, and extends down the mesial surface as far as the cingulate gyrus. As in the case of the primary motor area, the sensory areas of the body are, in a general way, represented mainly in inverted order, from the lowest part of the mesial surface to a corresponding part of the lateral surface. Thus, the area for the toes is at the lower part of the mesial surface, that for the leg near the upper border of the hemisphere, while the face, mouth and tongue areas are found in the lower part of the lateral surface. The parts of the face, however, are represented in uninverted sequence—brow, eyelids, nose, lips, in this order from above downward

FIG. 67-5. Diagram of a section through the somesthetic area to show cortical representation of the dermatomes. F.S., sylvian fissure; F.C., central fissure; s.c.m., callosomarginal sulcus; MAX., maxillary division of the trigeminal nerve; MAN., mandibular; OPTH., ophthalmic; C., cervical; T., thoracic; L., lumbar; S., sacral; Ca., caudal. (From Woolsey, Marshall and Bard, *Bull. Johns Hopkins Hosp.*, 70: 339-441, 1942.)

(fig 67 2) Though broadly speaking, sensory representation in the cortex has this regional representation, when the topography of the different parts is examined in greater detail it is found that the order of cortical representation conforms closely to that of the dermatomes, i.e., to the spinal innervation. For example, the cortical sequence for the upper limb (monkey) is postaxial arm, occiput, ear, side of head, neck, shoulder (C2-C6), preaxial arm, forearm, wrist, hand, digits (C7, C8, T1). But it will be seen from figure 67 5 that the dermatomal representation is not in continuous numerical sequence from head to tail. For example, if the sensory band of cortex (which turns over the upper border of the hemisphere) were straightened out, it would appear quite clearly that the projection of the dermatomes from the upper thorax to the tail (Thoracic 1 to Caudal 4) was in an order the inverse of that of the spinal segments, whereas, the representations of the head and neck were uninverted, the cervical segments being represented in ascending numerical order from above down and the ophthalmic division of the 5th nerve following C8. There is no obvious explanation for this arrangement. Excisions from the somesthetic cortex are followed by disturbances of cutaneous and kinesthetic sensations on the opposite side of the body. These subside to a greater or lesser degree with the passage of time.

Cushing and later, Penfield and his associates have stimulated different parts of the area in conscious patients, sensations on the contralateral half of the body were experienced, their locations bearing a constant relationship to the point stimulated. Dusser de Barenne discovered that the application of a strychnine solution to the postcentral gyrus in monkeys caused sensory effects (paresthesias, hyperesthesia and hyperalgesia) on the opposite side of the body, but also to some extent on the same side.

The sensory area of the cortex is not confined to the postcentral gyrus but extends forward into the precentral gyrus. Penfield and his associates found that 25 per cent of stimulations of the latter area in patients caused a sensation, with or without a motor response. On the other hand, 20 per cent of stimulations of the postcentral gyrus gave a motor response, instead of or accompanied by a sensation. Also ablations of postcentral areas cause motor defects which are not due simply to loss of kinesthetic sense. It appears that the precentral and postcentral areas are knit together by connecting neurons, and are so interrelated functionally as to be called appropriately, taken as a whole, the *sensory-motor area*. The question of the sensory function of the precentral gyrus and the motor functions of the postcentral still require accurate definition.

Marshall, Woolsey and Bard have used a method to map out the cortical representation of tactile sensibility in monkeys, based upon the fact that impulses set up by stimuli applied peripherally can be recorded as action currents from the surface of the hemisphere (fig 67 6). This is known as the *method of evoked potentials*. They found tactile sensations represented contralaterally in the postcentral gyrus (areas 3, 1 and 2). Ipsilateral representation was not observed except for a part of the face (e.g., lips, tongue and lower cheek). In no instance was evidence obtained for the precentral representation of this sensation.

As in the motor area the extent of the sensory representation in the postcentral gyrus is greatest for those parts of the body which are of most importance in acquiring information concerning surrounding objects. Thus, in man and in the monkey, the cortical area for the hand and arm is larger than that for the trunk or leg while in such animals as the rabbit, cat or pig, the area for the face, lips, snout and vibrissae is much larger.

FIG 67 6 Action potentials recorded from postcentral gyrus during tactile stimulation of points on palm. (Part of figure from Marshall, Woolsey and Bard.)

than that for the paws. In the pig the representation for the snout takes up a large part of the postcentral gyrus, whereas that for the feet is insignificant. In the Shetland pony the cortical area receiving impulses from the nostril is nearly as large as that representing the rest of the body surface. The large facial representation in man appears to be an exception for, after infancy, we do not gain information by feeling objects with the lips or by putting them into the mouth. It is looked upon, however, as an inheritance from our animal ancestry.

Somatic sensation as well as the visual and auditory senses have a double representation in the cortex of each hemisphere. Thus dual somatic representation was first observed by Adrian, in the case of the claws of the cat. The somesthetic area described above and long recognized, is now called the "primary" sensory area, or, as Woolsey has suggested, *somatic area I*. The more recently discovered sensory area is called *somatic area II*. Corresponding terms for the dual visual and auditory areas are employed, namely auditory and visual areas I and II. Somatic area II lies in the upper wall of the Sylvian fissure, that is, below the face area of somatic area I, which is much larger in extent. The order of representation in sensory area II is the inverse of that of sensory area I, the face being above the arm in the upper part of the wall of the fissure and the representation of the foot at the bottom. The significance of the dual cortical representation is unknown. Area II is thought to be the more primitive of the two, that is, to have been developed at a much earlier phylogenetic period. It is possible that it receives fibers subserving the cruder forms of sensation, (the protopathic system of Head) while the primary area receives impulses upon which more critical perception (epicritic) is based.

All somatic sensory impulses ascend in the medial, spinal and trigeminal lemnisci to the thalamus, which is the subcortical destination of crude sensations. Though rather vague sensations described as tingling, numbness, tickling, pricking, or as the movement of a limb, are aroused by stimulation of the postcentral gyrus, and are referred to some part of the body depending upon the area stimulated, pain is never aroused and rarely even discomfort. There does not appear to be an area of the cortex essential for the perception of pain for 'no removal of the cortex anywhere prevents pain from being felt' (Penfield). Impulses for pain reaching the thalamus can arouse this feeling without being transmitted to

the cortex. Though, as mentioned earlier, severe intractable pain, usually associated with disease of internal structures is relieved by frontal lobotomy or lobectomy, the perception of pain is not abolished, but the patient ceases to suffer and complain, he no longer worries about it.

The finer sensations of touch and temperature and the sense of position and movement are relayed to the cortex by fibers which ascend through the internal capsule and corona radiata. The function of the somesthetic cortex according to the theory of Head and his associates is not, however, simply to record these several primary sensations. Its activity lies in the psychic sphere: cortical sensation, to quote these observers, is one of the "elementary processes of the mind." The somesthetic area brings its discriminative and synthesizing abilities to bear upon the primary sensations which it receives, and from these are formed our perceptions of the qualities of external objects, such as their size, shape, weight, texture, etc., and of the positions of our limbs in space. Through cortical activity a particular sensation is subjected to critical appraisal and compared with or related to another simultaneous or consecutive sensation, thereby, its intensity and nature are accurately judged. Thus, according to Head, the somesthetic area of the cortex, through the integration of the primary sensations becomes endowed with three discriminative faculties. These are:

(a) **SPATIAL RECOGNITION**—the appreciation of relationships in space, e.g., the recognition of position and passive movement of the limb, the discrimination of two points and the localization of a point which has been touched.

(b) **RECOGNITION OF THE RELATIVE INTENSITY** of different stimuli, e.g., that one object is warmer or cooler.

(c) **RECOGNITION OF SIMILARITY AND DIFFERENCES**—appreciation of the shape, relative size and texture of objects, and the estimation of their weights—*stereognosis*.

With a lesion involving the cortical somesthetic area, one or the other, but usually all three, of these faculties are disturbed. Spatial recognition shows the greatest disturbance the farther forward the lesion lies in the somesthetic area. Appreciation of intensity is disturbed most by lesions involving the foot of the postcentral gyrus and the

* According to the conception of Penfield and Jasper, impulses received in the sensorimotor cortex return to the thalamus and other parts of the centrencephalic system where the highest level of functional integration is situated.

supramarginal and angular gyri. Recognition of similarity and difference is affected most by lesions of the middle of the postcentral gyrus.

If with lesions confined to the cortex, the related nuclei of the thalamus which are concerned with the *primary* sensations, e.g., light touch, temperature, passive movement and position etc., are intact and the sensations will be appreciated. The patient with such a lesion has difficulty, however, in bringing the necessary discriminative ability to bear upon the sensation in order to judge it, and he is unable to synthesize different sensations into a composite impression which will enable him readily to identify an object. When tested, he is uncertain in his answers, which tend to vary from moment to moment, and it is difficult for the examiner to determine the threshold for a given sensation. For example, though he recognizes that an object is warm, he cannot say whether it is warmer or less warm than another object which he has felt previously or at the same time. He responds to tactile stimuli, but also with inconstancy, and he is often even less consistent in his answers when the strength of the stimulus is increased. He cannot locate the point touched and may respond when not touched (hallucination of touch). The weights of objects placed upon the hand cannot be estimated, and a fabric (e.g., silk or tweed), though felt to be smooth or rough cannot be recognized.

It is not to be assumed that sensation is simply a matter of nervous conduction, that all stimuli of equal intensity are equally perceived by the person stimulated. The perception of a given stimulus is not always the same, the threshold varies. This in part is due to attention or inattention. If a person's attention is concentrated upon one part of his body he will become more acutely aware of stimulation of that part while at the same time he becomes less aware of stimuli received elsewhere. This is common everyday human experience. It also plays an important role in the symptomatology of disease. The patient whose attention is constantly focused upon a diseased or injured part is keenly aware of unpleasant sensations from that area, whereas another patient with a similar disease or injury who is busily engaged with other activities and does not concentrate upon his disease or injury suffers much less discomfort. Likewise, it is a matter of common experience on the part of physicians that some patients have a much lower threshold for pain than others. In general, the patient who is introspective, who concentrates his attention

upon himself, his body and its ailments is the one with the lowest threshold for pain and the one who suffers and complains more. What is the physiological explanation for these differences between patients, and from time to time in the same patient? It seems likely that several neural mechanisms are at work here. One of these is the reticular formation in the brain stem. There is ample evidence that it can influence sensory thresholds both peripherally and centrally. Other mechanisms which may be concerned are the corticothalamic, corticobulbar and corticospinal fibers. We have mentioned the projection of thalamic fibers to almost every area of the cerebral cortex. Sensory perception is the primary concern of those from the nucleus ventralis posterior of the thalamus to the postcentral gyrus. It has also been pointed out that there is also an extensive projection system from the cerebral cortex back to the thalamus. In general a given area of the cortex projects back to the same thalamic nucleus as that from which it receives fibers. It seems entirely reasonable that this corticothalamic system is a mechanism for controlling the threshold of the thalamus and thus for regulating sensory attention. There is also a corticobulbar system which extends from the postcentral sensory cortex to the spinal root of the trigeminal nerve and corticospinal fibers from the postcentral gyrus to the posterior gray horn of the spinal cord in the monkey (Kuyper, 1958). This same investigator also found evidence of a cortical projection from the "leg" areas of both the pre- and postcentral gyri to the nucleus gracilis. Projection from the precentral cortex to the nucleus euneatus was also found. Although conclusive evidence that these connections are concerned with modulation of sensory perception has not yet been presented, Hagbarth and Kerr (1954) have shown that stimulation of the postcentral sensory cortex (in the cat) will depress afferent responses from the spinal dorsal root transmitted over pathways in the spinal cord and the midbrain.

Hypotonia may also be a symptom of lesions of the sensory cortex, it corresponds in distribution to the loss of the sense of position and passive movement.

The cortex at the lower end of the somesthetic area (tongue and face area) appears from the studies of Bornstein to be the *area for taste*. This area lies adjacent to the motor cortex governing the muscles of mastication.¹ It had been generally

¹ This area probably extends into the upper bank of the Sylvian (lateral) fissure, for the sensa-

taught, but on doubtful evidence, that the center for taste lay close to that for smell, namely, in the region of the hippocampal gyrus. It appears from the results of the stimulation of the human cortex during operations that the taste area extends deeply into the fissure of Sylvius. An electrical stimulus applied to the cortex above the circular sulcus (surrounding the insula), or the surface of the insula itself causes a sensation of taste—a "terrific tight sensation of taste" as one patient expressed it (Penfield).

Motor effects of a generalized type are produced by electrical stimulation of the posterior part of the superior parietal lobule (area 5, parietal ad-versive field). These are movements of the head and eyes to the opposite side. Stimulation of the angular gyrus causes conjugate deviation of the eyes to the opposite side.

Attacks of Jacksonian epilepsy, due to lesions of the sensory cortex, may be preceded by sensory auras—comprising pricking sensations, "pins and needles," sensation of cold, etc.

THE TEMPORAL LOBE THE CENTERS FOR HEARING AND SMELL

The primary cortical center for hearing is situated in the transverse gyrus of Heschl lying in the floor of the lateral cerebral (Sylvian) fissure, and an adjoining small area of the superior temporal gyrus. Fibers from the medial geniculate body reach this audiosensory area (area 41) via the posterior limb of the internal capsule, they constitute the *auditory radiation* (p. 1205). In the audiosensory area the fundamental auditory sensations—intensity, quality and pitch—are appreciated. The area is bilaterally represented.

Equilibratory sense is represented in the posterior part of the first temporal convolution. Stimulation of this region in conscious patients causes dizziness or nausea, a sense of swaying, falling, or of rotation.

It has been asserted that memory resides in the temporal region, either in the neocortex or in the amygdala. It is certainly true that defects in memory occur with lesions of the temporal lobe, but the concept that "memory" is localized there is much too superficial and simplified a view of this complex neural process. Memory is composed of many things—the retention of various types of sensory experiences, the recollection of one's own thoughts, ideas and expressions,

tion has been aroused in patients by stimulation of the upper bank where it joins the insula (Penfield and Rasmussen).

and the recall of one's motor acts, to enumerate the more obvious categories. To postulate that the memory traces of these many varied things are stored in any one part of the brain is unsupportable. It can be shown readily that memory is often disturbed by disease processes in many different parts of the brain but it is unlikely that "memory" is localized anywhere.

As in the case of the somesthetic (p. 1243) and visual senses, auditory sensations have a dual representation in each cerebral hemisphere—*auditory areas I and II*. Woolsey and Walzl stimulated electrically the different levels of the exposed cochlea in cats and found a point to point projection on to the temporal cortex. In auditory area I, the apical turns of the cochlea were projected posteriorly, the basal turns anteriorly, whereas in the "secondary" area, which lies adjacent and ventral to the "primary" area, the different points of the cochlea showed the reverse distribution, apical turns anterior, basal turns posterior (fig. 677). A large part of the cortex of the superior temporal gyrus lying outside these audiosensory areas is considered to be *audito-psychic* in function. Herein the analysis and interpretation of auditory sensations, and their integration into more complex perceptions take place. The audito-psychic area is mainly unilateral, being on the left side in right-handed individuals and vice versa.

Fibers descend from the cortex of the temporal lobe to the *medial geniculate body* and *inferior colliculus*, the former is therefore connected with the auditory area by both ascending and descending paths.

It has been taught for many years that fibers

FIG. 677 Right temporal cortex of cat showing the representation of the right (ipsilateral) cochlea. This is a composite figure from data of a number of experiments. Upper hatched region, primary auditory area, lower cross hatched region, secondary auditory area. (After Woolsey and Walzl, redrawn with minor modifications.)

descend from the temporal lobe through the internal capsule and the lateral segment of the cerebral peduncle to the pons—the so-called *temporo-pontine* or *Turck's bundle*. However, in detailed studies of the brains of monkeys following temporal lobectomies neither Rundles and Papez nor Bucy and Kluver were able to demonstrate any such tract. It is possible that these fibers in the lateral part of the cerebral peduncle are parieto-pontine fibers as Mettler suggested. The temporal lobe also receives fibers from the posterior pole of the pulvinar of the thalamus (Bucy and Kluver), and it appears that these terminate in the anterior part of the cortex of the lateral surface of the temporal lobe (Simpson, 1952 and Chow, 1954). There is also a large bundle of fibers (Arnold's) which has an uncertain origin in the anterior part of the temporal lobe and which passes backward to end in the pulvinar of the thalamus. The functions of these connections are unknown.

THE CENTER FOR SMELL is situated in the uncus and the anterior part of the hippocampal gyrus (pyriform area). In man, stimulation of the uncus, olfactory lobe or the region of the amygdaloid nucleus causes an olfactory sensation. Owing to the close relationship of these parts of the rhinencephalon to the temporal lobe, lesions of the latter (e.g., tumor, abscess, etc.) are not uncommonly associated with disturbances of the olfactory sense.

A LESION OF THE TEMPORAL LOBE may result in

1 *Aphasia* Disturbances of the speech function—understanding, expression, recall of the names of objects, etc.—commonly occur with lesions of the dominant (usually the left) temporal lobe. Frazier and Rowe found aphasic disturbances in 36 per cent of such cases, Kolodny reported 57 per cent. The occurrence of aphasic difficulties will depend upon the location of the lesion. They are unlikely with lesions in the anterior or ventral part of the left temporal lobe and likely with lesions in the postero-superior part near the posterior part of the Sylvian fissure.

2 *Auditory disorders* may occur with lesions of the temporal lobes. Paroxysmal attacks of *tinnitus* (buzzing, ringing, etc.) or even of auditory hallucinations may occur. These are often associated with other manifestations of "temporal lobe seizures" or of uncinate attacks or dreamy states. Epileptic attacks induced by various auditory stimuli have also been described. Because of the extensive bilateral representation of both

cochleae in both auditory cortices deafness never occurs as the result of a unilateral cortical lesion and is very rare with bilateral ones because involvement of the auditory cortices in both cerebral hemispheres is most uncommon.

3 *Disturbances of smell and taste* in the form of paroxysmal hallucinations in these sensory fields occur commonly with lesions, especially tumors in the anterior temporal region. These smells and tastes are more often unpleasant. Such attacks are commonly called *uncinate seizures*. Impairment of the sense of smell occurs most often as the result of lesions of the olfactory bulb and tract, rather than from involvement of the so-called rhinencephalon. In fact, the rhinencephalon is much more concerned with the control of emotions and emotional expression and of vegetative functions than it is with the elementary sensations of smell and taste.

4 *Dreamy states* Lesions of the anterior part of the temporal lobe are not infrequently associated with peculiar attacks known as *dramy states*. In these attacks the patient has a feeling of unreality, a sense of familiarity of his surroundings (*dejà vu*). He may describe these attacks as being similar to a dream. They may be associated with certain activities on the part of the patient over which he appears to have no control and of which he subsequently has no memory. In these attacks he may remove his own clothing, or tear off the clothing of others. He may be destructive or he may merely wander about aimlessly as though looking for something. Because of this combination of psychological disturbance with certain motor activities these have been referred to as *psychomotor seizures*. These seizures may be associated with auditory, olfactory or visual hallucinations. Individuals with temporal lobe seizures not infrequently suffer from generalized convulsions as well.

5 *Visual symptoms* Lesions of the temporal lobes, particularly tumors may be associated with visual hallucinations. Although these hallucinations may take almost any form they commonly are of formed objects,—people, animals, etc. On occasion these may be smaller than normal or the figures may be incomplete. In some cases the hallucinations may be unformed, that is flashes of light. Lesions in the posterior part of the temporal lobe commonly involve the visual radiations which run from the lateral geniculate body to the calcarine cortex, and thus give rise to a defect in the contralateral halves of the visual fields—a homonymous hemianopia. If the

hemianopia is incomplete, it is usually the upper contralateral quadrants of the visual fields which are involved

6 *Extensive lesions* of the temporal lobes may be associated with defects in memory, but it would not be correct to conclude that memory is "localized" in the temporal lobes

In monkeys bilateral extirpation of the temporal lobes including both the neocortex and the rhinencephalon on the medial surface of the temporal lobes gives rise to a most interesting group of symptoms (Klüver and Bucy, 1939) (1) *Visual agnosia* These animals seem to have lost the ability to recognize and to detect the meaning of objects on the basis of visual criteria alone There also seems to be a similar agnosia in the auditory and tactile fields (2) *Oral tendencies* There is a very strong tendency to examine all objects with the mouth (3) *"Hypermelamorphosis"* There is a marked tendency to take notice of and to attend to every visual stimulus (4) *Tameness* These animals seem to have lost their sense of fear, and there is a marked diminution in their emotional responses (5) *Hypersexuality* There is a striking increase in various sexual activities and in their diversity This change does not occur until several weeks after the operation Females may show a complete lack of maternal behavior (6) *Changes in dietary habits* Monkeys do not ordinarily eat meat but after the removal of both temporal lobes they do so without hesitation There is also an increase in the amount of food consumed In some animals some "tameness" may be produced by a unilateral temporal lobectomy, but the other manifestations appear only following a bilateral removal In a few cases some of these symptoms have been observed in human beings following bilateral temporal lobectomy

THE OCCIPITAL LOBE

The gray matter forming the walls of, and surrounding the calcarine fissure (on the medial aspect of the occipital lobe) constitutes the primary cortical center for vision—the *visuosensory area* From the broad stripe of Gennari which can be seen with the naked eye this area is commonly known as the *area striata* or, following the numerical terminology as area 17 It will be considered in more detail in chapter 75 Its histological features have already been touched upon

It is commonly said that the *second visual area* wherein the visual sensations are interpreted and integrated into more complex perceptions is contiguous to the *area striata* and lies on the lateral

aspect of the occipital lobe (area 18) Definite confirmation of this hypothesis is lacking

Stimulation of the anterior part of the lateral surface of the occipital lobe causes conjugate deviation of the eyes to the opposite side (occipital motor eye field, area 19) In man, visual hallucinations, such as, flashes of light of different colors, or definite images have been evoked by the electrical stimulation of area 18 or 19

The Physiology of Speech and Some of Its Disorders

The first stage in the development of speech is the association of certain sounds—(words)—with visual tactile and other sensations aroused by objects in the external world These associations are "stored" as memories After definite meanings have been attached to certain words, pathways between the auditory area of the cortex and the motor area for the muscles of articulation become established, and the child attempts to formulate and pronounce the words which he has heard Thus act of verbal expression involves the coordinated movements of a large group of respiratory, laryngeal, lingual, pharyngeal and labial muscles Later, as the child is taught to read, auditory speech is associated with the visual symbols of speech, and finally, through an association between these and the motor area for the hand, the child learns to express his auditory and visual impressions by the written word

APHASIA

This term is applied to those disorders of speech resulting from defects in the nervous mechanisms underlying the comprehension and use of symbols (words, numerals) for the formulation transmission and reception of ideas General intelligence may be little impaired Yet aphasia is not a defect in the pronunciation of words as a result of the paralysis of the muscles of articulation The innervation of the latter—motor area, corticobulbar fibers, cranial nuclei or peripheral nerves—is not necessarily affected The defects in aphasia involve higher neural levels, they lie in the psychological sphere

The faculty of speech is based upon a highly complex neural mechanism and being one possessed by the human brain alone cannot, of course, be investigated in animals In conscious patients electrical stimulation of the cortex of either hemisphere within the lower part of the precentral gyrus (lips, jaw and tongue areas), or

FIG 678 Showing speech areas in the left (dominant) cerebral cortex (From Penfield and Jasper, *Epilepsy and the Functional Anatomy of the Human Brain* courtesy of Dr Penfield)

in the upper part of the supplementary motor area on the mesial aspect of the hemisphere, causes the emission of a crude vocal sound like the cry of an infant or of an epileptic at the beginning of an attack. The vocal response elicited from the lip, jaw and tongue region never even remotely resembles a spoken word, but that evoked from the supplementary motor area is more complicated. Ablation of one or other of these areas causes only temporary speech defects. If the cortex in the lower part of the precentral gyrus of the dominant hemisphere (left in the great majority of persons) is excised a temporary aphasia results which is probably due to some interference with the blood supply to area 44 (Broca's area). If while the patient is speaking, certain cortical areas are stimulated electrically, speech is arrested, he cannot think of a word or words which he wished to use. There are four such areas situated in the dominant hemisphere: (5) *lower frontal*, area 44, (2) *upper frontal*, motor cortex anterior to the foot area on the mesial aspect of the hemisphere, (3) *parietal*, posterior to the lower part of the postcentral gyrus, (4) *temporal*, posterior part of temporal lobe. Injury to one or other of these areas with the possible exception of (2), causes persistent aphasia (see fig 678).

Before giving Head's views on aphasia, a short account of previous ideas on the subject may be helpful to the reader.

The views of the neurologists of the 19th century had the merit of simplicity. These observers, to whom Head refers as the "diagram makers," conceived of the language faculty as built up of four separate components. Each of these, sup-

posedly, was represented by a definite anatomically circumscribed area of the cortex, and could be affected independently of the others.

Two of these centers were *sensory* and two *motor*. All four were linked together by association tracts. In such a scheme, memories of spoken words were stored in the superior temporal convolution—the audiotypic center, the cortex in the region of the angular gyrus was the repository of visual word memories. These two receptive areas comprised what was referred to as Wernicke's zone. The pair of motor centers, i.e., those presiding over the coördinated movements concerned in vocalization and writing were called respectively the glossokinesthetic and chirokinesthetic centers. The former was located in the posterior part of the left 3rd frontal convolution (area 44), the latter in the hind part of the left 2nd frontal convolution, in most instances on the left side. Diagrams were drawn confidently to show these four centers with their interconnections, and the type of aphasia which would result from the destruction of one or other component part of the neural mechanism. Broca (1861) believed that *motor aphasia* (see below) was the result of a lesion of the glossokinesthetic area (Broca's area), especially of the left side. Defects in the ability to write—*agraphia*—were held to be the result of the involvement of the chirokinesthetic center. *Sensory* aphasias were classed as *auditory*—loss of the comprehension of audible speech—and *visual*—the inability to understand written or printed words. The former was held to be due to injury of the second temporal gyrus, the latter to injury of the angular gyrus. The most extreme proponents of this view even considered that every memory, auditory or visual, had its anatomical representation, so that a lesion limited to a small group of nerve cells would cause the loss of only those word memories for which they served as centers.

The different types of aphasia which were recognized may be briefly described.

1. **MOTOR APHASIA (Broca's)** This term was applied to the type of speech defect in which the patient is almost speechless, but there is no paralysis of the muscles of articulation. Though unable to express his thoughts in words, he can understand what is said to him and can read. He is usually able to utter a few words of an ejaculatory nature, e.g., "oh my," "dear me," "damn" etc. Sometimes he is able to say the last words which he had spoken just before the onset of his

ness, as in the oft cited case of the librarian whose only words were, "lists complete"

2 **AGRAPHIA** This term indicated that the patient was unable to write though motor speech and the comprehension of written or spoken words were possible. The movements of the hand and arm for other acts were not impaired.

3 **AUDITORY APHASIA OR "WORD DEAFNESS"** were the names given to those defects of the language faculty in which the subject, though able to hear, does not understand spoken words. He is as a person listening to a strange language. The power of speech, writing and the comprehension of written or printed words are retained. He may be able to repeat words spoken to him, and instead of answering a question may simply repeat the questioner's words, this phenomenon is called *echolalia*.

4 **VISUAL APHASIA OR "WORD BLINDNESS" (ALEXIA)** Vision is unaffected yet the recognition of written words or numerals and the appreciation of their meanings are defective or lost.

In 1906 these mechanical conceptions of the speech faculty and the production of aphasia were challenged by Pierre Marie. He claimed that there was only one true type of aphasia—sensory aphasia—due to a lesion in Wernicke's zone, and associated with a lowering of those intellectual capacities upon which were based the use of symbols in the expression of ideas. Thus, not only was the comprehension of written or spoken words defective but the ability to solve problems in arithmetic, and to perform certain other mental tasks were impaired. He maintained that the classical motor aphasia of Broca was simply *anarthria* (see below) due to involvement of the motor cortex governing the muscles of articulation plus sensory aphasia, and that a pure motor aphasia, i.e., a defect of speech due to the loss of "motor images" did not exist. Marie denied the existence of isolated cortical centers governing the different aspects of the speech faculty, and attacked the belief that aphasia was the result of the destruction of images—motor, auditory or visual—in such specific areas. He re-examined the brains of Broca's first two patients, which had been preserved in the Musée Dupuytren in Paris, and found no confirmation of the view of Broca that the posterior part of the third frontal convolution was necessarily involved in aphasia. In the first brain, the lesion was not confined to Broca's area but involved Wernicke's zone. The second specimen did not show a circumscribed lesion but, on the contrary, a generalized wasting,

the posterior part of the third frontal convolution was not especially implicated.

The terms in the classification given above, e.g., motor aphasia, agraphia, "word deafness," etc., are still sometimes employed, but it is understood they refer to the outstanding features of a given case rather than that they denote clear-cut types.

Head's Classification of the Aphasias

Head's views, based upon an exhaustive study of patients suffering from gunshot wounds of the cortex, are also strongly opposed to the conception of the speech faculty being dependent upon circumscribed anatomical centers. He considers speech to be a highly integrated cortical process—a special aspect of intelligence—yet one which can suffer with little lowering of the general intellectual level. The different components of the speech faculty, he decides, cannot be separated from one another by disease. Nor, consequently, can the types of aphasia be classed as "motor" or "sensory," but in any type, deficiencies on both the receptive and the executive side can be demonstrated. Head concluded that cortical representation of speech mechanisms was more diffuse than had been supposed and that strict localization was impossible. Aphasia is a state in which the power to use words and other symbols as instruments of thought and expression is affected or, as he expresses it, "aphasia is a defect in symbolic formation and expression." The more complicated or abstract the idea which must be understood or expressed, the greater is the difficulty. Thus an aphasic may be able to name objects correctly but fails to find the word for a more *abstract idea*, e.g., color. Shown a black object, for instance, and asked to name its color he fails to do so, yet indicates that he recognizes that it is black by saying "what you do for the dead." An aphasic soldier when shown a red object said, "what the staff wear."

Head, as a result of his investigation of aphasic patients, devised a series of six tests of graded severity. These tests are briefly as follows:

1 **Naming and recognition of common objects** Six objects, e.g., a pencil, key, knife, etc. The patient is asked to name each object as it is pointed out to him. Next he is asked to point to each object as its name is called out. He is then given cards upon each of which the name of one of the objects is written. He is asked to indicate the object named.

2 **Naming and recognition of colors** This test is

carried out in a manner similar to that described for test (1) except that eight strips of differently colored silk are substituted for the six objects

3 *Man, cat and dog test* is designed to investigate the powers of reading and writing in their most elementary forms. The printed words "man," "cat" and "dog" are employed. The subject is asked to read these words, to write them from dictation, to copy them or to repeat them after hearing them spoken. Pictures of a man, a cat and a dog are also shown and the patient asked to write or to speak their names

4 *The clock tests* The patient is requested to set the hands of a clock in the same positions as those of a similar one set by the observer. He is then told to set the clock from verbal or printed commands. Again, he is asked to state the time aloud or by writing, of a clock set by the observer

5 *Coin bowl tests* Pennies are placed one in front of each of four bowls. The patient is asked verbally and in writing to place a coin in one or other of the bowls according to their number in the row. He is then asked to give an order himself and to carry it out according to his own words

6 *The hand, eye and ear tests* The patient is requested to repeat the movements of the observer which consist in touching an eye or an ear with one or other hand. When this is done correctly the patient's hand which moves is of course diagonally opposite to the hand of the observer. A much easier form of this test is the imitation of the observer's movement as reflected in a mirror. This simply requires matching without calculation

The aphasic frequently fails to recognize that when the one hand is brought to his contralateral eye or ear the hand crosses the face. A further part of the test is to ask him to imitate the positions shown in pictorial form upon cards or to carry out the movements from printed and verbal instructions. Finally, he is asked to write down movements made by the observer

Employing these tests Head divided aphasia into four types, as follows

1 **VERBAL DEFECTS** The outstanding feature is a defect in the utterance of individual words of all kinds. The power to express an idea in words is practically lost. The patient, however, is not entirely speechless but can usually utter a few monosyllables, "yes" or "no", etc., or ejaculations and emotional expressions, such as, "damn", "oh dear me". When the disorder is less severe, the words are mispronounced but sentences are correctly constructed. For example, one patient said that he had trouble with "technical terms" (technical terms) and that he "had difficulty in remembering what you do with a skull, *tri-tre-tripine*"

(trepan). Another spoke of "claration of war by the *Ollies*" (declaration. Allies). Another would say "pyramerad" (pyramid), "sissors" (scissors) and "oboid" (ovoid). Such patients read with difficulty and writing is very defective or impossible. They usually understand printed or oral commands. This form of aphasia resembles the classical motor aphasia described on page 1250

2 **SYNTACTICAL DEFECTS** (agrammatism, jargon dysphasia). The patient is voluble but speaks a jargon in which, though the individual words may be fairly accurately pronounced, they are strung into short phrases or badly constructed sentences without articles, prepositions or conjunctions. The ability to read aloud is impaired, and curiously enough such a patient, though he can write a well constructed letter, may be quite unable to read it coherently. Such a one when asked the contents of a letter which he had just written replied, "I can't, I know, I suppose in time, not now, funny thing, why." In other instances the words themselves are often slurred over, mutilated and may be unrecognizable. Speech sometimes resembles "baby talk". Thus one patient when asked what his right arm felt like replied "Tiffrent from uffer um" (different from other arm). The understanding of ordinary conversation is defective

3 **NOMINAL (NAMING) DEFECTS** In this form of speech disorder the patient has difficulty in finding the right word to express his meaning or in naming a well known object. He will often employ a descriptive phrase in substitution for the word which he cannot recall. For example, a painter when asked to name a series of colors could not say "violet" but instead explained that "it was made with black, red and a bit of blue." Another when asked to tell the time from a clock which had both hands at 12 replied "That is when you eat." These patients can draw from a model either directly or from memory, after it has been shown and then removed, but are usually unable to draw from imagination. They write a coherent letter with difficulty, usually fail to carry out simple arithmetical exercises and confuse the values of coins

4 **SEMANTIC* DEFECTS** A patient suffering from this type experiences little difficulty in articulate speech, can name objects, understands individual words and some sentences, but the general meaning of what he hears escapes him

* Semainein = to signify

He often fails to follow his own utterances to an intelligent conclusion, his sentences trailing off as though he had forgotten what he had started out to say. When shown a picture he picks out the details but fails to grasp the meaning which it conveys to others. Such a patient therefore misses the point of a joke whether this is printed, told to him, or is in pictorial form. He fails to comprehend the significance of much that he sees and hears. There is no impairment in the pronunciation of words and, though speech tends to be in short jerky sentences, syntax and intonation are not disturbed.

Head, though he discards the conception that the neural basis of speech consists of strictly localized anatomical 'centers' wherein resides exclusively one or other of the speech functions—auditory, visual or motor—believes that regions exist in the cortex "where the progress of some mode of action can be reinforced, deviated or inhibited." These regions constitute foci of integration—convergence points for association paths. Destruction of one or other of such foci or 'knots' of association paths will depress as a whole the psychological processes underlying speech. The speech faculty is disabled, certain faculties are lost, while others are retained. Yet he points out that it is not logical to conclude that the abilities which remain and those which have been abolished constitute essentially separate and distinct functions from which the normal processes of speech have been synthesized, or that they are represented in specific circumscribed areas. To make a rather crude comparison—a person who has injured his foot, knee or hip, adjusts his locomotor apparatus as best he can. He hops or limps, yet it cannot be argued that the hopping or the limping motion which he employs is simply one of the component movements employed in the normal act of walking and which the injury has left intact. Nevertheless, the form which the disability assumes is undoubtedly influenced by the site of the injury. The ambulatory abnormality, for example, which results from an injury to the foot is different from that resulting from injury to the knee or hip. So too the nature of the speech disability is influenced by the particular region of the cortex involved. Thus if the lesion is in the neighborhood of the lower part of the precentral and postcentral convolutions of the dominant hemisphere the speech defect tends to be of the verbal type. In injury to the temporal lobe the speech defect tends to be of the syntactical type.

In a lesion in the region of the angular gyrus of the dominant hemisphere the patient has difficulty, particularly, in finding names for things (*nominal defect*), damage to the cortex in the region of the supramarginal gyrus results in a *semantic defect*.

Anarthria or dysarthria is loss or difficulty of speech due to paresis, paralysis or ataxia of the muscles concerned in articulation. There is no impairment of the psychical aspects of speech, i.e., 'internal speech' is unaffected, there is no difficulty in the comprehension of spoken or written speech. Other functions, e.g., swallowing which are dependent upon the same groups of muscles as those used in speech are also frequently affected. The condition may result from a lesion in the internal capsule or corpus striatum, bulbar nuclei or peripheral fibers or from disease of the muscles themselves. Since the muscular mechanism of speech is innervated from both sides of the brain unilateral central lesions are not followed by permanent anarthria. A lesion of the cerebellum or of its connections may also cause disordered control of the muscles of articulation (p. 1258).

Apraxia and Agnosia

Apraxia (unable to act) is the inability to perform purposeful movements at will either at command or in imitation though the muscles normally engaged in the act are not paralysed. It is allied to aphasia which might be called *apraxia of the speech faculty*. *Apraxia* may be *sensory* or *motor*. In the former, the patient does not recognize the significance of an object (*visual agnosia*) and therefore cannot put it to its proper use: this is simply *visual agnosia*. When, for example, he is given a pencil he may, upon a request to use it, attempt to clean his teeth with it or smoke it like a pipe. In *motor apraxia* the patient has no conception or a very defective one of the pattern of muscular movement required to perform a purposeful act. For example, *apraxia of the tongue* is frequently seen in hemiplegic patients. The tongue cannot be protruded upon request but a moment later the patient may without thought lick his lips. When given an object and asked to use it, though he recognizes it and knows its use, he cannot form the 'motor picture' required to execute the act but manipulates the object in an awkward aimless manner. The defect is evidently in the physical sphere and not due to disease of the cells of the motor area or of the corticospinal fibers. It is thought to be due to the interruption of association tracts connecting the precentral gyrus with higher psychical regions of the cortex where impressions of the movements of muscles are received, synthesized and stored as kinesthetic

memories. This higher ideational area probably lies in the region of the left supramarginal gyrus in right handed persons. A lesion of this region may cause bilateral apraxia, one confined to the anterior part of the corpus callosum is likely to interrupt fibers passing from the left hemisphere to the right precentral convolution and may cause apraxia of the left side.

Agnosia (not knowing) is a defect of a higher level of consciousness than the mere inability to perceive tactile, visual, auditory or other forms of sensation, it results rather from the failure to interpret sensory impressions which enable an object, sound, symbol, etc., to be recognized and have meaning. A patient suffering from auditory agnosia, for example, cannot appreciate music or the meaning of other sounds. "Word blindness" and "word deafness" are forms of auditory and visual agnosia, respectively. The subject of visual agnosia is unable to name an object, not that he is aphasic in the true sense, but simply because the object is quite strange to him. When shown an object and asked to use it he behaves quite differently from the patient with motor apraxia who recognizes it but is unable to perform the necessary movement.

Astereognosis is a disorder in which though sensations of touch and muscle sense are retained the patient cannot recognize an object placed in his hand if his eyes are closed. Visual agnosia is seen in lesions of the occipital lobe of the dominant hemisphere, auditory agnosia in injury to the temporal cortex, and astereognosis in lesions of the parietal lobe posterior to the postcentral gyrus.

Agraphia or *dysgraphia*, the inability to write or difficulty in writing is usually associated with visual agnosia in so far as the recognition of written words is concerned, i.e., word blindness.

Epilepsy

Epilepsy is a disorder arising as the result of an abnormal and severe discharge of nervous energy from some part of the central nervous system, usually the cerebral cortex. Epilepsy may be generalized, involving the entire organism or localized. Generalized seizures are of three types, grand mal, petit mal and psychomotor. In *grand mal* there is an abrupt loss of consciousness and a generalized convulsion. Two stages of the attack or seizure are recognized. In the first or *tonic stage* the muscles contract tonically, the spasms often twisting the facial features and holding the head and limbs in distorted positions. The arms are most commonly flexed and the lower limbs rigidly extended. After a few seconds the tonic spasm gives place to jerking movements, often violent,

of the limbs, face and muscles of mastication. This is spoken of as the *clonic stage*. Either during this stage or in the tonic stage the tongue may be bitten. Before the onset of the convulsion a large proportion of epileptics receive a warning in the form of a sensation or hallucination, the character of which varies in individual cases. The warning sensation or *aura*, as it is called, may be auditory, e.g., voices, music, etc., visual, e.g., flashes of light, sparks, etc., olfactory, gustatory, cutaneous, visceral or vasomotor, equilibratory, or anesthetic, i.e., a numbness in some part of the body. Turning of the head and trunk to one side and deviation of the eyes are commonly observed. The patient sometimes utters a cry or scream—the epileptic cry—just before consciousness is lost. After the convulsion the subject remains for a time in a stupor. Sometimes a number of convulsive seizures occur in rapid succession, the patient failing to regain consciousness in the intervals between them. This very serious condition is called *status epilepticus*. Minor seizures known as *petit mal* are characterized by brief periods during which the patient loses contact with his environment. He stares into space. There are no convulsive movements. A third form known as *psychomotor epilepsy* is marked by automatic movements, such as smacking of the lips, chewing, together with a clouded, "dreamy" feeling of unreality, or of having seen or heard before some eight or auditory impression which is actually happening at the moment ("déjà vu" or "déjà entendu" phenomenon, respectively). Or there may be a confused mental state persisting for a minute or two, or for a longer period. During this time the patient may perform automatic acts of which he is quite unaware and does not remember. Generalized convulsions do not occur nor does the subject fall to the ground during the psychomotor seizure, but patients who have such seizures may also suffer from generalized convulsions. Psychomotor seizures are most commonly due to disturbances in the temporal lobe.

A tumor in the hypothalamic region may cause an outburst of autonomic phenomena.

Localized epilepsy may occur in several different forms. These are often referred to as *Jacksonian epilepsy* because they are indicative of an abnormality in a particular part of the brain. Thus motor Jacksonian seizures are indicative of a disturbance in the precentral motor cortex, hallucinations of taste and smell are indicative of

an abnormal nervous discharge from the uncus on the medial surface of the temporal lobe, sensory Jacksonian seizures indicate disease in the parietal region, etc

Motor Jacksonian seizures commonly begin by a turning of the head and eyes toward the side opposite the lesion in the brain if it is located in the anterior part of the precentral motor cortex, or by a twitching of the foot or leg if it is in the upper part of the precentral region. Such attacks may also begin with a twitching of a finger, or of the hand or the face depending upon the seat of the irritation in the cortex which initiates the attack. These convulsions may remain localized to the part of the body in which they start or they may spread by a steady march to neighboring parts as portions of the cortex lying near to the original focus become involved in the irritative process. The spreading convulsion may cease after extending to all of one extremity or to one side of the body or it may continue until a generalized convulsion has occurred.

Such focal or localized convulsive seizures or seizures with localized onsets may develop as the result of many different kinds of disease processes in the brain. Tumors, abscesses, traumatic scars, vascular abnormalities are among the more common processes found to be responsible for such attacks. It must be noted that not all patients who have such disease processes suffer from epileptic attacks and that even in those patients who do have them the attacks occur at relatively infrequent intervals although the disease process is constantly present. It is thus obvious that some other process, neurological or metabolic, is essential to the development of such seizures. The tumor or scar alone is not enough.

Idiopathic or cryptogenic epilepsy. Epilepsy which cannot be explained by the presence of a demonstrable lesion of the brain is called idiopathic or cryptogenic. Though many theories have been advanced, the cause of this type of the disease remains obscure. There is a tendency today to look upon epilepsy as a symptom, or rather a group of symptoms common to several rather than to a single primary pathological state. Convulsions, whose features are undistinguishable from those of the epileptic seizure, occur in a number of conditions. In animals convulsions may be produced by injections of absinth or caffeine. Hypocalcemia (ch 59), hypoglycemia (ch 48), cerebral edema or anemia and other states may be accompanied by generalized convulsions of an epileptiform character.

With regard to the neural mechanism through which the fits are produced, some authorities have thought that the convulsions are the result of *increased excitability of the cortex* and therefore, comparable in their mode of production to those of the Jacksonian type, or to those produced by experimental stimulation of the cortex. Others view the convulsions as a *release phenomenon* due to the inhibition of cortical areas which normally exert a controlling influence upon lower motor centers, e.g., weakening of suppressor action. Finally, there is the view of Penfield and his colleagues that the *primary disturbance in idiopathic epilepsy* has its origin in a subcortical mechanism.

The close correspondence between the convulsive seizure as seen in focal epilepsy or to artificial stimulation of the cortex, and the fits of idiopathic epilepsy appears to support the first alternative as a cause of the generalized seizure known as grand mal. However, the *primary disturbance* responsible for the cortical discharge in idiopathic epilepsy probably lies outside the cortex. Evidence for a subcortical origin of petit mal attacks is provided by electroencephalographic studies. During such an attack, electrical potentials of the wave-spike type (fig 67 10)—appear synchronously over prefrontal areas as well as from other widely separated cortical areas. This suggests that the cortical discharges are initiated in a common subcortical region (centrencephalic system) connected with extensive areas of the cortex. Jasper and Drooglever Fortuyn experimenting with cats produced electrical potentials from wide spread areas of the cortex synchronously in both hemispheres by rhythmical stimulation of a small area (2 mm in diameter) in the anterior part of the massa intermedia of the thalamus. The cortical potentials were of the wave-spike form characteristic of petit mal.

Moreover the general convulsions which occur with focal epilepsy are thought to be due to the discharge of impulses from the cortical focus into the subcortical mechanism and causes unconsciousness. The subcortical structures then fire back and cause widespread excitation of the cortex of both hemispheres.

The nature of the underlying bodily state responsible for the convulsive seizures of idiopathic epilepsy are unknown. There are a number of drugs e.g., metrazol which are capable of inducing convulsions, and several others, e.g., phenobarbital and tridione, which are anticonvulsive, but they have not led to an understanding of the

TABLE 67 1

	Conditions Which May Tend To	
	Prevent seizures	Precipitate seizures
Oxygen	Rich supply	Poor supply
Acid base equilibrium	Acidosis Ingestion of acids or acid forming salts Breathing CO ₂	Alkalosis Hyperpnea—"blowing off" CO ₂
Water balance	Dehydration	Edema
Serum calcium	Increase	Decrease (hypocalcemia)
Blood glucose	Normal level	Decrease (hypoglycemia)
Acetylcholine	—	Increase
Cholinesterase	—	Decrease
Body temperature	—	Increase

pathogenesis of the convulsive seizures of epilepsy. Susceptibility to an epileptic seizure is influenced by several physiological and biochemical factors which are given in table 67 1, but they do not bear a specific relationship to the cause of idiopathic epilepsy, but merely affect the tendency to convulsive seizures of any kind.

The view that the actual seizure was initiated by cerebral ischemia resulting from a spasm of the cortical vessels has not been sustained. The blood flow through the brain of epileptics and the oxygen consumption have been found to be no different from that of nonepileptics. In focal epilepsy, however, local ischemia may play a part. Biochemical studies of such epileptogenic areas have not however revealed any important abnormality. The pH of the extracellular fluid shows no change from the normal, or a slight rise.

The induction of a dehydrated state of acidosis (by means of a ketogenic diet) has been employed to reduce the susceptibility of epileptics to seizures but not very effectively, and pitressin combined with an increase in the water intake is used as a test (*water-pitressin test*) in diagnosis. But in only about 30 per cent of epileptics is a seizure

FIG 679 Normal electroencephalogram taken from the occipital region O and C refer, respectively, to open and closed eyes (After Adrian and Matthews)

precipitated, so a negative result does not exclude epilepsy.

The Electroencephalogram (EEG)

In 1929 Berger reported his discovery that changes in electrical potential could be recorded from the head of the human subject by means of electrodes applied to the scalp or needle electrodes placed in contact with the periosteum of the skull. These brain potentials were later studied by Adrian and Matthews. In normal subjects three wave frequencies may be recorded, the *alpha*, *beta* and *delta* rhythms.* The *alpha* rhythm consists of rhythmical oscillations in electrical potential occurring at the rate of 8 to 10 per second (fig 67 9). The waves have a voltage of about 50 microvolts on the average. The *beta* rhythm has a frequency of 15 to 60 per second, and the waves are of lower voltage (5 to 10 microvolts), the frequency of the *delta* waves is from 1 to 5 per second and the voltage is relatively high (20 to 200 microvolts). No precise cytoarchitectural area can be said to have a characteristic rhythm as was once supposed, but differences are found between rather large areas of the cortex. Thus the *alpha* rhythm dominates records from the occipital region or from the posterior parts of the parietal and temporal lobes. The sensorimotor region emits waves with a frequency of from 20 to 25 per second, the anterior frontal areas give out waves at the rate of from 8 to 5 per second.

The *alpha* rhythm occurs in the *inattentive* brain, as in drowsiness or light sleep, narcosis or when the eyes are closed, it is abolished by visual and other types of stimulus or by mental effort (e.g., mathematical calculation). It, therefore diminishes when the eyes are open. This is true even if the subject opens his eyes in the dark and tries to see. It is apparent, therefore, that it is the attention rather than the visual stimulus itself that abolishes the *alpha* rhythm when the eyes are opened. On the other hand if

* A faster rhythm (*gamma*) appears in rare instances.

FIG 67-10 Showing electroencephalograms in epilepsy (Modified after Gibbs and associates)

the visual field is uniform, that is without pattern, or glasses are worn which blur the visual image so that it has no meaning, the rhythm is not abolished. An attempt to discern any detail causes the alpha wave to disappear immediately. A visual field that flickers causes the waves to assume the same rate as that of the flicker within certain definite limits. The delta waves can be recorded very rarely from a normal adult while awake, but appear normally during deep sleep or during the waking hours in early childhood. Generally speaking, their presence in an adult, except during sleep, indicates some pathological process in the brain—tumor, epilepsy, raised intracranial pressure, mental deficiency or depression of consciousness by toxic or other factors. When present they tend to displace the alpha rhythm. Neither the beta nor the delta waves are affected by opening or closing the eyes.

There has been a difference of opinion as to the origin of the potential changes as recorded in the EEG. Whether they are inherent in the cortex, or are dependent upon subcortical structures has been argued. Definite conclusions as to the source and significance of the alterations in electrical potential recorded in the electroencephalogram can not yet be drawn. Certainly the electroencephalogram is to a considerable degree dependent upon the activity of neurons in subcortical centers, notably the reticular formation.

The EEG is affected profoundly by certain general states. Hypoxia causes at first a moderate slowing of the rhythm, but as the oxygen lack becomes more severe large delta waves appear, with persistent and severe hypoxia the amplitude

of the waves declines and may reach almost the vanishing point. Hypoglycemia causes an effect somewhat similar to that of hypoxia, when the blood sugar falls below about 60 mg per cent, delta waves (1 to 3 per second) are seen though the alpha rhythm is not abolished entirely. The effects of hypoxia and hypoglycemia enhance one another, their summed effects being much greater than the effect of each alone. Hyperglycemia has little effect upon the cortical potentials. Increase in carbon dioxide tension increases the rate, but reduces the amplitude of the waves. Blowing off of CO_2 , as by overbreathing, has the opposite effect.

Abnormalities of the electroencephalogram in brain tumor, especially of so-called "silent areas of the brain, and in epilepsy, may be of diagnostic value. In cerebral tumor or brain abscess, as shown by Walter and by Case, the functionally depressed brain tissue surrounding the lesion gives out waves of slow rhythm (delta waves) which, combined with a loss or diminution in the alpha rhythm over the occipital region may be of considerable aid in localization. However, the electroencephalogram may give misleading information as to the location of a brain tumor and a "normal" electroencephalogram in the presence of a brain tumor is not rare.

Epileptic seizures are characterized by pronounced departures from the normal rhythm. In *petit mal* attacks, large slow waves appear about a second before the attack is clinically manifest, and displace the previous rhythm. Each large wave is followed by a sharp spike deflection (fig 67-10). In the tonic stage of a *grand mal* seizure, waves of relatively high frequency (10 to 30 per second) and of low voltage appear, but as the

attack progresses into the clonic phase these fast waves give place to slower and large waves which continue into the stage of stupor following the seizure. Delta waves may be a prominent feature of the electroencephalogram of epileptics between seizures (fig. 67-10). Approximately one third of epileptic adults have 'normal' electroencephalograms.

In normal sleep the pattern of the electrical potentials recorded from the brain varies with the depth of unconsciousness. During light sleep delta waves make their appearance while the alpha waves superimposed upon the slower rhythm of the latter persist. In deep sleep the alpha rhythm disappears being replaced by delta waves, or in some instances by a faster rhythm with a frequency of about 14 per second. During the light sleep before awakening the record shows only an odd slow wave. As consciousness returns the tracing consists of an intermittent alpha rhythm which becomes continuous upon waking.

Headache

Headache is one of the commonest of symptoms and occurs in a great variety of diseased states, e.g., arterial hypertension, chronic nephritis, eye strain, chronic disease of the paranasal sinuses, brain tumor, etc.

Headache may also be due to disturbances in the scalp or in the skull, such as osteitis, periostitis, osteomyelitis, tumor of the bone, etc. The temporary but severe pain felt in the frontal region by a normal person after eating ice cream is an example of a referred pain. The pain is most probably due to a stimulation of sensory nerve endings in the roof of the mouth producing reflex vasomotor changes, or it may be referred to the forehead through central connections with the sensory nucleus of the trigeminal nerve.

The two principal causes of the more common types of headache are either vascular in nature (stimulation of sensory nerves which accompany the vessels in the scalp or in the meninges) or a sustained reflex contraction of the posterior muscles of the neck which insert into the scalp and the skull. This latter reflex mechanism is mainly responsible for the headache of eyestrain—refractive errors, or unbalanced action of the extraocular muscles, excessive and prolonged accommodation—increased intraocular pressure also may contribute to the pain. Disease of the cervical spine may also induce reflex protective spasm of the muscles of the posterior neck and produce headaches.

The headache associated with an intracranial tumor, and with hypertension, are of vascular origin. The arteries and smaller veins on the convexity of the human hemispheres have been shown by neurosurgeons to be insensitive, but the larger arteries in the Sylvian (lateral) fissure and at the base of the brain, e.g., circle of Willis, vertebral, basilar, the larger of cerebral vessels of the dura, the branches of the anterior and posterior meningeals, as well as the arteries of the scalp, are accompanied by pain fibers which are stimulated by any stretching force. The larger veins where they empty into the dural sinuses are also sensitive. The brain substance itself is painless. The headache of intracranial tumor or abscess is not due primarily to the high intracranial pressure itself, but is the result of the displacement of the brain, local mechanical effect of the tumor, or to blockage of some part of the ventricular system. In this way traction or distortion of the vessels with consequent stretching of the sensitive vascular nerve endings, and, in some cases, of cranial nerves results. In a large proportion of cases of headache due to brain tumor, the intracranial pressure is not elevated (Wolff and Wolff), and when headache exists, lowering the pressure within the skull does not always relieve it. Raising the intracranial pressure in a normal person or one with an intracranial growth does not necessarily cause headache. In fact intracranial tumors may be present with a considerable increase in intracranial pressure and still be unassociated with headache. On the other hand, lowering the intracranial pressure below the usual level as by drainage of cerebrospinal fluid causes severe headache. A normal subject experiences headache when about 20 cc. of fluid are withdrawn by lumbar puncture, and he is raised into the erect position. In the horizontal position, or if the fluid removed is replaced by an equal quantity of saline, the head pain is abolished or at least reduced.

Headache presumably of vascular origin, can be produced in any normal person, as was shown by Wolff and his associates, by a sudden sharp rotary movement of the head. When a subject with headache due, apparently, to overdistension of the cerebral vessels was centrifuged, so as to drive blood out of the vessels, the pain was relieved. The intense headache caused by an injection of *histamine* appears to be due to cerebral vasodilation and distension of the vessels, it is relieved by increasing the cerebrospinal fluid pressure, and thus providing a circumferential

support for the vessels, and protecting the pain endings from stretch. The headaches of fever and toxic states are similar in their origins to histamine headache, they, too, are ameliorated by raising the cerebrospinal fluid pressure.

Hypertensive headache is not due essentially to the high blood pressure (Wolff and Wolff), but rather to the amplitude of the movement of the arterial wall at each pulse beat which varies with the contractile state of the vascular wall itself. When the latter is relaxed and resilient a given distending force will exert a greater degree of stretch upon the pain endings than when the walls are firmer and do not so readily permit stretching of the nerve terminals. The headache of arterial hypertension therefore varies with the amplitude of the movement of the arterial wall and is relieved by pressure upon the common carotid which reduces the pulse amplitude. Though the headache is not directly related to the height of the blood pressure, (since it may occur with equal intensity when the pressure is high, moderate or relatively low), with any given degree of relaxation of the vascular wall the pain will of course be more intense when the pressure is high than when low, because a greater excursion of the vascular wall will occur in the former instance. Ergotamine, while it tends to increase the blood pressure rather than to reduce it, diminishes the amplitude of the arterial pulsations and, as a consequence, has a moderating effect upon the intensity of the headache.

The site of the headache in brain tumor may be of some value as a localizing symptom. The pain *overlies the tumor or is on the same side in about 60 per cent of cases*. In tumors of a cerebral hemisphere (supratentorial tumors) the pain is usually in the front of the head, the pain impulses being transmitted through branches of the 5th nerve, whereas in those of the posterior fossa the pain is felt in the occipital region, the impulses travelling by branches of the 9th and 10th cranial and upper cervical nerves.

MIGRAINE (Synonyms, *megrum*, *hemicrania*, *sick headache*) This is a type of headache whose special features entitle it to be placed in a class by itself. The headache is periodic, severe and often accompanied by nausea and vomiting. In many instances some type of sensory disturbance (*aura*) ushers in the attack. This frequently takes the form of scintillating colored lights or the so-called fortification figures that is, zig zag luminous bands which are suggestive of the walls of a turret. The visual hallucinations have a homonymous

distribution, that is, they occur in the right or the left halves of the visual fields (ch 75). Temporary hemianopia may follow or blindness of the central part of the retina may accompany the visual sensations. Cutaneous, auditory or gustatory auras occasionally occur. The headache is localized at first but soon spreads to involve the entire half of the head, the pain is then on the side opposite to that of the hallucinations. Not unusually, however, the headache is bilateral, or is unilateral to start with, and later spreads to involve the opposite side of the head. In most cases of migraine, the pain has its origin in extracranial vessels—the branches of the external carotid, such as the temporal or occipital artery being most commonly involved. When the pain originates intracranially the anterior and middle meningeal arteries are probably implicated.

The mechanism underlying the migrainous headache is not universally agreed upon. It is thought by some (Wolff and Wolff) to have a vascular origin, similar in nature to that causing hypertensive headache—namely a relaxed state of the vascular wall, and a resulting pulsatile movement of greater than usual amplitude. The pain varies in intensity with the amplitude of the arterial pulsations and is reduced in intensity by compression of the common carotid or by ergotamine which, as mentioned above, reduces the pulse amplitude. In other cases the headache of migraine appears to be due to cortical vasodilation (like the histamine headache) which follows upon a period of vasoconstriction. The ischemia of the cortex during the vasoconstrictor phase would explain the visual hallucinations mentioned above, which an increase in pulse amplitude is unable to do, though the phase of vasodilation might quite well be associated with a relaxed state of the larger cerebral vessels. It has been suggested that migraine may sometimes be of allergic origin, dilation of the cortical vessels being the result of the local liberation of histamine (H-substance). The relatively high incidence of eosinophilia in migraine lends support to the idea of an allergic reaction.

CONDITIONED REFLEXES. SLEEP

Definitions

The ordinary reflex with which we are all familiar is an inherited characteristic of the species and is not dependent upon previous experience. Its pathways are established at birth. This type Pavlov termed an *inborn or unconditioned reflex*. For example, food placed in the mouth of a new born puppy evokes a secretion of saliva. The reaction depends solely upon the stimulation of receptors (taste, touch, etc.) in the mouth, the afferent and efferent nerves and the salivary centers in the medulla oblongata. When, on the other hand, the young animal sees or smells a piece of meat for the first time no secretion of saliva results. Yet if an animal who has eaten meat on previous occasions sees a morsel, a profuse secretion of saliva occurs. This reaction, which depends upon previous experience, Pavlov has termed a *conditioned or acquired reflex*. Its pathways are not fully established at birth but are developed by training. Quite evidently the reaction of the older animal is the result of an association established in the past between the stimulus applied to the receptors of the mouth, and the appearance of the food, i.e., a visual stimulus. The former is called the *unconditioned*, the latter the *conditioned stimulus*. Not only the qualities of the food itself but changes in the environment extraneous to the food, if they occur in association with feeding, can serve as conditioned stimuli.

Conditioned reflexes may be either of an excitatory character, e.g., the secretion of saliva, or have an inhibitory action. The former are termed *positive or excitatory*, the latter *negative or inhibitory*.

Positive or Excitatory Conditioned Reflexes

In the great majority of the experiments performed by Pavlov and his school, the secretion of saliva was chosen as the indicator of the conditioned response. In order to follow the secretory reaction with precision the opening of the parotid or submaxillary duct was transplanted to the cheek or chin, respectively. The saliva is collected

by means of a special apparatus consisting of a funnel sealed over the duct opening and leading into a system of tubes. The secretion is measured in drops by means of an electrical recorder. The animal is held in a stand by means of straps and occupies a sound proof chamber separate from that of the experimenter (fig. 68 I).

The reflex is established in the following way. While the animal is being fed (unconditioned stimulus) a stimulus, e.g., a flash of light (conditioned stimulus) which is quite alien to the food itself is applied. After this association of the two stimuli has been repeated a number of times, the flash of light alone (i.e., food is withheld) evokes a secretion of saliva. This is called a *conditioned alimentary reflex*. Motor reactions, e.g., movements of the lips and jaws, snapping, whining or barking, and movements of the limbs, accompany the salivary secretion and constitute an integral part of the reflex. The number of repetitions of the experimental procedure, or "lessons," necessary to establish the reflex varies in different animals and in experiments of different types. Many types of conditioned stimulus (visual, auditory, olfactory and cutaneous) have been employed by Pavlov and his associates.¹ In establishing the reflex the conditioned stimulus must precede or accompany the unconditioned stimulus and, except in the case of secondary and trace reflexes, to be presently described, must overlap it for at least a brief period. If the conditioned stimulus follows the actual feeding it is quite ineffective, i.e., it will not evoke a reflex when subsequently applied alone. After the period of training, in order to demonstrate the conditioned response satisfactorily

¹ Among these are the following—the sound of a metronome, horn, bell, buzzer, tuning fork, organ pipe or of bubbling water, variously shaped objects, lights, figures or rotating disks, thermal, tactile and painful cutaneous stimuli, the odor of such chemicals as amyl acetate or vanilla. The cessation of a previously continuous stimulus, e.g., a buzzer, the rapid change in the intensity of a stimulus or even the change in the rate of a rhythmic sound, e.g., a beating metronome may serve as a conditioned stimulus (see also p. 594).

FIG 681 Illustrating arrangements for experiments upon conditioned reflexes (From Pavlov *Lectures on Conditioned Reflexes*, International Publishing Company New York)

rily, the animal should be alert, not drowsy, and preferably hungry, furthermore it should not be distracted by extraneous stimuli, e.g. a strange sound or light

OTHER TYPES OF POSITIVE CONDITIONED REFLEXES

CONDITIONED DEFENSE REFLEXES Acid injected into an animal's mouth (unconditioned stimulus) causes a profuse secretion of saliva which washes away the offending material. A conditioned reflex to acid is readily established by a series of trials in which a conditioned stimulus, e.g., a light and the unconditioned stimulus (acid) are applied in combination. Or if an animal has been given a colored acid it salivates when shown water of the same color. Also, if a painful stimulus is applied to the animal's paw (unconditioned stimulus) during some form of conditioned stimulation (e.g., sound of a buzzer) the motor reactions (e.g., drawing up the limb, turning the head towards the injured part, etc.) which follow the application of the combined stimuli occur, after a few trials when the conditioned stimulus is employed alone. The painful stimulus may serve also as a conditioned stimulus for a salivary reflex, then unless the painful stimulus is intense the usual defense reactions are suppressed, salivation alone resulting when the stimulus is applied. The alimentary reflex is in this case stronger than the defense reflex. Pavlov points out that the subordination of the defense reaction by the alimentary reflex is seen when dogs are struggling among themselves for food. Minor injuries (e.g., of the skin) may then be sustained, but they do not evoke a reaction of defense, this is suppressed by the domi-

nant food reflex. On the other hand, if the stimulus (such as one applied to bone) signals a more severe type of injury, or threatens the life of the animal, the defense reaction becomes prepotent.

Of great practical interest is the reflex which becomes established to the repeated injection of morphine. In the dog morphine administration causes vomiting and salivation, followed by sleep. After a series of injections, these effects result from the mere sight of the syringe, or the approach of the attendant who had previously administered the drug.

SECONDARY AND TERTIARY CONDITIONED REFLEXES A second stimulus may be conditioned by linking it up with a conditioned stimulus already firmly established. A defense conditioned reflex, let it be supposed, has been established with an electric shock to the front paw as the unconditioned and a touch upon the hind paw as the conditioned stimulus. A second neutral stimulus (e.g., the sound of bubbling water) is now applied and withdrawn a few seconds before the application of the primary conditioned stimulus (touching the hind paw) but the unconditioned stimulus (electric shock) is omitted. If the two stimuli are associated in this way a number of times it is found that the second stimulus (sound of bubbling water) has itself acquired conditioned properties, when applied alone the defense reaction occurs. If a third stimulus (e.g., the sound of a tuning fork) is applied a short time before the second but the primary conditioned and the unconditioned stimuli are omitted it now, when employed alone, causes the conditioned response. It has not been found possible to establish a conditioned reflex of the fourth order, and condi-

tioned reflexes beyond the second order cannot be established for alimentary conditioned reflexes

TRACE CONDITIONED REFLEXES In establishing this reflex the unconditioned stimulus is made to follow the conditioned stimulus after an interval, when the reflex has been established the conditioned response follows the conditioned stimulus by an interval of the same duration. For example a tactile stimulus is applied to the skin for half a minute and then withdrawn, one minute later acid is injected into the mouth. After a number of repetitions it is found that when the tactile stimulus is applied alone, although no secretion occurs during its application, a response follows after a minute's interval. Also if an animal is fed at regular intervals, say every 30 minutes, it is found that after a series of such feedings secretion occurs spontaneously, thereafter, at intervals of approximately 30 minutes, although no food is given. In these instances the time interval itself has evidently acquired the properties of a conditioned stimulus.

The Biological Significance of Conditioned Responses

Conditioned reflexes enter very largely into animal and human behavior. Many such reflexes are developed naturally as the experiences of every day life become enriched, and associations accumulate. Stimuli arising in the environment are constantly calling forth conditioned responses of various types serving as signals to guide the animal in its choice of action. By training and discipline more complicated reflexes can be established such as those forming the basis for the tricks of performing animals. In such instances the sound of a word (command) or a movement made by the trainer serves as a conditioned stimulus to some motor reaction of the animal. In the training and education of the child conditioned reflexes also play a prominent role. Animals with more highly developed nervous systems are capable of the more complicated reflexes, and although one can scarcely speak of certain conditioned reflexes such as the secretion of saliva following the flash of a light or the sound of a tuning fork, as an intelligent act, the ability of an animal to develop conditioned responses is, nevertheless, a measure of its intelligence. Conditioned reflexes also play an important role in the psychology of sex and, according to Pavlov, in the induction of sleep (p. 1270). Conditioned reflexes which are established under the ordinary circumstances of life are termed *natural*. Those which are established experimentally or by special methods of training are called *artificial*. There is, however, no essential

difference between the two. Gantt has enrolled the mid of the conditioned reflex in the investigation of psychiatric conditions. In organic mental disease there was impairment or failure to establish conditioned motor responses to an electric shock, whereas in the psychogenic (functional) types, the responses may be impaired but are not abolished. The conditioned reflex is also used to test sensations, especially hearing, in very young children before they can talk.

Inhibition of Conditioned Reflexes

Inhibition as applied to conditioned reflexes is divided by Pavlov into *external* or *indirect* and *internal* or *direct*.

EXTERNAL INHIBITION. The conditioned reflex is inhibited by some form of stimulation quite apart from the conditioned stimulus itself. The inhibition arises in a part of the brain other than that in which the conditioned reflex is initiated. For instance, some disturbing factor—a sudden noise, a strange smell, a light, a fresh object in the room or the entrance of a stranger tends to abolish a conditioned reflex which in quiet surroundings can be elicited readily. The extraneous stimulus arouses the animal's curiosity and distracts its attention or, in Pavlov's words, evokes an *investigatory reflex*. This purely unconditioned reflex consists of what its name implies—pricking of the ears and turning the eye and head toward the source of the distraction. If the extraneous stimulus is repeated often enough its inhibitory effect is weakened or abolished; the conditioned responses of an animal placed in strange surroundings are at first inhibited but return later. A painful stimulus also sets up an *unconditioned defense reflex*—barking, struggling and other motor reactions which exert an inhibitory effect upon the conditioned response.

INTERNAL INHIBITION. This will be considered under the following headings: (1) *extinction of the conditioned reflex*, (2) *conditioned inhibition*, (3) *inhibition of delay* and (4) *differential inhibition*.

(1) *Extinction of the conditioned reflex.* If a conditioned reflex is repeated a number of times and the unconditioned stimulus (e.g., feeding in the case of an alimentary reflex) always omitted, the response becomes weaker with each repetition; its latent period lengthens progressively and the reflex finally disappears. The reflex is said to have undergone *extinction*. If, however, after every few repetitions of the reflex the conditioned stimulus is followed by the unconditioned stimulus, *extinction does not occur*. The former stimulus is then

said to have been reinforced by the latter. For example, if a conditioned alimentary reflex has been established to the sound of a buzzer, the application of the latter alone calls forth at first a prompt and ample secretion of saliva. After a variable number of repetitions in which the conditioned stimulus is not followed by feeding, i.e., not reinforced, the secretion becomes less each time and finally ceases. After an hour or two the reflex recovers spontaneously. Extinction is due to inhibition of the cortical elements of the reflex. That is not due simply to fatigue of the salivary gland or of the medullary centers is shown by the fact that after complete extinction, reinforcement of the conditioned stimulus causes the reestablishment of the reflex. Moreover, the reflex continues at full strength after a great number of repetitions if it is followed every few times by reinforcement.

After a reflex has undergone extinction, some external stimulus may temporarily remove the inhibition. That is, just as an extraneous stimulus can inhibit the excitatory phase of a conditioned reflex, so also can it inhibit the inhibitory state. This is called *dissinhibition* or the "inhibition of inhibition."

(2) *Conditioned inhibition*. If, after a positive conditioned reflex has been firmly established another stimulus is combined with the conditioned stimulus for a number of trials but reinforcement is always omitted, then though the conditioned stimulus still causes the customary response when applied alone (and regularly reinforced), it is quite ineffective when in combination with the extra stimulus. For example an alimentary conditioned stimulus is established to the beat of a metronome. Later, a buzzer is sounded with the metronome, but the combination is not followed by feeding. After a series of such trials the metronome causes a secretion, but the combined stimuli, metronome plus buzzer, are without effect. The sound of the buzzer is termed a *conditioned inhibitor*, and the inhibitory effect which it produces, a *negative or inhibitory conditioned reflex*. Usually, in order to demonstrate the inhibitory effect, the primary conditioned stimulus and the conditioned inhibitor must overlap.

(3) *Inhibition of delay*. If during the establishment of a conditioned alimentary reflex, the conditioned stimulus is continued for only a brief period, 1 to 5 seconds, before the unconditioned stimulus is applied, then the conditioned response (secretion of saliva) follows almost immediately upon the commencement of the conditioned stimulus. That is, the reflex has a very short latent

period. If after such a *simultaneous reflex* has been established, it is repeated day after day, but the conditioned stimulus is continued a little longer each time before the reflex is reinforced, the latent period becomes lengthened in proportion to the interval between the application of the two stimuli. The almost simultaneous reflex has been converted into a *delayed reflex*. In other words, postponement of reinforcement has caused the conditioned response to be inhibited during the first part of the action of the conditioned stimulus, during the latter part of the action of the conditioned stimulus the secretion of saliva commences and increases in amount up to the moment when reinforcement ordinarily would have occurred.

(4) *Differential inhibition*. This will be described in the next section.

The examples of internal inhibition just given show the high degree of discriminative and adaptive powers of which the cerebral cortex is capable. Although such adjustments are purely automatic they are effected with great delicacy and an apparent purpose. In the case of extinction, for instance, the futility of secreting saliva for food which does not follow appears to have been "recognized." The purpose in conditioned inhibition is quite as evident as in positive conditioned reflexes and the inhibition of delay is clearly an adjustment which economically times the secretory response to the moment when food is "expected."

It is not in these special instances that internal inhibition occurs, for all positive conditioned reflexes, although reinforced regularly, undergo inhibition if repeated over a period varying in different animals from weeks to months or even years. They become progressively weaker, the latent period lengthens out and they ultimately disappear. The tendency of conditioned reflexes to undergo inhibition is an inherent property.

Analyzing and Synthesizing Functions of the Cerebral Cortex

Of the numerous agencies in the environment to which the organism is exposed the great majority might be termed neutral in that they exert neither a beneficial nor an injurious effect. The actions of others are either of definite physiologic value or detrimental to the animal's existence. Through the analyzing mechanism possessed by the nervous system the stimuli to which the latter types of agent give rise are given conditioned properties. Such stimuli are picked out to serve

as signals for reactions on the part of the animal appropriate to the respective agents (beneficial or noxious), they are therefore of the utmost biological importance. The cerebral cortex also possesses synthesizing mechanisms whereby individual stimuli are fused into conditioned complexes (p. 1266).

THE ANALYZERS

Pavlov divides the neural mechanism of the organism upon which the discriminative faculties depend into a number of *nervous analyzers*. These are constituted of the nerves of special sense, and the afferent nerves of the joints and skeletal muscles, together with their respective receptors and central connections. Thus he speaks of *visual, auditory, olfactory, gustatory, cutaneous and motor analyzers*. The receptor of each class is especially responsive to its own type of stimulus—light, sound, etc. The central part of each analyzer, i.e., its terminations in the cerebral cortex, is capable of a very fine discrimination between the different intensities and qualities of stimuli within its own class. The visual analyzer, for example, discriminates between the intensity and quality of different visual stimuli, the auditory analyzer between the intensity, pitch and quality of sounds, the motor analyzer between the various messages (proprioceptive) received from the muscles and joints—and so on for the other analyzers.

In the past, the study of these analyzers, i.e., of the sense organs, has been based very largely upon subjective data gleaned from experiments upon the human subject. The discovery of conditioned reflexes, however, has provided a reliable method for the study of the analyzing functions which being purely objective can in consequence be employed in animal experimentation, the conditioned salivary secretion, for example, is a reaction which readily lends itself to precise measurement and timing.

GENERALIZATION AND DIFFERENTIATION

If a conditioned reflex is established, say to the sound of a tuning fork of 800 cycles per second (c p s), it is found that tones somewhat higher or lower in the scale have also acquired conditioned properties. Also, after a conditioned reflex has been established to a tactile stimulus applied to a certain definite skin area, the stimulation of neighboring areas is also effective. The response, however, becomes weaker the farther away from the original area that the stimulus is applied. This *generalization of stimuli*, as Pavlov calls the

phenomenon, is seen also in the case of olfactory, visual and other analyzers. If, however, the original definite stimulus, for example the tone of 800 c p s, is always followed by reinforcement whereas other tones having a higher or lower frequency are employed without reinforcement, then only the tone of 800 c p s evokes a response. The allied stimuli are said to have undergone *differentiation* from the primary stimulus. Pavlov ascribes the phenomenon to a form of internal inhibition—*differential inhibition*. He believes that originally the excitatory process in the cortical part of the analyzer is widespread, but through the antagonism offered by the internal inhibition set up by nonreinforcement of the allied stimuli, it becomes localized to only a minute cortical area corresponding to the receptors affected by the primary stimulus.

The degree to which differentiation between various types of stimulus can be developed is a measure of the analyzing ability of the cerebral hemispheres and is often amazing. The following examples are taken from Pavlov's monograph.

1 AUDITORY STIMULI (a) *Differentiation of pitch*. Primary stimulus 800 c p s. Differentiated stimulus 812 c p s. (b) *Differentiation of rhythm*. Primary stimulus 120 beats per minute of a metronome. Differentiated stimulus 118 beats per minute of a metronome (Andreyev). (c) *Differentiation of intensity*. The difference in the intensity of two sounds was so slight that it was detectable by the human ear only when one stimulus was followed immediately by the other. Differentiation was perfectly effected by the dog when the two stimuli were separated by an interval of 17 hours.

2 VISUAL STIMULI (a) *Differentiation of direction of movement or of the position of an object*. Primary stimulus, clockwise rotation of a disk. Differentiated stimulus, anticlockwise rotation of the disk. (b) *Differentiation of figures and shapes*. Some of the figures which were differentiated are shown in figure 68.2. A luminous circle thrown upon a screen was readily differentiated from a series of ellipses of the same luminosity, the series started with one having its axes in the ratio of 1.2, of the remainder each successive one approached a little nearer to the circular shape. Differentiation just failed when the ratio of the axes was 8.9. (c) *Differentiation of luminosity*. Two shades of gray which to the human eye appeared exactly the same, even when viewed simultaneously were perfectly differentiated by the dog when an interval of a minute separated the primary from the differentiated stimulus. (d) *Differentiation of colors* failed in all but one animal investigated, and even it gave a doubtful

FIG 682 Examples of different figures which were successfully differentiated in experiments upon a dog. The letter T, shown in the upper left-hand corner of the figure, served for the positive stimulus; the other black figures and the white letter T were differentiated from the positive stimulus. In another dog the white cross was the positive stimulus from which the other white figures were differentiated. (From Pavlov, *Conditioned Reflexes*, Oxford University Press.)

result. Color vision in the dog is therefore either absent or very rudimentary.

3. DIFFERENTIATION OF CUTANEOUS AND PROPRIOCEPTIVE STIMULI. Differentiation was obtained for various types of tactile stimuli, e.g., contact with rough or smooth surfaces, pressure with blunt points arranged in different patterns, scratching with a small brush in different directions. Differentiation was also demonstrated between stimuli applied to different areas for variations in temperature and between various passive movements, e.g., flexion of ankle as against extension.

4. DIFFERENTIATION OF OLFACTORY AND GUSTATORY STIMULI. Corresponding differentiations were established for various odors (e.g., vanilla, amyl acetate, camphor, etc.) and for taste sensations (e.g., meat powders, sugar, cheese, etc.).

Conditioned vasomotor responses have been established in human subjects: the unconditioned response (vasoconstriction of the opposite hand) being induced by immersion of one hand in ice-cold water. Ringing of a bell, a light pattern or a word spoken aloud by the experimenter and whispered by the subject were used as conditioned stimuli.

"Experimental neurosis." When an animal is presented with a problem which requires a fine degree of differentiating ability, i.e., when a con-

flict between inhibitory and excitatory processes is set up, either inhibition or excitation may gain the upper hand with the suppression of the opposite process. In the former event the animal may become drowsy and fall into a deep sleep (p. 1273), whereas in the latter a nervous disturbance may develop during which even gross differentiation cannot be accomplished. To give an example, a dog was required to discriminate between two visual stimuli, a circle and an oval, the former being followed by feeding (positive stimulus), whereas the latter was not reinforced (negative stimulus). Differentiation was made more and more difficult by making the oval at each successive trial more nearly circular. The experiment proceeded smoothly until the axes of the two figures had a ratio of 8:9. The animal then became fractious, howled and whined in its cage, struggled with its harness and became incapable of discriminating between any oval shape and a circle. Not until after a prolonged rest was the animal's power of discrimination between the two shapes restored, but upon being then confronted with the same problem the nervous disorder returned. "Experimental neurosis," as this state was termed by Pavlov, has also been induced in sheep and pigs by Anderson and Liddell. In some instances the condition was permanent, and Gantt has reported such a state which has persisted for 12 years. The neurosis in this latter instance developed as a result of a conflict aroused in the differentiation of two auditory conditioned stimuli—two closely similar tones. These observations upon experimental neuroses have important psychiatric implications and may give a lead in the interpretation of certain nervous conditions in the human subject. Sexual excitement, as manifested by erections, are not uncommonly associated with the neurosis (see Gantt).

SYNTHESIS OF STIMULI

The development of the conditioned response is, in itself, evidence of the synthesizing or associative ability of the cortex. Further evidence is afforded by experiments with compound stimuli, i.e., the fusion of separate individual stimuli, whether these act upon the same or upon different analyzers, into a conditioned complex.

As an example of simultaneous stimuli acting upon the same analyzer—an alimentary conditioned reflex was established to a chord of three tones of equal intensity but having a frequency of 85, 256 and 786 c.p.s., respectively. Later each tone when sounded separately caused a response.

The responses to the different tones were approximately equal but weaker than that caused by the chord

A conditioned reflex may be established to a compound stimulus made up of two stimuli acting *simultaneously* but upon different analyzers. If the component stimuli are then applied separately and without reinforcement, it is found that one of the pair is effective but not the other. For example, a conditioned reflex to acid was established to a compound stimulus consisting of the simultaneous application of a tactile stimulus and a thermal stimulus of 0°C. The tactile stimulus when applied alone was found to be about as effective as the compound stimulus, whereas the thermal stimulus was quite ineffective. The results of experiments in which the component stimuli of the compound stimulus were of unequal strengths, and applied to the same analyzer, indicate that the factor determining the effectiveness of the stimuli, when applied separately, is their relative intensity. The thermal stimulus used in the foregoing experiment may therefore be regarded as being the weaker of the two stimuli. Visual stimuli are also weaker than those acting upon the auditory analyzer. For example, after a conditioned reflex had been established to a compound stimulus made up of a tone and a light, the tone by itself caused a response, whereas the visual stimulus was quite ineffective. However, the weaker stimulus undoubtedly plays its part in the combination, for if the stronger component is applied repeatedly without reinforcement by the unconditioned stimulus, but the compound stimulus is constantly reinforced, the stronger stimulus by itself becomes ineffective, whereas the compound stimulus retains its full effect.

The cortex is also able to synthesize *successive* stimuli into a compound conditioned stimulus. For instance, a flash of light (L), a cutaneous stimulus (C) and the sound of bubbling water (S) when applied in the order (L—C—S) were compounded into a positive conditioned stimulus. The reverse order (S—C—L) after differentiation (by nonreinforcement) was entirely without effect.

Similarly, four tones having vibration frequencies of 290, 325, 370 and 413 c.p.s. respectively when sounded in this order (1, 2, 3, 4) were successfully differentiated by a dog from all other sequences (e.g., 4, 3, 2, 1, 4, 3, 1, 2, 4, 1, 3, 2, 4, 2, 3, 1, etc.)

The series of sounds in a word (e.g., a dog's

name) or in a command is a familiar example of a *successive* compound conditioned stimulus.

IRRADIATION AND CONCENTRATION

These features are best illustrated by citing an actual experiment. The skin of the hind limb was stimulated at five separate places. One of these situated upon the paw was differentiated by non-reinforcement in the usual way from the other four. That is, the place upon the paw was given inhibitory properties (p. 1263). The other four places, which through reinforcement were given positive conditioned properties, were placed at progressively further distances along the limb from the inhibitory place. It was found that if the latter was stimulated three times in succession, and one minute after the last stimulation, the positive place nearest the inhibitory place was then stimulated, there was complete failure of the usual conditioned response. Stimulation of the next (second) excitatory place one minute after the last application of the inhibitory stimulus was followed by a response half as great as usual. The remaining two places (third and fourth) gave a normal or somewhat greater than normal response (see positive induction, p. 1268). When the number of the previous stimulations of the inhibitory place was increased, and the interval following the last one shortened to 15 seconds, all four excitatory places gave a reduced response. As time elapsed the furthest place was first freed from the inhibitory influence, and the others in the order of their positions from the inhibitory place. The point nearest to the latter in some cases did not give a full response until the lapse of 10 minutes after the application of the last stimulus to the inhibitory place. It can also be shown that if, by means of extinction, inhibitory properties are given to one of the four excitatory places the inhibitory process spreads to involve the others.

These results are taken to indicate that each stimulated area has its circumscribed representation in the cortex. Inhibition initiated in the cortical cells to which the inhibitory place is projected *irradiates* to involve the cortical projection areas of the positive places. The gradual release of the cortical areas from the inhibitory influence, and its retreat to the original cortical cells corresponding to the inhibitory place is called the *concentration of inhibition*. Irradiation and concentration are antagonistic processes. These processes can also be shown for the acoustic analyzer and they most probably exist for other analyzers as well. The following is an illustration of irradiation.

tion within the acoustic analyzer. Positive conditioned reflexes were established respectively to the beat of a metronome, to a musical tone and to a buzzing sound. When the reflex to the buzzing sound or to the metronome was extinguished the inhibitory process spread to involve the reflex to the musical tone.

Irradiation is not always confined to the analyzer in which the inhibitory process originates. It can be shown that the inhibitory process initiated in one analyzer spreads to others and may involve the entire cortex. For example, a positive alimentary conditioned reflex was established to a tone of 4000 c p s, a note a semitone lower than this was given inhibitory properties. When the inhibitory stimulus was applied a short time before a visual conditioned stimulus, the reflex which had been established to the latter, as well as that established for the positive auditory stimulus (tone of 4000 c p s) was inhibited.

Irradiation and concentration of excitation occur in a manner analogous to that described for inhibition. Generalization (p. 1265) is ascribed to the irradiation of excitation from the primary cortical focus. Differential inhibition, on the other hand, antagonizes the excitatory process and concentrates it within the original cortical area.

INDUCTION

Induction is a feature of conditioned reflex action analogous to the phenomenon of the same name described as occurring in spinal reflexes, namely, the increase of inhibition caused by a preceding state of excitation (*negative induction*) or an increase of excitation caused by a previous state of inhibition (*positive induction*). Induction is therefore a reciprocal process.

Negative induction. The inhibitory properties of a stimulus developed by means of differentiation can be readily destroyed again (disinhibition) by repeated reinforcement. If, however, each application of the inhibitory stimulus is preceded by a

positive one, and both are reinforced, the inhibitory properties of the former are strengthened and can be abolished only after a great number of trials. Thus, a metronome beating at a rate of 120 beats per minute served as a positive conditioned stimulus and a rate of 60 beats per minute was differentiated (differential inhibition). The inhibition was then almost abolished (disinhibition) by reinforcement but was restored again when the differentiated stimulus (rate of 60 beats per minute) was preceded by the positive stimulus (rate of 120 beats per minute). The data are shown in table 6S 1, as given by Pavlov.

Positive induction in its simplest form may be illustrated as follows. A positive conditioned reflex was established to stimulation of the forepaw. A stimulus to the hind paw was given inhibitory properties by differentiation. When the excitatory place (forepaw) was stimulated immediately after the application of the stimulus to the inhibitory place, the positive conditioned reflex was enhanced (salivary secretion increased by 50 per cent). The excitability of the cortical area receiving impulses from the forepaw had evidently been increased as a result of inhibition of the cortical area corresponding to the hind paw. Thus the excitability of the cortex in proximity to the inhibited area is enhanced for the moment but later becomes depressed as a result of the irradiation of the inhibitory process. When dealing with irradiation it was pointed out that the inhibitory effect was demonstrable for several seconds or minutes after the inhibitory place had been stimulated. Positive induction occurs during the application of the inhibitory stimulus. Pavlov holds the view that these two processes, positive induction and irradiation of inhibition (or negative induction and the irradiation of excitation) are constantly interacting with one another and spread wave-like over the cortex. Positive or negative induction precedes, respectively, the spread of the inhibitory or excitatory process.

THE EMPLOYMENT OF CONDITIONED REFLEXES IN THE STUDY OF CORTICAL FUNCTION. Information concerning the localization of function in the cortex was obtained by, first, firmly establishing a conditioned reflex involving one or other analyzer then exciting a certain portion of the cortex and studying the effects of the operation upon the conditioned response.

REMOVAL OF THE ENTIRE CORTEX

It was reported that in the dog removal of the entire cortex results in the complete and perma-

TABLE 6S 1

Time	Conditioned Stimulus Applied during 30 Seconds	Salivary Secretion in Dogs during 30 Seconds (Drops)
11 25 a m	60 beats	0
11 30 a m	60 beats	0
11 42 a m	60 beats	3
11 49 a m	60 beats	4
11 56 a m	120 beats	8½
12 06 p m	60 beats	0

All the stimuli were accompanied by reinforcement

nent loss of all conditioned responses, natural or artificial, now conditioned reflexes cannot be established. The decorticated animal responds to crude *unconditioned* stimuli, e.g., a bright light or sound, its reactions being frequently those of resentment or anger (p. 1168). The unconditioned salivary reflex is lost at first but eventually becomes stronger than the normal. More recent work has demonstrated that in a limited way and with considerable difficulty it is possible to establish some simple conditioned reflexes in both the decorticate dog and cat. This does not alter the fact that basically these reflexes are dependent upon the cerebral cortex. In addition we must not lose sight of the fact that in the dog and cat the cerebral cortex is not comparable to the cortex in man or even in the subhuman primates. There can be little doubt but that in the primate brain conditioned reflexes are developed only in the presence of the cerebral cortex.

REMOVAL OF A LIMITED PORTION OF THE CORTX

Removal of a limited portion of the cortex, e.g., the temporal or occipital lobes, causes the disappearance for a time of all "artificial" conditioned reflexes, and sometimes of the "natural" ones as well. Unconditioned reflexes, which are dependent upon subcortical centers, remain in abeyance for only a few hours or may not disappear at all. Complete recovery of conditioned reflexes dependent upon analyzers, other than the one which has been directly injured, occurs after a few days, analyzers nearest to the excised area recovering later than those farther removed. Incomplete recovery of the injured analyzer eventually takes place.

THE ACOUSTIC ANALYZER is centered in the temporal lobe. Extirpation of both temporal lobes is followed by a very temporary loss, if any, of the auditory unconditioned reflexes (e.g., pricking of the ears to sound). The auditory conditioned reflexes may not return for several weeks or even months, and are never fully restored. The finer and more discriminating reactions are permanently lost. Discrimination of the intensity, pitch and quality of sound is possible, but the powers for more complicated analyses and syntheses are not regained. The animal, for example, never answers to its name, and the differentiation of other types of compound auditory stimuli (p. 1266), e.g., a descending from an ascending scale of tones, cannot be established.²

² An experiment upon the peripheral portion of the acoustic analyzer may be mentioned here, since it has a bearing upon Helmholtz' theory of

THE VISUAL ANALYZER is situated mainly but not exclusively in the occipital lobe. According to Pavlov the visual analyzer is probably spread over the entire cortex. Complete bilateral extirpation of the occipital lobes causes effects upon the visual conditioned reflexes corresponding to those upon the auditory reflexes which follow removal of the temporal lobes. Conditioned responses to changes in the intensity of illumination (e.g., switching on a high power lamp) established before operation returned upon the fifth day following the extirpation of the occipital lobes as well as of a considerable area of the cortex lying anterior to them. Differentiation was established between a luminous cross and a circle illuminated to the same intensity. It was found impossible, however, to establish conditioned reflexes to specific objects for the reason, most probably, that the appearance of an object changes with the illumination, with its distance from the eye and the angle from which it is observed. Its recognition under different conditions of lighting position etc., therefore requires a much greater power of analysis and synthesis than that required for the differentiation of a flat luminous shape. The animal deprived of its occipital lobes is able, nevertheless, to avoid objects placed in its path. They are detected simply by the changes in illumination (lights and shadows) which their presence creates.

The findings described above, namely, that complete decortication in the dog abolishes all conditioned reflexes, and that removal of the temporal or occipital lobes impairs, respectively auditory, and visual conditioned reflexes, but does not destroy them permanently and completely, lead to the following conclusions concerning the functions of the cortex, so far at any rate as the auditory and visual senses are concerned. (a) Although rudimentary reactions can be carried out through subcortical connections, the processes underlying conditioned reflexes are dependent upon the activity of the cerebral cortex. (b) The highest powers of analysis and synthesis are localized to definite areas each of which may be regarded as the "nucleus" of a given analyzer. (c) The analyzer, however, is not rigidly confined to this area but extends into other cortical regions in which less complicated types of analysis can be

hearing. Destruction of the organ of Corti in the upper part of the cochlea (receptors for lower tones) resulted in a loss of conditioned reflexes which had been established to tones of the lower part of the musical scale (frequencies lower than 600 d b per minute). Reflexes to higher tones were unaffected.

undertaken. Experiments involving other analyzers have yielded evidence pointing in the same direction.

These results of cortical extirpation cannot be directly applied to the human subject since the functions of subcortical centers of hearing, sight, etc., in lower animals have not, as in man, been so largely usurped by the cortex. Nevertheless, Pavlov's observations are, broadly speaking, in harmony with modern conceptions of cortical functions (see ch. 67). A given sensory function, although primarily "centered" in a certain cortical area, is, through association tracts, dependent for its full development upon other areas as well.

The Effects of Drugs upon Conditioned Reflexes

Caffeine and strychnine increase the effects of positive conditioned stimuli and weaken internal inhibition. After a dose of less than 1 grain (0.025 to 0.05 gram) of the former drug, extinction (inhibition) of a conditioned reflex is effected with the greatest difficulty. *Bromides* act by strengthening internal inhibition, and not by directly depressing excitatory processes, under their influence the extinction of positive conditioned reflexes is facilitated. *Alcohol* in moderate doses weakens internal inhibition. Andrejev and Pugsley have found that the *hypercalcemia* resulting from parathormone or ergosterol overdosage causes an exaggeration of inhibitory processes, the after effect of inhibitory stimuli is enhanced and extinction of positive conditioned reflexes accelerated.

The Physiology of Sleep The Depth of Sleep

The depth of sleep is not constant throughout the sleeping period but varies from hour to hour. Experiments upon man in which auditory stimuli were employed to arouse the subject at different times, or the movements of the sleeper were recorded (the depth of sleep being assumed to be inversely related to the amount of muscular movement) indicate that the depth of sleep follows a characteristic curve. In most adults sleep deepens rapidly to the end of the first hour, after which it lessens sharply for a time, and then more slowly till the time of waking. In children the sleep curve shows two maxima, i.e., two periods of the deepest sleep, one of these is reached in the first or second hour, the other between the eighth and ninth hours, the curve then falls rapidly to the time of waking. Generally speaking, sleep taken during the daytime is lighter than that during the night. Deep sleep is dreamless, dreams occur only during light sleep and chiefly in the

period which just precedes waking. In sleep, unconsciousness is not uniform for all senses, the depth of sleep is greatest for the sensations of smell and least for those of pain, hearing and touch.

The *sleep requirement* of different persons varies widely, it also alters with age. The following are average figures for the hours of sleep required at different periods of life.

	hours
New born infant	18 to 20
Growing children	12 to 14
Adults	7 to 9
Old persons	5 to 7

PHYSIOLOGICAL CHANGES ACCOMPANYING SLEEP

During sleep most bodily functions are reduced to their basal levels. The *blood pressure* is lowered, the systolic pressure showing a decline of from 10 to 30 mm Hg. The lowest level is reached about the fourth hour of sleep, and remains at this level until a short time before awakening when the pressure commences to rise again. Mac William found that if the sleep was disturbed by exciting dreams the blood pressure might be elevated well above the normal waking level, of 125 or 130 mm Hg. The *pulse rate* is slowed by from 10 to 30 beats. The *metabolic rate* is reduced by from 10 to 15 per cent below the basal level and the *rectal temperature* by a fraction of a degree Fahrenheit. The heat regulating mechanisms are depressed. The *respirations* are slowed as a rule, and are said to become more costal in character; they also tend to become irregular or periodic. *Muscle tone* is minimal, the knee jerk is abolished, and a positive Babinski may be present. The thresholds for most *somatic reflexes* are definitely raised. Vasomotor reflexes, however, are more active. In most animals the *righting reflexes* are abolished. The pupils are usually constricted, the *light reflex* is retained. The eyeballs are turned upwards and outwards. *Urine volume* is reduced, but the absolute excretion of urinary phosphate is increased, and the specific gravity raised. The *secretion of the sweat glands* is considerably increased, according to Hartridge the quantity of fluid lost per hour in sleep is nearly equal to that lost during a corresponding period of strenuous muscular exercise. *Plasma volume* is reduced by about 10 per cent. *Gastric secretion* is increased or little altered during sleep. The contractions of the empty stomach continue and may be more vigorous than usual, the rate of digestion is about the same as during the waking state. *Lacrymal* and

salivary secretions are reduced. The EEG during sleep is described in chapter 67.

It may be of interest to give an account of the effects upon the nervous system of prolonged wakefulness. In Kleitman's human experiments the subjects were kept awake for periods ranging from 60 to 114 hours. The knee jerk remained unaffected but disappeared promptly when the subject went to sleep at the termination of the period of forced insomnia, and a positive Babinski was obtainable. The latter was attributed to the establishment of a block in the corticospinal pathway. The pupillary response remained brisk throughout the wakeful period. There seemed to be little impairment of the mental processes, and the reactions to auditory and visual stimuli were as prompt as usual. The threshold for pain stimuli was definitely lowered, whereas that for touch was unaltered. The power to maintain equilibrium, as judged by the ability to stand with the eyes closed, was grossly impaired. This defect was attributed to neuromuscular fatigue and the consequent reduction in muscle tone, rather than to any impairment of labyrinthine function itself.

Tyler, in more recent experiments upon some 600 human subjects who went for periods of up to 112 hours without sleep, found no significant changes in blood chemistry, hemoglobin, red or white blood cell count, body weight or temperature, and only slight changes in blood pressure, respirations and heart rate. Notable psychological changes, however, were observed, e.g., loss of memory, irritability, inattention and hallucinations or illusions. These alterations in behavior, were noticeable after from 30 to 60 hours of sleeplessness, and, although mild in most subjects, in a few, they were severe and resembled those of acute schizophrenia.

The period of wakefulness which would be lethal for the human subject is not definitely known. Dogs may die after being kept awake continuously for 14 days, although they may survive for much longer periods. Young animals are much more susceptible to loss of sleep than older ones. Changes in the nerve cells of the cortex, e.g., chromatolysis and shrinkage of the cell bodies, have been described as resulting from prolonged periods of enforced wakefulness in animals.

THEORIES OF SLEEP

The cause and nature of sleep have aroused speculation from the time of the Greek philosophers but although hypotheses are many and often ill founded, facts which might throw light upon the underlying processes are few and dif-

ficult to obtain. A discussion of only some of the many theories will be undertaken.

NEURON THEORY (Lépine Duval) This theory arose from the demonstration by Cajal that there was not anatomical continuity between adjacent neurons but merely points of contact for which the term *synapse* was later suggested by Foster. The neuron theory postulated that the function of the cells of the higher cortical centers was suspended as a result of the retraction of the dendritic processes and the consequent break in contact between neurons. Although some histological evidence was cited in support of this conception, the theory was mainly speculative.

CEREBRAL ISCHEMIA THEORY Howell suggested that fatigue of the vasomotor center with consequent vasodilatation of the peripheral vessels especially of the skin, and reduction in cerebral blood flow was the primary change responsible for the onset of sleep. The flushed skin of the sleeping subject, the fall in blood pressure and the well known feeling of drowsiness following a meal (which presumably was the result of the diversion of blood to the splanchnic area) lent plausibility to the theory. From ancient times the carotid artery (*karos* = I sleep) has been believed to be connected in some way with the mechanism of sleep, for it was recognized that compression of this vessel was not uncommonly followed by unconsciousness. In later times the loss of consciousness following pressure upon the neck was attributed to vagal stimulation, with consequent inhibition of the heart and a reduction in intracranial blood flow. Unconsciousness may be produced by the fall in blood pressure and the cardiac asystole brought about by the compression of a hyperactive carotid sinus on one side or as the result of cerebral ischemia and anoxia produced by bilateral occlusion of the carotid arteries.

The unconscious states caused by a reduction in cerebral blood flow are not, however, akin to normal sleep. Vulpian observed some years ago that, although stimulation of the cervical sympathetic in animals caused cerebral ischemia, sleep was not induced. Moreover, Gibbs has shown by means of an electrically heated stylet that no diminution in blood flow through the brain occurs during natural sleep. It is possible nevertheless, that there may occur a reduction in the blood supply to a limited area of the brain whose activity is essential for the waking state. A limited vascular change of this nature might not be revealed by observations upon the total intracranial blood flow.

CHEMICAL THEORIES Several chemical theories of sleep have been proposed. One of the earliest of these was that fatigue products, especially lactic acid formed in the tissues generally, acted by depressing the function of the cortex. Against this view is the well known fact that one need not be fatigued in order to sleep, on the other hand a person may be unable to sleep although utterly fatigued. Furthermore, the brain tissue actually derives energy from the oxidation of lactic acid.

Another chemical theory is that of Piéron. This observer claims that a substance which he terms *hypnotoxin* is produced by the brain tissue and acts as a soporific. He claims that the cerebrospinal fluid of a dog killed during sleep induces sleep when injected into another animal. Kroll makes similar claims, stating that an acetone extract of the brain of a sleeping or hibernating animal will cause sleep when injected into another. Holmes has been unable to confirm Kroll's findings. An extract prepared by Kroll's method either from sleeping or waking animals was found to be lethal through its toxic effect upon the heart. Ivy and Schnedorf have repeated Piéron's experiments and confirmed his observation. They found that the injection of cerebrospinal fluid of a dog kept awake for several days induced a state of depression resembling deep sleep in rested dogs when introduced into the cisterna magna or cerebral ventricle. The effect, however, is probably due not to the presence of a sleep inducing substance in the fatigued cerebrospinal fluid but to a rise in intracranial pressure since the injection of cerebrospinal fluid from rested dogs had a depressing action not considerably less than that of the fatigued fluid. No evidence in support of the theory (Dikshit) that *acetylcholine* liberation by the brain tissue is a factor in sleep was secured by these observers.

Zondek and Bier have advanced an interesting but unsubstantiated theory in which the pituitary plays a leading role. They state that the pituitary during the waking state has a higher concentration in bromine than any other tissue but that during sleep the bromide concentration of the gland diminishes whereas that of the medulla increases. These observers therefore believe that sleep is induced through the liberation of a bromine compound from the hypophysis. They have named this substance *bromhormone*. The evidence upon which this theory is based is far from convincing.

Other chemical theories based upon the sup-

posed affinity of a subcortical area for certain ions, especially calcium whose depressant action upon nervous tissue is well known, have been advanced but little substantial evidence has been secured for their support.

THE DIENCEPHALON AND SLEEP Several observations both clinical and experimental point to the existence of a sleep center in the diencephalon. Hypersomnolence is a frequent accompaniment of tumors of the structures in the floor and walls of the third ventricle or of inflammatory lesions involving the hypothalamic region. Hess claims to be able to cause sleep in animals by mild electrical stimulation of the diencephalon towards the anterior end of the cerebral aqueduct, and Gagel reported the production of sleep in human subjects during operations by mechanical stimulation of the posterior part of the hypothalamus. Hess also reported that ergotamine injected directly into the third ventricle induces sleep. Ergotamine paralyzes the motor and secretory fibers of the sympathetic. Since parasympathetic and sympathetic centers are apparently situated in the hypothalamus, Hess argued that the drug by suspending the activity of the sympathetic center caused a preponderance of parasympathetic effects. Sleep, he concluded, was a parasympathetic function. He also draws support for his theory from certain manifestations of parasympathetic activity, namely, the pupillary constriction, bradycardia and vasodilatation which accompany sleep. Although this observer's idea that sleep is a parasympathetic function requires further experimental support before it can be accepted, the evidence for the participation of the hypothalamus in the sleep mechanism is strong. Yet contrary to the idea that sleep is caused by excitation of some part of the hypothalamus, other investigators believe that it results from the depression of hypothalamic activity. The hypothalamus is thus regarded as containing a waking center, sleep following its destruction or inhibition.² Ranson and his associates, for example, have reported that sleep can be readily induced in cats by lesions placed in the posterior and lateral part of the hypothalamus or by injury confined to the mammillary bodies but

² The electroencephalogram recorded from the cortex of the cat after transection at the lowermost limit of the medulla is essentially that of the normal waking state, after section at the upper border of the pons the electroencephalographic pattern is that characteristic of sleep. From this it could be inferred that the latter section interfered with the transmission of alerting impulses to the cerebral cortex.

that it did not result from the *stimulation* of any part of the hypothalamus. Harrison also found that electrical stimulation of the hypothalamus caused somnolence only when the current exerted a destructive action.

Whether the thalamus plays a role in the sleep mechanism is unknown. Although unconsciousness may result from manipulations in the region of the thalamus and a stuporous state may be associated with a thalamic lesion, true sleep has not been produced by either stimulation or injury.

Pavlov's theory. Pavlov believes sleep and internal inhibition to be essentially one and the same process, i.e., sleep is simply the spread (irradiation) of internal inhibition over the entire cortex with the subsequent involvement of subcortical levels, and internal inhibition confined within the boundaries of a single analyzer is a localized sleep. He was led to this conclusion by the behavior of animals during his investigations of conditioned reflex action. Drowsiness and sleep were frequent accompaniments of all forms of internal inhibition, e.g., inhibition of extinction and of delay (p. 1264), conditioned and differential inhibition, or the inhibition which ensued spontaneously after the repetition of positive conditioned reflexes over a long period of time. An animal, for example, which is quite alert during the establishment of a reflex to a definite musical tone becomes drowsy and falls asleep in the stand during attempts to develop differentiation (p. 1265) of a closely similar tone. Its muscles relax; it may snore loudly and other positive conditioned stimuli fail to awake it. Moreover, drugs such as caffeine (p. 1270) which reduce internal inhibition, and those such as bromides which increase it, have corresponding effects upon the mechanism of sleep. As mentioned previously, positive conditioned reflexes after having been repeated over a long period ultimately undergo inhibition. At this stage in the investigations the experiment is frequently terminated by the animal falling asleep. Experiments involving the use of thermal and tactile stimuli are most frequently interrupted by the onset of sleep; auditory conditioned stimuli are the least likely to have this effect.

Protracted mild stimulation of an extraneous nature was also found to cause cortical inhibition and lead to sleep. It has been mentioned (p. 1263) that an extraneous stimulus induces inhibition through setting up an investigatory reflex, upon repetition the inhibitory effect disappears and the conditioned responses return. With further repetition, however, the extraneous stimulus

again causes inhibition; this time, it exerts, of itself, a direct inhibitory effect upon the cortex.

Pavlov's theory has much to recommend it. The drowsiness which results from some oft-repeated form of monotonous stimulation, e.g., reading or being read to in a low even voice, a dull lecture, or boredom from whatever cause, is well known. Also, the preparations for sleep—the various agencies in a familiar environment—probably serve themselves as inhibitory conditioned stimuli. A dog, for example, which has fallen asleep during previous experiments may do the same when merely brought into the room where the experiments have been performed or when preparations are being made to repeat them. The customary hour for retiring probably acts also as a time conditioned stimulus.

For a critique of Pavlov's theory see Denny Brown.

In some experiments described by Pavlov the inhibitory process involved the cortex but did not descend to subcortical levels governing equilibrium and the postural reactions of the skeletal muscles. The animal assumed a trance-like or cataleptic state in which muscular tone was retained, the general attitude being one of alertness. It stood with wide-open eyes but was quite unresponsive to all ordinary forms of stimulation. Pavlov looks upon this state as a transition stage between wakefulness and deep sleep, due to a less widespread diffusion of the inhibitory process and similar in nature to hypnosis. It is suggested that during sleep also all cortical areas, analyzers as Pavlov terms them, are not necessarily under the inhibitory influence. The alertness of a mother apparently in deep sleep to the slightest noise made by her baby is a case in point. In such an instance it is the auditory analyzer, or a part of it, which has remained apparently outside the inhibitory influence.

These observations have undoubtedly some bearing upon the production of dreams. Dreams are evidently due to cortical activity, especially of the temporal lobes (ch. 67) since they involve vivid memory and the ability to recall and bring together various sensory impressions. It would seem, however, that the activity of other regions possessing a more critical ability—those areas endowed with a higher analytic and synthesizing capacity—is in abeyance. The illogical, uncritical and often grotesquely absurd character of dreams is well known, yet the mental pictures are often drawn with great vividness, and a stimulus which in the waking state would leave little imprint upon consciousness is sometimes magnified enormously during sleep. As Descartes says, *A flea bit me and I dreamt of a sword cut!* Sensations arising

in the viscera, such as those due to hunger, a distended stomach or bladder, thirst, etc., which during the day may cause no more than a passing thought may give rise to dreams filled with the most exciting events. It has been mentioned that dreams occur only during light sleep, that is, at a time when one would expect the internal inhibitory process to be restricted to the more highly specialized parts of the analyzer and before it has spread to involve the entire cortex. Dreaming may therefore be reasonably looked upon as being dependent upon a state of partial sleep—certain areas of the cortex being freed from the restraint which during the day is exercised by more critical regions.

KLEITMAN'S THEORY According to Kleitman, sleep is due to the inactivity of the cerebral cortex resulting from a reduction in the number of afferent impulses, especially from the muscles, reaching the sensorium. Fatigue of the neuromuscular mechanism mediating muscle tone, with consequent suppression of impulses from muscle proprioceptors, is considered to be the most important factor in the onset of sleep. According to this author loss of muscle tone is an invariable prelude to sleep.

Kleitman claims to have demonstrated a diurnal variation in the speed, accuracy and steadiness with which certain muscular acts are performed. The efficiency of performance was maximal in the afternoon and minimal late at night and in the early morning. It is suggested that the variability is due to a corresponding rhythm in the tone of the skeletal musculature. But quite apart from these experiments, many observations give credence to the theory that cortical inactivity resulting from the blockage of afferent impulses is an important element in the onset of sleep. The exclusion of stimuli from visual, auditory and cutaneous receptors and the diminution of the flow of proprioceptor impulses as a result of muscular relaxation, are well known means employed to induce sleep, whereas cortical activity, whether from psychic causes—*anxiety, worry, excitement, etc.*—or as a result of impulses set up in exteroceptors or muscle receptors, prevents sleep. In extreme fatigue when muscle tone is presumably at a minimum and the threshold of other afferent paths also probably raised as well, sleep comes on irresistibly. Kleitman and his associates found that after a prolonged period of wakefulness the only way in which they could keep from falling asleep was by moving about, or at least remaining in a standing or sitting position. Upon lying down and permitting their mus-

cles to relax they were immediately overpowered by sleep.

An attempt has been made by Kleitman to reconcile the cortical theories of sleep with the undoubted fact that the hypothalamus is in some way concerned in the sleep process.

That sleep is not solely dependent upon the cortex is evident from the fact that decorticated dogs show periods of sleep alternating with intervals of wakefulness. The sleep rhythm in these animals is not, however, related in any way with night and day but consists of a number of shorter or longer periods throughout the 24 hours. The sleep periods occur most constantly after feeding. During the waking periods the animals walk around almost incessantly. Lower orders in the animal scale in which the cortex is rudimentary and which, in consequence, are unable to develop a wide variety of conditioned responses show a similar sleep rhythm. This more primitive sleep mechanism is dependent conceivably upon a center located at a subcortical level, and most probably in the hypothalamus. We may regard it as presiding over vegetative functions and acting continuously to keep the animal asleep unless inhibited by impulses arising out of the more primitive processes and reactions, e.g., hunger, thirst, cold or distention of the bladder or rectum.

The diurnal sleep rhythm, that is, the ability to keep awake throughout the day, is dependent, on the other hand, upon the development of conditioned reflexes. So long as the cortex can bring its analyzing ability to bear upon the stream of impulses received from the different distance receptors, muscles, skin, etc., the functions of the primitive sleep center are held in abeyance. With the spread of internal inhibition over the cortex, or as a result of the elimination of stimuli from the periphery, the center asserts itself, and the subject is unable to remain awake. The diurnal sleep rhythm is therefore an acquired phenomenon—not inborn. Infants and very young animals do not show it but, like decorticated animals, have several sleeping periods throughout the day.

Those who believe that sleep results from the inhibition of a waking center in the hypothalamus take a somewhat different view. According to them sleep is a negative rather than a positive state, that is, it is due to the inactivity of the waking center. The activity of this center it is conceived is maintained by impulses received from the cortex. Cortical function is dependent in turn upon a flow of impulses along various afferent channels.

RETICULAR FORMATION. The common observation, noted above by Kleitman, that sleep is often produced by a reduction in exteroceptive and proprioceptive stimuli correlates well with what is known regarding the reticular formation in the brain stem. This mechanism receives afferent impulses set up by various forms of external stimuli (e.g., light, sound, touch and pain) as well as by impulses set into motion by muscular tension. Furthermore, this mechanism when stimulated by afferent impulses (or electrically) in turn arouses or alerts the animal and converts the electroencephalographic pattern from one characteristic of sleep to that typical of the waking state. In addition states resembling sleep are produced by certain drugs which decrease the activity of the reticular formation.

Although it appears likely that the activity or inactivity of the reticular formation are important in the production of wakefulness or sleep, it is equally obvious that many other parts of the nervous system are also concerned with this phenomenon. The peripheral nerves and the spinal cord are important in bringing afferent impulses which activate the reticular formation, the cerebral cortex is the structure which is aroused, whereas the diencephalon (the hypothalamus and the intralaminar nuclei of the thalamus) exercise an influence on the cortex exactly opposite to that of the reticular formation.

THE CEREBELLUM¹

General Structure and Divisions

The cerebellum consists of a narrow central body, the *vermis* (or worm) and two lateral masses, the *right* and *left cerebellar hemispheres*. On its upper surface the demarcation between the vermis (*superior vermis*) and the hemisphere is slight. Upon the under surface the hemispheres are separated by a deep depression—the *vallecula*, the floor of the latter is formed by the inferior surface of the vermis. The inferior aspect of the vermis (*inferior vermis*) consists of four subdivisions, these are called (in order from the front backwards) the *nodule*, *uvula*, *pyramid* and *tuber*. On either side and continuous with the nodule, is an elongated, somewhat lobulated structure called the *flocculus*. It should be noted that these gross subdivisions of the cerebellum are not related to either the developmental or the functional divisions of the cerebellum and are useful only as descriptive terms.

The cerebellar surface is not convoluted like the cerebral cortex but is divided by parallel and curved furrows into numerous laminae or folia (leaves). The total cortical area of the human cerebellum is about 100,000 sq mm, or less than half of that of the cerebral cortex.

Although the division of the cerebellum into the vermis and two hemispheres possesses considerable descriptive value, comparative neurologists (chiefly Bolk, Ingvar, Elliott Smith and Larsell), have suggested other divisions which possess greater significance from a phylogenetic and functional point of view. In Larsell's description the cerebellum is divided into two fundamental or primary parts, (a) the small flocculonodular lobe or vestibular part, and (b) the corpus cerebelli. These two parts are separated by a deep fissure—the *posterolateral fissure*—which is present in all vertebrate brains.

The *flocculonodular lobe* (or archicerebellum) the most ancient part of the cerebellum, comprises

the flocculus and the nodule. It is developed from the structures in the region of the vestibular nuclei. The *corpus cerebelli*, which includes the rest of the cerebellum, is separated from the flocculonodular lobe by the *fissura posterolateralis*, and is divided by a well marked fissure—the *fissura prima* of Elliot Smith—into a small anterior and a large posterior lobe. The *anterior lobe* (or paleocerebellum) consists of three subdivisions, the *lingula*, *lobulus centralis* and *culmen*. The *posterior lobe* (or neocerebellum) includes the *lobulus simplex*, declive, tuber, pyramid and uvula, together with the associated parts of the hemispheres (*lobulus ansiformis* and *lobulus paramedianus*, see below) and the *paraflocculus* (fig. 69 I). In higher forms a fissure appears in front of the pyramid, known as the *sulcus* or *fissura prepyramidalis*. The part of the posterior lobe between this sulcus behind and the fissura prima in front is sometimes referred to as the middle lobe of Ingvar (fig. 69 I), from the functional view this is a convenient subdivision. The flocculonodular lobe,² the anterior lobe, and the lobulus simplex, pyramid, uvula and paraflocculus of the posterior lobe are the phylogenetically old parts of the cerebellum and are referred to as the *archicerebellum* and *paleocerebellum*. The remainder of the cerebellum, i.e., the lateral expansions or hemispheres (*ansiform lobules*) declive and tuber (*superior vermis*) are late acquisitions, and constitute the *neocerebellum*, they correspond to most of Ingvar's middle lobe, and appear in phylogenetic development at about the same time as the cerebral cortex and the corticospinal tracts, and the pons. The neocerebellum, cerebral cortex and pons are absent or rudimentary in submammalian forms.

The *paramedian lobule* (or *tonsil*) is a small compact mass lying on either side of the inferior vermis. The ansiform lobule, which constitutes a large proportion of the posterior lobe and forms the expanded lateral mass of the hemisphere, reaches its greatest development in the human brain, its function is concerned with the tonic ad-

¹ Those interested in a more detailed review of the anatomy of the cerebellum are referred to Larsell, O., "The Cerebellum from Myxinoidea to Man" (In press), Univ. of Minnesota Press, and for physiology and pathology of the cerebellum to Dow, R. S. and Moruzzi, G., "The Physiology and Pathology of the Cerebellum", Univ. of Minnesota Press, Minneapolis, 1958.

² The first appearance of a cerebellum, phylogenetically, is in the primitive fish *Petromyzon* (lamprey), and consists merely of a bridge of nervous tissue formed by an outgrowth from either side of the medulla which fuse in the midline over the fourth ventricle. This is the forerunner of the flocculonodular lobe of higher forms.

INTERNAL STRUCTURE

When sectioned in the sagittal plane each hemisphere of the cerebellum presents a branching core of white matter which from its foliate appearance has been named the *arbor vitae*. The terminal branches of the white matter are covered with a coating of gray substance which constitutes the cerebellar cortex. The leaflike structures so formed are spoken of as *folia* and are responsible

for the laminated appearance of the cerebellar surface (fig 69.2). Unlike the cortex of the cerebrum all areas of the cerebellar cortex show a uniform histologic structure.

The Gray Matter

THE CORTEX Three cell layers are distinguished.

(1) *The molecular (or plexiform) layer* is outermost and consists largely of unmyelinated nerve fibers derived from (a) the white substance, (b) the cells of the two underlying layers, and (c) the

FIG 69.3 Diagram to show structure of cerebellar cortex G, granule cell B, 'basket' cell

cells within this layer itself. The cells of the molecular layer are arranged in a deep and a superficial stratum, their axons synapse with the Purkinje cells, whose dendrites arborize throughout this layer. The cells of the superficial stratum are small, star-shaped and few in number. The deep stratum is composed of larger stellate cells whose axons run transversely in relation to the long axis of the folium and arborize by means of collaterals around the bodies of several Purkinje cells. They are referred to as "basket" cells (see fig. 69.3).

(2) *The intermediate layer of Purkinje cells.* The large flask-shaped bodies of these cells, which are peculiar to the cerebellum, form a layer between the molecular and the granular layers. Their dendrites pass outwards through the entire thickness of the molecular layer where they arborize luxuriantly. The axons of the Purkinje cells enter the white substance, and end by synapsing with cells in the cerebellar nuclei.

The Purkinje cells have been referred to as the "final common pathway" of the cerebellar cortex. It is through these cells that the efferent impulses of the cerebellum pass to the central nuclei of the cerebellum (dentatus, emboliformis, globosus and fastigii) and thence to other parts of the central nervous system.

(3) *The granular layer,* which rests upon the white matter, is composed of small, round, closely packed cells, and numerous nerve fibers. The cells possess four or five dendrites which end in a tuft of branches close to the cell body and connect with those of neighboring cells. One long process

(axon) of each extends into the molecular layer where it connects with the dendrites of a large number of Purkinje cells. Afferent fibers ("moss fibers," p. 1281) arriving via the inferior cerebellar peduncles make connections with the granule cells.

The Cerebellar Nuclei

The cerebellum contains on either side four separate gray masses. These are (a) *nucleus fastigii* (nucleus of the roof), (b) *nucleus globosus*, (c) *nucleus emboliformis*, and (d) *nucleus dentatus*. (The nuclei globosus and emboliformis of primates are comparable to the nucleus interpositus of lower mammals.) The first three of these are phylogenetically older than the nucleus dentatus, which is found only in mammals. The fastigial nuclei, which are the most ancient of all, lie near the midline on either side in the roof of the fourth ventricle. They receive fibers from the paleocerebellum (anterior lobe, pyramid, uvula and flocculonodular lobe), and from the vestibular nuclei and eighth nerve through the inferior peduncle; they also project to the vestibular nuclei. The globose and emboliform nuclei, which are placed more laterally than the roof nuclei, receive fibers chiefly from the anterior lobe. The globose nucleus also receives fibers from the flocculonodular lobe. Both nuclei project through the superior peduncles to the large celled portion of the red nucleus. The more lately acquired dentate nucleus, which is placed most laterally, is a large, crenated mass of gray matter, bent acutely upon itself. It

FIG 69.4 Diagram of a horizontal section through the cerebellum to show the cerebellar nuclei (viewed from in front)

receives fibers from the neocerebellum chiefly from the Purkinje cells of the ansiform lobule. It projects through the superior cerebellar peduncle to the small-celled portion of the red nucleus (and to some extent also to the large-celled part), and to the ventrolateral group of the thalamic nuclei (fig 69.4).

The White Matter, Connections of the Cerebellum with Other Parts of the Central Nervous System—Cerebellar Peduncles

The white matter of the hemispheres is composed of (a) *projection fibers*, i.e., fibers which leave or enter the cerebellum via the peduncles, (b) *association fibers*, which connect different regions of the same hemisphere, and (c) *commissural fibers* connecting cortical areas of the two hemispheres.

The flocculonodular lobe, mainly the nodule, is connected by both afferent and efferent fibers (some of which are relayed in the fastigial and globose nuclei) with the vestibular nuclei and the vestibular nerve. The anterior lobes and the ansiform lobules receive spinocerebellar and ponto-cerebellar fibers, respectively, and project to brain stem and thalamic nuclei. The fibers, afferent and efferent, connecting the cerebellum with extra-cerebellar regions are all carried in three large bundles called the *inferior*, *middle* and *superior cerebellar peduncles*.

THE INFERIOR PEDUNCLES (RUSTIFORM BODIES)
Its fibers are predominantly afferent and convey nonsensory impulses from the labyrinth, joints

voluntary muscles and skin (tactile). Its constituent fiber tracts are (figs 69.2 and 69.5)

A. Afferent (Entering) Fibers

(1) **Dorsal (posterior) spinocerebellar (direct cerebellar) tract.** The fibers of this tract end in the cortex of the anterior and posterior lobes of both sides but mainly of the same side. Some fibers also end in the nodule.

(2) **Dorsal external arcuate fibers** (p. 1193) from the nuclei gracilis and cuneatus of the same side and the *ventral external arcuate fibers* from the corresponding nuclei of the opposite side. These fibers carry impulses aroused by tactile stimuli to the cortex of the paramedian lobule of the posterior lobe and to the lobulus simplex of the anterior lobe.

(3) **Vestibulocerebellar tract** from the vestibular nuclei of the same side and also directly from the vestibular nerve. They pass to the three cerebellar nuclei (nucleus globosus, nucleus emboliformis and mainly to nucleus fastigii) and are relayed to the cortex of the flocculonodular lobe and of the uvula.

(4) **Olivocerebellar tract** arising in the inferior olive of the opposite side and to some extent in the nucleus of the same side. The fibers of this tract end in the cortex of those portions of the vermis and hemispheres constituting the posterior lobe.

(5) **Fibers of the fifth nerve** and possibly of the ninth and tenth nerves which terminate in the pyramid, uvula and paraflocculus.

(6) **Tectocerebellar**, from the colliculi of the mid brain to the cerebellum, the exact course and termination of this tract is unknown.

FIG. 69.5 Diagram of chief cerebellar connections. Afferent fibers black; efferent fibers red. R N, red nucleus; D N, dentate nucleus; F N, fastigial nucleus; N P, pontine nuclei; V N, vestibular nucleus; N C G, nuclei cuneatus and gracilis; S G, cell of Scarpa's ganglion; C C, Clarke's column (lateral nucleus). 1, dentato rubrothalamic tract; 2, dentatothalamic fibers which pass through the red nucleus; 3, frontopontine tract; 4, rubrospinal tract; 5, ventral (indirect) spino-cerebellar tract; 6, fastigiovestibular tract; 6', fastigio-bulbar tract; 7, external arcuate fibers passing from N C G to cerebellum; 8, fasciculus gracilis and cuneatus; 9, vestibulospinal tract; 10, dorsal (direct) spino-cerebellar tract.

B. Efferent (Leaving) Fibers

(1) *Fastigio-bulbar (or cerebellovestibular) tract*. This is a pathway from the flocculonodular lobe and the roof nucleus to the vestibular nuclei and the reticular formation of the medulla. Impulses are relayed from the medulla via (i) the reticulospinal and the vestibulospinal tracts to the spinal centers and (ii) the medial longitudinal

fasciculus to the nuclei of the ocular nerves and into the anterior ground bundle of the cord.

(2) *Cerebello-olivary tract* to the inferior olives of both sides. The latter may be connected with the spinal centers through the olivospinal tracts (p. 1196).

THE MIDDLE PEDUNCLES (BRACHIA PONTIS) are also mainly efferent. Each contains

(a) fibers which arise from cells of the pontine nuclei and end in the cortex of the posterior cerebellar lobe (declive, tuber, and the ansiform and paramedian lobules) of the opposite side, but also in smaller numbers in the homolateral hemisphere and vermis. These fibers constitute the secondary neurons of the corticopontine tracts, particularly the frontopontine-cerebellar tracts (b) fibers which pass from the cerebellar nuclei to the hemisphere of the opposite side (see fig. 69.5)

THE SUPERIOR PEDUNCLES (BRACHIA CONJUGATIVA) enter into the formation of the upper part of the roof of the fourth ventricle and plunge into the midbrain just beneath the inferior colliculi. The superior cerebellar peduncle contains both efferent and afferent fibers but is composed predominantly of the former. It is through the superior peduncle that the cerebellum exerts its main influence upon the cerebral cortex and upon voluntary movement.

A. The efferent fibers arise chiefly from the dentate nucleus but a few are also derived from the nuclei globosus and emboliformis. The Purkinje cells of the cerebellar cortex constitute the primary neurons of these paths. The fibers decussate in the midbrain with those of the opposite side and then divide into an ascending and a descending group.

(1) The ascending fibers pass (a) directly to the lateral ventral nucleus of the thalamus where the impulses are relayed in areas 4 and 6 of the cerebral cortex, (b) from the dentate nucleus in the small celled nucleus (*n. parvocellularis*) of the red nucleus, and from the globosus and emboliform nuclei to the large-celled nucleus (*n. magnocellularis*). The impulses reaching the small celled nucleus (from dentate nucleus) are relayed via the rubrothalamic tract to areas 4 and 6 of the cerebral cortex.

It will be noted that the ascending fibers connect one cerebellar hemisphere with the red nucleus, thalamus and cerebral cortex of the opposite side but as a result of the crossing of the rubrospinal and corticospinal and corticobulbar tracts each cerebellar hemisphere is ultimately connected with the same side of the brain stem and spinal cord.

(2) The descending fibers terminate around cells of the reticular formation of the pons, medulla and cervical cord.

B. The afferent fibers of the superior cerebellar peduncle are

(1) The ventral (indirect) spinocerebellar tract. This ascends through the spinal cord, the medulla oblongata and pons and, reaching the upper level of the latter, turns backwards, arches over the peduncle, enters the anterior medullary sulcus,

and passes within this to the cerebellum. The fibers end in the cortex of the anterior lobe mainly of the same side.

(2) The *telectocerebellar tract* composed of fibers which originate in the superior colliculus. It probably conveys retinal impulses and so constitutes a pathway for visuocerebellar reflexes.

Afferent-efferent (cerebro cerebello-cerebral) circuit. This consists of fibers (frontopontine) from areas 4 and 6 of the precentral motor cortex to the pontine nuclei, and from the latter through the opposite middle cerebellar peduncle to the cerebellar cortex. The activity of the cerebellar cortex is finally centered in the Purkinje cells. Their impulses are transmitted to the dentate nucleus from this nucleus (described on p. 1278) via the superior peduncle to the brain stem where they cross to the red nucleus of the opposite side thence to the lateral ventral nucleus of the thalamus, whence they return to areas 4 and 6 of the cerebral cortex. Through these paths a steady action is exerted upon voluntary movements initiated through the precentral motor cortex.

The fibers reaching the cerebellar cortex via the peduncles are of two main types (a) *moss fibers* which end in mosslike appendages around the cells of the granular layer (fig. 69.3) and (b) *climbing fibers*, which pass outward to the molecular layer, here they give off collaterals resembling the tendrils of a vine which appear to cling to the arborizations of the Purkinje cells. According to Cajal the climbing fibers are derived from the vestibular and pontine nuclei, whereas the direct spinocerebellar and olivocerebellar tracts are constituted of moss fibers. Through their connections with the cells of the granular layer each moss fiber is connected indirectly with a large number of Purkinje cells, whereas a climbing fiber is in communication with only one or two Purkinje cells.

In the foregoing paragraphs the anatomical connections of the cerebellum have been outlined as far as they are known at the present time. Over these many pathways a multitude of afferent impulses bring information to the cerebellum. These different types of afferent impulses are distributed variously to the different lobes of the cerebellum. Thus the vestibular impulses concerned with the position of the body in space pass largely to the flocculonodular lobe, with some going to other parts of the cerebellum.

The impulses from the spinal cord pass over the dorsal and ventral spinocerebellar pathways and the posterior columns (*fasciculi gracilis and cuneatus*) particularly to the anterior lobe. These

bear proprioceptive impulses from muscles, joints and tendons to the cerebellum and in view of this organ's predominant preoccupation with the regulation of reflex muscular activity, this is as one would anticipate. But in addition impulses of tactile origin arrive in large numbers in both the anterior lobe and in the cortex of the neocerebellum or posterior lobe. Furthermore, there is a strict topographic localization of the termination of these impulses. The tactile area of the anterior lobe lies near the midline with each side of the body represented ipsilaterally. The impulses from the lower extremity are received more anteriorly, those from the upper extremity farther back, and those from the face most posteriorly. Tactile impulses are received in the neocerebellum on either side of the vermis. Here the face is represented most anteriorly, then the upper extremity and finally the lower extremity, just the reverse of the representation in the anterior lobe. It is doubtless significant that there are both afferent and efferent connections between these same areas of the neocerebellum and the pre- and postcentral gyri of the cerebral cortex. Although there is no evidence that the cerebellum is in any way concerned with the conscious perception of tactile or other external stimuli, such a possibility cannot be excluded. The significance of the arrival of these tactile impulses in the cerebellum and of the connection of the same areas of the cerebellum with the sensory areas (postcentral) of the cerebral cortex are not understood at the present time.

The cerebellum also receives afferent impulses produced by visual and auditory stimuli and is connected with the cortical centers subserving auditory and visual functions. The auditory and visual center of the cerebellum occupies the midline at the junction of the anterior and posterior lobes. This auditory-visual area overlaps the face area of the tactile center in the cortex of the anterior lobe. Again the significance of these connections is not fully understood.

As we have indicated above, there are many afferent connections from the cerebral cortex to the cerebellum. Those from the precentral motor cortex, which are very numerous, are easily understood. They are essential for the cerebellum's prominent role in the regulation of movement and they pass predominantly to the neocerebellum. The other connections are with the postcentral gyrus, the auditory cortex in Heschl's gyrus and the visual cortex along the calcarine fissure. It is also interesting and doubtless very significant that the connections between all of these areas of

the cerebral and cerebellar cortices are circular, i.e., each area of the cerebral cortex projects to a localized area of cerebellar cortex and the latter in turn projects back to the same cerebral area.

In addition to the prominent vestibular connections from the brain stem, the cerebellum also has extensive connections with other nuclear structures in the midbrain, pons and bulb. Probably the most important of these, other than the vestibular nuclei, is the reticular formation. This important part of the brain stem has both afferent and efferent connections with all lobes of the cerebellum. There are also extensive connections with the red nucleus, the nuclei of the fifth cranial nerve and with the inferior olive. Through these the cerebellum is able to exert its great influence over the control of muscular tone, postural reflexes, righting reflexes and even over the γ fibers and the innervation of the intrafusal fibers of the skeletal muscles. It has been demonstrated that the cerebellum is also capable of exerting a controlling influence over various visceral and vasomotor phenomena as well.

The Experimental Study of the Cerebellum

EFFECTS OF EXCISION OF THE CEREBELLUM AND OF SECTION OF THE PEDUNCLES

The earliest experiments upon the cerebellum were performed by Rolando (1809) and the French neurologist Flourens (1822). The latter removed the cerebellum of pigeons in which he observed as a result of the ablation grave disturbances of equilibrium and abnormal postures of the wings, neck and limbs. Luciani in the latter part of the 19th century, carried out cerebellar ablations upon dogs and observed three cardinal effects: (a) muscular weakness or *asthenia*; (b) a reduction in muscle tone, which he called *atonia* (really hypotonia); and (c) unsteadiness of voluntary movement to which he gave the name *astasia*. These defects, which appeared about a month after the operation, gave rise to a coarse, jerky tremor when an attempt was made to perform any voluntary act.

Dis-equilibrium, due to the removal of the vestibular impulses, which is readily demonstrated in monkeys, causes a staggering, reeling, drunken-like gait. The animal—dog or monkey—stands with limbs spread in order to provide a broad base, sways from side to side with oscillations of the head.

Another characteristic symptom of cerebellar ablation, and which is also seen with lesions of the cerebellum in man, is *dysmetria*—the inability to gauge the strength or duration of the muscular contraction required to execute a certain voluntary act. For example, if the arm reaches for an object it may overshoot the mark (*hypermetria*) or fall short of it (*hypometria*).

The effect of the cerebellum upon muscular tone and muscular reflexes varies with the animal concerned. In the cat and dog the anterior lobe forms a large part of the cerebellum. In these animals excision of the anterior lobe gives rise to a state of increased muscular tone similar to decerebrate rigidity and if decerebrate rigidity has already been produced ablation of this portion of the cerebellum will increase the already existing rigidity. On the other hand stimulation of the anterior lobe of the cerebellum will cause the rigidity characteristic of the decerebrate state to relax. From this evidence it has been concluded that the anterior lobe of the cerebellum is concerned with the inhibition of the stretch reflexes and the postural reflexes of the skeletal musculature. Certainly this is an important part of the function of this part of the cerebellum in these animals but it has now been shown that stimulation of the cortex of the anterior lobe and of the fastigial nuclei to which it projects can produce both inhibition and enhancement of muscular rigidity. It thus appears that the anterior lobe of the cerebellum is an organ for the regulation of muscular tone rather than merely an inhibitor of reflex muscular activity. It should be noted, however, that these effects upon muscular tone and muscular reflexes are most marked in the carnivores. They are much less pronounced in subhuman primates and still less so in man. In fact, nothing resembling decerebrate rigidity or enhancement of pre-existing rigidity has ever been reported as the result of a cerebellar lesion in man. In human beings if there is any alteration in muscular tone as the result of a cerebellar lesion it is in the direction of a decrease. The involved extremities tend to become flaccid or hypotonic and tendon reflexes may become pendular.

Unilateral destruction or damage of the cerebellum causes a reduction in tone of the muscles of the same side and a tendency to fall to that side.

Section of the peduncles Section of all six peduncles causes effects identical with those of complete decerebellation, and division of the three of one side results in effects described for unilateral

ablation. In the chimpanzee, *asynergia*, *hypotonia*, *easy fatigability* and a *coarse tremor* appear on the same side as the section. Severance of one superior peduncle causes at first defects somewhat similar although less severe than those following unilateral section of all three peduncles and is later compensated for through those which have been left intact. Little is known with respect to the disabilities following section of one or both middle peduncles. A lesion interrupting the fibers of the inferior peduncles causes mainly equilibrium disturbances (due to division of vestibular connections), and ataxia as a result of the interruption of spinocerebellar fibers. Compensation through the intact cerebellum tends to occur later, so that the effects become progressively less severe.

Even after unilateral section of the three peduncles compensation is brought about after a time through the remaining half of the cerebellum and through the frontal lobes (Botterell and Fulton).

The experiments of Aring and Fulton indicate that the nervous mechanism involved in the production of cerebellar tremor lies in the excitable part of the cerebral cortex (area 4 and the upper part of area 6). Removal of these areas after contralateral section of the cerebellar peduncles abolished the tremor. Large parts of the cortex of the cerebellum can be removed with little permanent neurologic deficit so long as all of the cortex of one hemisphere is not removed. On the other hand damage to the central nuclei or the cerebellar peduncles produces much more severe and lasting disturbances.

STIMULATION OF THE CEREBELLUM

Electrical stimulation of the cerebellum, both of the cortex and of the central nuclei, has supplied relatively little information concerning the functions of this important structure. The results are far less than those produced by stimulation of the precentral motor cortex of the cerebral hemispheres. This is rather surprising in view of the fact that the cerebellum is primarily concerned with muscular activities. In general the responses to stimulation of both the cerebellar cortex and the nuclei are slow and tonic in character. They are also diffuse and complex in contrast with the well localized discrete movements which can be obtained by stimulating the precentral gyrus. It is also common to obtain diphasic responses, i. e. one type of response during stimulation which is followed by an opposite type of

response after the stimulation has ceased. Many of the responses concern movements of the eyes toward the same side as that to which the stimulus is applied, or a movement of the eyes to a position in which they gaze forward. If there is a "rebound" response following the termination of stimulation the eyes turn toward the side opposite that on which the stimulus is applied. Such movements of the eyes may or may not be associated with similar movements of the head either to the side or straight ahead. Stimulation may give rise to movements involving the head, extremities, trunk and tail in the long axis of the body producing a concavity of the body on the side stimulated. Stimulation of the cortex of the anterior lobe and of the fastigial and globose nuclei sometimes causes flexion of the ipsilateral limbs and extension of the contralateral ones. It is interesting to note that most responses are obtained by stimulating the anterior lobe and the fastigial and globose nuclei. Stimulation of the posterior lobe or neocerebellum or of the dentate or emboliform nuclei is far less effective. This is surprising in view of the fact that these latter structures are the ones connected with the precentral motor cortex and primarily concerned with the regulation and integration of voluntary muscular activity.

Localization in Cerebellar Cortex

In recent years representation in the cerebellum, afferent and efferent, have been shown to be much more circumscribed than had been supposed. Yet, even so, localization has not been found to be as precisely discrete as in certain regions of the cerebral cortex, e.g., in the motor area. Owing to the double crossing of the pathway for impulses from the cerebellum, as they ascend in the midbrain (dentatorubral tract) and as they descend to the spinal cord (rubrospinal tract), each half of the cerebellum exerts its influence mainly on the musculature of the same side of the body.

FIG 69-6 Spinocerebellar receiving areas for hind limb, fore limb and face (vibrissae) in the cat as determined by the method of evoked potentials (From Adrian)

Representation in the cerebellar cortex of somatic receptive areas has been studied by Dow, by Snider and his associates, and by Adrian by means of the method of evoked potentials. Adrian recorded the potentials evoked in the cortex of the anterior lobe of cats and monkeys by means of a fine wire electrode inserted beneath the surface. Various areas over the limbs and face were stimulated by touch, pressure, joint movement, or stretching of muscles (fig. 69-6).

The representation in the anterior lobe of the different somatic areas is in reverse order. That is to say, the hindlimb area is placed anteriorly to the areas for the forelimbs and face. Thus, stimulation of the hindlimb evoked potentials from the lobulus centralis and an anterior strip of the culmen, stimulation of the forelimb induced responses from the remainder of the culmen, and stimulation of the face (vibrissae in cat) from the lobulus simplex. The spinocerebellar impulses from the tail are probably received by the most anteriorly situated part of the anterior lobe, namely, in the lingula.* An even, more precise localization was mapped out within these areas, in the area for the hindlimb, the foot is in front of the knee and the knee in front of the thigh, in the forelimb representation the shoulder is in front of the wrist, with the wrist and hand following in corresponding order.

Potentials were also evoked from the anterior lobe by stimulation (electrical or local application of strychnine) of the motor area of the cerebral cortex, i.e., by causing a discharge over corticopontine and pontocerebellar pathways. The anterior part of the precentral motor cortex (area 6) projects to the lateral part of the neocerebellum, where the posterior part (area 4) projects to more medial structures in both the anterior and posterior lobes. Most of this cerebrocerebellar projection is crossed but some of it is to the ipsilateral cerebellar hemisphere. The projections of area 4 to the cerebellar cortex correspond closely with the termination of tactile impulses. The topographic representation of the face, arm and leg of impulses from the precentral motor cortex followed the same pattern as that for tactile impulses. In the anterior lobe the "leg" area lies most anteriorly and the "face" area most posteriorly. In the posterior lobe the reverse is true. Stimulation of the caudate nucleus will evoke alterations in electrical potentials in the posterior lobe.

*In the giraffe the lobulus simplex is greatly enlarged, and in monkeys with a prehensile tail the lingula is elongated.

Impulses from the auditory and visual systems, from the olfactory bulbs and from the trigeminal ganglia are also conveyed to the cerebellum. Sound, or flashes of light, evoke potentials from an area covering the lobulus simplex, declive and tuber, and extending laterally into the ansiform lobule. The visual impulses are relayed to the cerebellum from the superior colliculus, the auditory from the inferior colliculus. The tectocerebellar tracts probably provide the pathways for these impulses. The auditory and visual cortices project to the same areas.

From ablation experiments topographical localization similar in character to that described above for the spinocerebellar and corticopontine cerebellar systems has been demonstrated for the efferent side. The tail muscles are represented in the linguli, the muscles for the hindlimbs in the lobulus centralis, the forelimb muscles in the culmen, and the cervical and facial muscles in the lobulus simplex. Representation of the limbs in the middle lobe of Inguar (ansiform lobule, declive and tuber) has not been demonstrated, but from the relatively enormous size of this part of the cerebellum in higher mammals and from the fact that it (ansiform lobule) is the chief receiving station for corticopontocerebellar impulses, it can not be doubted that it is of paramount importance in volitional movement.

The flocculonodular lobe, through its vestibular connections is concerned with equilibratory function, severe disturbances of balance resulting from its ablation. Ablation of the nodule in dogs confers complete immunity to motion sickness (Bard and associates). Removal of no other part of the cerebellum or of the cerebral cortex has this protective action (ch. 64). Ablation of the *nodule* and *flocculus* (flocculonodular lobe, p. 1276, 1277) in monkeys or of the nodule and part of the uvula (Dow) which causes injury to vestibular paths, is followed by pronounced disturbances of balance. In man a lesion of this part of the vermis is also associated with disturbances of equilibrium. Removal of the *nodule* alone in monkeys is followed by oscillation of the head and neck (and, in some instances of the whole trunk) falling backwards and an unsteady gait with the extremities spread widely apart to provide a broader and thus more certain base.

The functions of the uvula are largely obscure, its destruction alone is followed by some transient disturbance of equilibrium. Very little is known of the function of the *pyramid*, although it appears to be concerned in some way with vision or eye movement. Its excision causes no defect of bal-

FIG. 69-7 Subdivisions of pontocerebellar receiving area in the monkey showing their connection with different parts of the motor cortex (From Adrian).

ance. Ablation of the *pyramid* in the monkey results in an inability to halt its forward progression in time to prevent it from crashing into some obstacle. Faradic stimulation of the *pyramid* elicits an upward movement of the eyes. Fulton suggests from this fact and the preceding observation the possibility of the *pyramid* being concerned in some way with the integration of proprioceptive impulses essential in judging distance.

Summary of Functional Localization

(1) All cerebellar activities afferent and efferent, are carried out beneath consciousness.

(2) In the anterior lobe are represented in regular order the various receptive and muscular regions of the body. It is concerned mainly with the adjustments of muscle tone and synergic action necessary for posture in subprimate mammals, but appears to be much less important in primates.

(3) The posterior lobe (middle lobe of Inguar) (neocerebellum) is the chief receptive region for corticopontocerebellar tracts. It is most highly developed in the primates. It is concerned with the integration and regulation of well coordinated muscular activities.

(4) The flocculonodular lobe, the most ancient part of the cerebellum, is intimately connected with the vestibular apparatus both through the vestibular nuclei and directly by fibers from the vestibular nerve and therefore constitutes an important part of the neural mechanisms underlying equilibratory function.

(5) The functions of the uvula and *pyramid* are little known, although the latter probably has to

do with eye movements and the former, to a minor degree, with equilibrium

GENERAL SUMMARY OF CEREBELLAR FUNCTION

The cerebellum is concerned primarily with the regulation of muscular activity. It does not initiate movement and its removal does not result in paralysis but it does coordinate the various muscles concerned in any given act to produce smooth, efficient movement. When the precentral motor cortex initiates a voluntary movement it simultaneously "informs" the cerebellum over the frontopontocerebellar pathway. The cerebellum has also been "informed" regarding the position of the body in space over the vestibulocerebellar connections, of the position of the muscles and of the trunk and extremities over the spinocerebellar pathways and of the contact of the body with other structures by means of tactile impulses. The cerebellum is then able to regulate reflexes and the contraction or relaxation of the various muscles concerned by means of its connections with the precentral motor cortex, the reticular formation, the vestibular nuclei and perhaps the inferior olive. Beevor has classified the muscles concerned in voluntary muscular activity as follows:

(a) **PRIME MOVERS OR AGONISTS**, those whose contraction is essentially responsible for the movement of the part

(b) **ANTAGONISTS**, those which oppose the prime movers

(c) **SYNERGISTS**, those which assist the prime movers and reduce unnecessary movements to a minimum

(d) **FIXATION MUSCLES**, those whose contraction causes the fixation of the neighboring joints and maintains the limb or body in a position appropriate for carrying out the particular movement

Normally these muscle groups act as a unit. The contraction of the prime mover, e.g., the biceps, is accompanied by inhibition of the contraction of its antagonist, i.e., the triceps. The reciprocal inhibition, however, is not absolute, the antagonistic muscle as shown by Tilney and Pike, gives a coincident but weaker contraction, and thus serves the function of a "brake" or "snubber" to check the action of the agonist. At the same time the fixation muscles of the neighboring joint contract, thus enabling the agonist to exert its force with a minimum of waste effort. Any increase in the force of contraction of the agonist is accompanied by a corresponding rise in

tone of its opponent (antagonist). Also, the muscles of fixation and the synergists contract more powerfully as the contraction of the prime movers increases, whereas groups of fixation muscles and synergists, which in a weaker movement remain quiescent, may be called into play. To give an example, when the fingers are closed with moderate force the only fixation muscles which show activity are the extensors of the wrist. When, however, the fist is clenched forcibly, muscles of the elbow and even those of the shoulder contract to fix these joints. Through such action between the various muscles taking part in a given act, smoothness and steadiness of movement are ensured and muscular force thereby economized. After destruction of the cerebellum these nice cooperative actions are lost. The synergia results in jerkiness, overaction and imperfect muscular control (ataxia). "The force of a given muscular movement is not graded with precision for the work to be done, but 'overshoots the mark'." This led Babinski to suggest originally, that cerebellar activity (through the cerebellar cortex) served as a "brake" to check such a tendency, that is to overcome the inertia of the moving part.

It has also been shown that the cerebellum exerts some controlling or regulatory influence over various visceral and vasomotor phenomena. This influence does not appear to be great. The possibility exists that the cerebellum may exert some control over the perception of stimuli but this has never been conclusively demonstrated. There is evidence that the cerebellum, like the reticular formation, exerts some influence over the γ motoneurons and thus over the muscle spindles which are proprioceptive end organs.

The Manifestations of Cerebellar Disease

The signs of cerebellar disease are much more pronounced in acute lesions, e.g., abscess, hemorrhage or trauma, than in those, e.g., tumor, which develop more gradually. In slowly developing lesions or after the subsidence of acute cerebellar disease a certain degree of compensation for the cerebellar defect always occurs. The majority of the signs of cerebellar disease are the result fundamentally of *asynergia* of the voluntary muscles.

⁴ Holmes denies that the cerebellum exerts any specific function in respect to the distribution of tone among various muscles acting synergically. The steadying action which tonic muscles normally exert over their antagonists is absent in cerebellar disease but Holmes maintains that this is due merely to the general hypotonicity

According to Holmes the chief features of cerebellar lesions are (1) *hypotonia*, (2) *asthenia*, *fatigability* and *slowness of movement*, (3) *tremor*, (4) *asynergia*, (5) *decomposition of movement*, (6) *dysmetria*, (7) *rebound phenomenon*, (8) *adiadochokinesis*, (9) *vertigo and past pointing*, (10) *deviation of the eyes and nystagmus*, (11) *altitude and gait*, (12) *disturbances of speech*, (13) *reflexes*.

HYPOTONIA This is usually a prominent feature in acute cerebellar lesions. The muscles are flabby. The limbs for this reason assume unnatural attitudes and can be moved passively into positions of extreme flexion or extension. The extremities flop about when shaken vigorously and, if the patient is suddenly rotated when standing, the arms swing loosely from the shoulders.

ASTHENIA, FATIGABILITY AND SLOWNESS OF MOVEMENT The muscles on the affected side are definitely weakened and tire easily. The commencement of any voluntary movement is delayed, and both contraction and relaxation phases are abnormally slow. Neither hypotonia nor asthenia are notable features in chronic lesions. Some also question whether weakness is a manifestation of cerebellar deficit, but Holmes considers it to be due to involvement of the cerebellar nuclei.

TREMOR This is a coarse involuntary rhythmic oscillation which supervenes upon any attempt at voluntary movement (*intention tremor*), or when the muscles are engaged in maintaining a steady posture (*static tremor*), as in holding the head erect on the arms outstretched. Removal of the precentral gyrus will abolish such a tremor. This probably is due to the destruction of the corticospinal fibers which arise there.

ASYNERGIA It should be pointed out that this term as used by Holmes has a much more restricted meaning than that which is usually given to it. This observer applied the term especially to the asynchronism observed between the actions of the fixation muscles and the prime movers, as well as to the lack of cooperation which normally exists between the muscles of the limbs, trunk and neck during walking and standing, and other acts necessitating postural adjustments of the various members of the body against gravity. For example, when the patient is asked to clench his fist, the extensors which normally fix the wrist as the fingers are flexed, either contract too early, and so over-extend the joint, or too late. In the latter event the wrist is flexed as the fist closes. Also, the patient may fall when he throws his head back owing to his failure to flex his knees, and so maintain his center of gravity over his

base. Similarly when he attempts to sit upon a low stool he may fall backwards because he cannot at the same time flex his trunk at the hips.

DECOMPOSITION OF MOVEMENT The patient "breaks down" a given movement into its parts. When, for example, he is asked, as he lies in bed, to extend his arm vertically, and then to touch his nose with his forefinger, the latter movement is not performed naturally by simultaneously lowering the arm and bending the elbow. The extended arm is first lowered to the side, not until this position is reached is the elbow flexed and the finger brought to the nose.

DYSMETRIA is the lack of ability to adjust the force of the contraction necessary for the accomplishment of a given act. For example, when asked to touch a point with his finger the patient overshoots the mark or, less commonly, fails to reach it. Dysmetria in a lower limb may be demonstrated by the heel to knee test, when the patient, while recumbent, is directed to rest the heel of the affected side upon the opposite knee. He brings it in contact with the thigh or with the leg below the knee. Dysmetria is another manifestation of the general lack of synergic muscular control.

REBOUND PHENOMENON If the patient is asked to attempt a movement against a resistance which is then suddenly removed, the limb moves forcibly in the direction towards which the effort was made. For example, if the observer holds the wrist of the patient, then asks him to bend the elbow, and, while he is making the effort, the forearm is suddenly released, flexion of the arm occurs with an unusual degree of force. This rebound phenomenon can be attributed to the absence of the 'braking' action (p. 1236) of the antagonistic muscles.

ADIADOCHOKINESIS (a = private, diadocho = succession, kinesis = movement) is the name given by Babinski to the inability to execute alternating movements rapidly, e.g., pronation and supination of the forearm, or flexion and extension of the fingers.

PAST POINTING AND VERTIGO (p. 1181) When the patient with his eyes closed is asked to raise the arm of the affected side and to touch a prescribed mark, the arm deviates outwards, rarely inwards. When directed to move the finger in the horizontal plane and touch the mark the arm in some cases, deviates upwards, in others downwards. Vertigo, the sensation that the environment is rotating, is not a symptom of cerebellar disease but of involvement of the vestibular nuclei or of the labyrinth in the inner ear.

DEVIATION OF THE EYES AND NYSTAGMUS. In

an acute unilateral lesion there may be conjugate deviation of the eyes to the uninjured side. In all probability this is the result of involvement of or pressure on the brain stem and not of the cerebellar involvement *per se*. When the patient is asked to look at an object in front of him the eyes move into position but then slowly deviate again to the uninjured side, after full deviation the eyes may return again to the central position with a sharp jerk. These alternate horizontal movements occur repeatedly and are known as nystagmus (p. 1179). Although no deviation of the eyes is evident, nystagmus can sometimes be demonstrated in a patient with a cerebellar lesion when he is asked to turn his eyes towards either the injured or the uninjured side, the eyes are moved in the direction indicated and then deviate slowly towards the midline, only to be returned in a series of jerks toward the point in which he is attempting to look. The nystagmus is due to injury of vestibulocerebellar paths (see also p. 1279).

Skew deviation of the eyes is sometimes observed with acute cerebellar disease but is probably the result of involvement of the brain stem.

ATTITUDE AND GAIT Cerebellar disease sometimes results in abnormal attitudes. The trunk may be concave towards the affected side and sometimes rotated with the affected shoulder advanced. Rotation of the head with the chin towards the sound side, and flexed towards the shoulder of the affected side is not uncommonly seen in unilateral cerebellar disease. (This attitude is probably due to an associated lesion of the vestibular paths in the brain stem.) In standing the body is inclined towards the side of the lesion and tends to fall to that side. Falling backwards or forwards may occur (especially in lesions of the vermis). The abnormal attitudes of the limbs resulting from the muscular hypotonicity when this is present, have been mentioned.

The gait is often staggering, reeling or lurching in character. The patient's line of travel is not straight but tends to be curved, the deviation is towards the affected side. When he is able to see his way he attempts to correct his tendency to deviate to one side by bringing himself back from time to time to his intended line of travel. Thus he follows a zig zag course to his objective. The movements of the lower limbs are ataxic, they are often thrown about in an awkward, uncontrolled manner. The upper extremity on the affected side does not swing as the patient walks as does the normal one.

DISTURBANCES OF SPEECH are due to asynergia of the muscles of phonation and articulation. It is seen most frequently with diffuse degenerative lesions rather than with localized ones. The speech may be drawing, scanning, singsong or explosive in type.

THE REFLEXES The cutaneous reflexes are normal and the deep reflexes, with the exception of the knee jerk, show as a rule no marked departure from the normal. The knee jerk is not uncommonly pendular in character. That is to say, when the leg is hanging free a tap on the patellar tendon causes a slower, less brisk response than normal, but one of greater amplitude. Also, unlike the response of the sound side, the return excursion of the leg is not arrested when, as a result of the influence of gravity, it reaches the resting position, but swings beyond. Several to and fro movements follow before the limb finally comes to rest. This behavior is evidently due to the hypotonicity of the flexor and extensor muscles and thus to a lack of the restraining effect which they normally exert upon one another to prevent exaggerated excursions of the limb in either direction.

Muscle sense and other forms of sensation are unaffected in cerebellar disease. The following are the principal types of cerebellar lesion: (1) *tumor*, (2) *abscess*, (3) *injury* e.g., gunshot wounds, (4) *degenerations* of (a) the cerebellar cortex, (b) the middle and inferior peduncles, (c) more rarely, of the cerebellar nuclei and superior peduncles, (d) of the spinocerebellar tracts, e.g., Friedreich's ataxia, a hereditary condition.

A lesion involving the neocerebellum (superior vermis and hemispheres) is associated with hypotonia, dysmetria, weakness, slowness and irregularity of voluntary movement, tremor and nystagmus. In disease of the flocculonodular lobe, there are marked disturbances of balance with a swaying, staggering gait and a tendency to fall backwards. There is no syndrome of the anterior lobe in man.

water content of a unit weight of spinal fluid is somewhat greater than that of blood

The question arises, how is the fluid formed? It will be apparent from the table that if certain constituents are investigated, diffusion from the blood plasma will be sufficient to account for the findings. However, before a decision can be reached as to whether the process is one of simple diffusion or of secretion, the concentrations of all the substances on both sides of the semipermeable membrane (the choroid plexus) must be determined. This was done by Flexner whose findings indicate that work must be done to form this fluid, i.e., that it is not merely a filtrate from blood plasma. Since the hydrostatic pressure of the capillary blood is believed to be greater than that of the spinal fluid, except under grossly abnormal conditions, this factor and the secretory power of the cells of the plexus are the two forces to be considered. Thermodynamic considerations indicate that the hydrostatic pressure difference would provide only a small fraction (about one-thirteenth) of the energy necessary. This leads to the conclusion that ultrafiltration will not account for the formation of the cerebrospinal fluid and that the cells of the choroid plexus perform work in this process.

The Amount and Pressure

Accurate figures for the volume of the fluid in the various age groups are not available. The methods used to investigate the problem involve a change of conditions which invalidate the results secured. The total volume in healthy adults has been given as approximately 200 cc. The normal rate of formation has not been established. When artificial drainage is provided very large volumes, several liters per day, may drain away. The results of the urinary excretion of dye injected into the cerebrospinal space suggest that the volume of fluid is renewed every three or four hours but this rate of formation is probably too high. In experiments in which precautions were taken to interfere as little as possible with normal pressure conditions, Flexner and Winters found in experiments with adult cats, that approximately 12 cc. of fluid per day could be collected from a cannula fixed in the aqueduct. Of course, this figure bears no relationship to the amount formed in man. The pressure of the cerebrospinal fluid may be taken as 110 to 175 mm. of cerebrospinal fluid for man in the recumbent position. Pressure on the internal jugular vein or the rise of venous pressure produced by crying or cough-

ing causes an increase in pressure of the fluid because of the direct transmission of the venous pressure to the cerebrospinal fluid.

EFFECT OF FLUID AND SALT INJECTIONS ON PRESSURE (WEED AND HUGHSON) When large volumes of isotonic solutions are injected intravenously there is a transient rise in venous and cerebrospinal pressure. Hypotonic solutions cause a prolonged rise in fluid pressure due presumably to the passage of fluid into the brain. There is a less marked and more transient rise of venous pressure.

Hypertonic solutions (30 per cent NaCl) administered intravenously, produce a fall in cerebrospinal pressure which may persist for a considerable period. Fluid is attracted by the raised osmotic pressure of the blood from the brain substance, perivascular spaces, etc., into the blood stream. Such a dehydration is not limited to the brain; other tissues react similarly. As the blood volume is thus increased urinary output is also increased and the patient is soon dehydrated. Accordingly, the use of hypertonic solutions or of urea injected intravenously is very limited. Such treatment may be useful as an emergency measure in preparing a patient for operation or in tiding him over until a surgical decompression can be made or in reversing a vicious circle of cerebral edema and venous congestion.

EFFECT OF CHANGE OF POSITION ON PRESSURE It is important to realize that the fluid in the subarachnoid space of the brain and spinal cord may be regarded as a single column (approximately 600 mm. long in the man of medium height). There are no structures to act as valves and restrictions of flow are not sufficient to interfere appreciably with this relationship. The change in pressure produced by a change of position can largely be predicted by hydrostatic considerations. The pressures in the lumbar and occipital regions are identical when the subject is horizontal. When the patient is sitting the pressure of the fluid in the lumbar region will vary with the length of his back and his posture. Using a water manometer the upper level of the fluid will reach to the midthoracic region. Accordingly, with the patient sitting the intracranial pressure and the pressure in the cisterna magna will be below atmospheric pressure under normal conditions.

Function of the Cerebrospinal Fluid

The fluid within the elastic meningeal sac serves as a protective covering for the central nervous system. By change in its volume, compensation

for change in the amount of blood is effected, and the contents of the cranium thus tend to remain of constant volume. It is doubtful if there is any considerable exchange of metabolic materials between the nerve cells and the fluid.

Ventriculograms and Encephalograms

The location of air injected into the cerebral ventricles (ventriculography) or through a lumbar puncture (pneumoencephalography) can be visualized by the X-rays. By thus outlining the ventricular system alterations in the size and position of the ventricles can be detected. This is often of great value in neurological diagnosis.

Radio-opaque oils (pantopaque) may be injected into the ventricles of the brain or into the spinal subarachnoid spaces. In this way these spaces may be visualized roentgenographically. This is particularly useful in the diagnosis of space-occupying intraspinal lesions.

Hydrocephalus

A consideration of the formation, circulation and absorption of the spinal fluid leads to the assumption that hydrocephalus might be produced by (1) Increased rate of formation of fluid. A very definite increase can be produced by the administration of hypotonic solutions (Weed), but the decreased tonicity of the blood cannot be maintained long enough to permit the develop-

ment of hydrocephalus. Clinically papillomas of the choroid plexuses might produce this condition and suggestive cases have been reported (Davis). (2) Obstruction to the passage of the fluid. An obstruction by tumor or inflammation in the right foramen of Monro, for example, would produce a right internal hydrocephalus. Blockage of the aqueduct of Sylvius would produce a bilateral internal hydrocephalus as would an obstruction in the fourth ventricle or at the foramina of Magendie and Luschka. (3) Interference with the absorption of fluid by way of the arachnoid villi. Blockage of many of these villi or interference with their function by other means may lead to an external hydrocephalus. Increased intracerebral venous pressure may produce a temporary decrease in absorption of fluid.

THE AUTONOMIC NERVOUS SYSTEM

(Synonyms—*involuntary nervous system, vegetative nervous system*)

The *autonomic nervous system* has been touched upon in many of its aspects in other sections of this book. There remains to be given an account of the structural plan of this system as a whole, a general summary of its functions and of the structures which it innervates. From anatomical, physiological and pharmacological viewpoints the autonomic system falls naturally into two main divisions—the *sympathetic* or *thoracolumbar outflow* and the *parasympathetic* or *craniosacral outflow* (see fig. 71 I).

The Sympathetic Division

The cells of origin of the sympathetic division are situated in the lateral horns of the spinal cord (intermediolateral cell column) from the 8th cervical or 1st thoracic to the 2nd or 3rd lumbar segments. The axons of these cells leave the cord by the corresponding anterior nerve roots and synapse with nerve cells in one or another of the outlying ganglia. The fibers arising from the spinal cord are medullated and are called *preganglionic*, those arising from cells of the ganglia are nonmedullated, and are called *postganglionic*. Evidence for the existence of a higher center in the posterior region of the hypothalamus has been considered in chapter 66, and in the cerebral cortex in chapter 67.

The ganglion cells are all motor or secretory in function (p. 1301). They have no afferent connections from the periphery. However, many afferent fibers from the various visceral and blood vessels pass through the sympathetic nervous system. They have their ganglion cells in the posterior root ganglia as have the somatic afferent fibers.

The ganglia are arranged in three systems or groups: (A) *paravertebral*, (B) *prevertebral* (or *collateral*) and (C) *terminal* (or *peripheral*).

A THE PARAVERTEBRAL GANGLIA AND THE GANGLIATED CORD

The paravertebral group lies in close relation to the vertebral bodies and consists, on each side,

of a series of some 22 ganglia connected together by intervening fiber tracts to form a nodular cord extending from the base of the skull to the front of the coccyx. This is known as the *sympathetic chain* or the *gangliated cord of the sympathetic nervous system*. It will be described in sections.

The Cervical Part of the Sympathetic Chain

The cervical part of the sympathetic chain possesses three ganglia—the *superior*, *middle* and *inferior cervical ganglia*. They are relatively large and are believed to result from the fusion of two or more smaller ganglia.

THE SUPERIOR CERVICAL GANGLION, situated below the base of the skull, is the largest of the three. It receives preganglionic fibers from the upper thoracic segments of the spinal cord, and its cells supply fibers (postganglionic) to the vessels, glands and cutaneous muscle of the head. It is probably formed by the fusion of the uppermost three or four cervical ganglia. Its branches are:

(1) THE INTERNAL CAROTID NERVE. This nerve composed of postganglionic fibers, arises from the upper pole of the superior cervical ganglion and, passing into the cranium with the artery of the same name, forms the internal carotid and cavernous plexuses.

(a) The *internal carotid plexus*, situated on the lateral side of the internal carotid artery sends branches to the following:

(a) The abducent nerve.

(b) The tympanic branch of the glossopharyngeal nerve.

(c) The sphenopalatine ganglion. These fibers pass by way of the deep petrosal nerve and the nerve to the pterygoid canal which is formed by the union of the former nerve with the great superficial petrosal nerve. Orbital branches of the sphenopalatine ganglion convey sympathetic fibers to the lacrimal gland, the soft palate, nasopharynx and pharynx receive fibers through the palatine and pharyngeal branches of the ganglion.

(d) The semilunar (trigeminal) ganglion.

The sympathetic fibers pass through the sphenopalatine and semilunar ganglia without interruption.

FIG 71.1 Showing plan of autonomic nervous system from a functional viewpoint. C.G., ciliary ganglion. The celiac, inferior mesenteric and hypogastric ganglia are represented in this order from above downwards, by the circles in the lower right portion of the diagram.

(1) The *cavernous plexus*, situated on the inner side of the internal carotid artery as it lies in the cavernous sinus, sends branches to the following

(a) The oculomotor, trochlear and abducent nerves and the nasociliary branch of the ophthalmic division of the trigeminal nerve. Through the long ciliary nerves (twigs of the nasociliary nerve), sympathetic fibers are conveyed to the dilator pupillae muscle (see also p. 1410).

(b) The ciliary ganglion, through which the sympathetic fibers pass without interruption into the short ciliary nerves. These fibers provide an additional pathway for sympathetic impulses to the dilator of the pupil.

(c) The pituitary body (vasomotor).

Through the communicating branches of the cavernous plexus the vessels of the eyeball and nasal mucosa are supplied with constrictor fibers, and the skin of the nose with vasoconstrictor, motor (smooth muscle) and secretory (sweat) fibers. The terminal filaments of the internal carotid

and cavernous plexuses are continued as delicate networks over the anterior and middle cerebral arteries to the minute vessels of the pia mater, and along the ophthalmic artery to the structures of the orbit.

(2) Branches to and distributed with the UPPER FOUR CERVICAL NERVES.

(3) Twigs to the GANGLION JUGULAR AND GANGLION NODOSUM OF THE VAGUS, to the PETROUS GANGLION OF THE GLOSSOPHARYNGEAL NERVE and to the HYPOGLOSSAL NERVE.

(4) Filaments to the CAROTID SINUS and CAROTID BODY.

(5) Fibers to LARYNGEAL and PHARYNGEAL PLEXUSES.

(6) The SUPERIOR CARDIAC NERVE to the cardiac plexuses.

(7) Branches which ramify in a plexiform manner upon the external carotid artery—the EXTERNAL CAROTID PLEXUS. This plexus is continued over the branches of the external carotid and sup

plies fibers to the vessels, sweat glands and cutaneous muscles of the face, and to the thyroid gland. Filaments from the plexus investing the facial artery pass to the submaxillary ganglion. The plexus on the middle meningeal artery sends fibers to the otic ganglion, these pass without interruption into the auriculotemporal nerve through which they reach the parotid gland.

THE MIDDLE CERVICAL GANGLION is formed presumably by the coalescence of the 5th and 6th cervical ganglia. Its branches are as follows:

(1) Branches to the 5th and 6th cervical nerves and thence to the blood vessels, sweat glands and cutaneous muscle within the area of distribution of these nerves.

(2) *The middle cardiac nerve* to cardiac plexuses.

(3) Branches which extend along the inferior thyroid artery to the *thyroid* and *parathyroid* glands.

THE INFERIOR CERVICAL GANGLION probably represents the union of the 7th and 8th cervical ganglia. In the dog and cat, and in most human subjects, it is usually fused with the first thoracic ganglion, and occasionally with the second as well, to form the so-called *stellate ganglion*. It gives off the following branches:

(1) Branches to the 7th and 8th cervical and the 1st thoracic nerves sometimes also to the 6th cervical and the 2nd thoracic.

(2) *The inferior cardiac nerve* to cardiac plexuses.

(3) Branches which form plexuses upon the subclavian artery and its branches. Sympathetic fibers are thus carried into the cranial cavity along the vertebral artery, and over the axillary and commencement of the brachial.

The Thoracic, Lumbar, and Sacral Ganglia

The thoracic ganglia are 10 or 12 in number on each side. They are evenly spaced, one to each spinal segment. As mentioned above the first thoracic and inferior cervical ganglia are commonly partially or completely fused to form an irregularly shaped mass, called the *stellate ganglion*. There are usually 4 lumbar and 4 or 5 sacral ganglia.¹ The sacral portions of the two sympa-

¹ Small accessory ganglia, called *intermediate ganglia*, are found outside the sympathetic chain proper, attached to the ram communicantes close to the spinal nerve roots in the cervicothoracic and lumbar regions. From these ganglia sympathetic postganglionic fibers proceed for distribution by the brachial and lumbar plexuses to the limb vessels. Preganglionic fibers leaving the cord by the anterior roots and entering the intermediate ganglia without passing through the sympathetic chain offer a possible alternative pathway

thetic trunks converge below and fuse upon the anterior surface of the coccyx to form a terminal swelling—the *coccygeal ganglion* or *ganglion impar*.

B THE PREVERTEBRAL (OR COLLATERAL) GANGLIA

These lie in the thorax, abdomen and pelvis in relation to the aorta and its branches. The larger of the prevertebral ganglia are (a) the *celiac* (solar or semilunar) *ganglion*, lying in relation to the origin of the celiac artery, (b) the *superior mesenteric ganglion*, situated below the origin of the superior mesenteric artery, and (c) the *inferior mesenteric ganglion*, which bears a corresponding relation to the inferior mesenteric artery, this ganglion is rarely present in man (see also p 1300).

C THE TERMINAL GANGLIA

These consist of small collections of ganglion cells situated in close relation to the innervated organs, especially those of the pelvis, e.g., the bladder and rectum.

THE OUTFLOW OF SYMPATHETIC FIBERS FROM THE CENTRAL NERVOUS SYSTEM

It has already been stated that the cells giving rise to the sympathetic fibers (p 1294) are situated in the thoracic and upper lumbar segments of the cord. It is from this limited region (8th C or 1st T to 2nd or 3rd L inclusive) that the sympathetic (preganglionic) fibers emerge. *This region constitutes the only outlet for sympathetic impulses*. So the term *thoracolumbar outflow* simply means the sympathetic division of the autonomic nervous system. The fibers emerge from the spinal cord through the anterior root of the spinal segment in which their cell bodies are placed. In a cross section of the anterior root they appear as fine medullated fibers (2.5 μ or less in diameter) intermingled with the larger, medullated, somatic (motor) fibers. They separate almost immediately, however, from the motor fibers of the anterior root—which are concerned with movement of the skeletal musculature—and enter the corresponding ganglion of the sympathetic chain. Thus, the spinal nerves from the 8th cervical or 1st thoracic to the 2nd or 3rd lumbar,

for sympathetic impulses to the limbs. Such fibers would remain intact though the sympathetic chain were excised, their presence would, thus, offer an explanation in some instances for the failure of sympathectomy to completely denervate the vessels of the limbs.

FIG 71 2 Diagram showing the connections of sympathetic fibers. Efferent fibers in black, preganglionic, solid lines, postganglionic interrupted lines. Afferent visceral fiber in red.

but not others, are connected each to a paravertebral ganglion by a delicate white strand composed of preganglionic fibers and known as the *white ramus communicans* (plural, *rami communicantes*, fig 71 2 and fig 71 1, p 1293). A preganglionic fiber after entering the ganglion may pursue one of three courses: (a) form synapses with cells in the ganglion which it first enters, (b) pass up or down the sympathetic trunk for some distance to terminate in a ganglion at a level higher or lower than that of the segment from which it originated. It may give off collateral branches to ganglion cells along its course. In any event, the preganglionic fibers issuing from a given segment connect with several ganglia (from five to nine). Furthermore, each preganglionic fiber may form a large number of synapses within a given ganglion. Ranson and Billingsley found that in the case of the superior cervical ganglion each fiber communicated with some thirty-two ganglion cells, thus accounts for the diffuse nature of the sympathetic discharge. (c) Traverse the gangliated cord without interruption to find a cell station in either a prevertebral or a terminal ganglion.

PLAN OF DISTRIBUTION OF SYMPATHETIC FIBERS TO THE PERIPHERY

To the Limbs and Trunk

The ganglia of the sympathetic chain are connected with the spinal nerves supplying the limbs and trunk by delicate filaments called *gray rami communicantes*. They are composed of the axons of the ganglion cells in the paravertebral ganglia, and are therefore called *postganglionic*. The gray rami in the thoracic and upper lumbar regions join the spinal nerves close to the points at which the white rami arise. Their constituent fibers are contained in the peripheral nerves for the supply of the blood vessels, sweat glands and smooth muscle of the skin. Whereas, as already mentioned, only a limited number of spinal nerves possess white rami, *every spinal nerve receives a gray ramus*. It therefore follows that sympathetic impulses going to parts supplied by upper cervical, lower lumbar or sacral somatic nerves, must travel considerable distances up or down the sympathetic trunk before reaching an outlet through a gray ramus. The preganglionic fibers to the upper limb arise from the 2nd to the 7th thoracic spinal segments, most of these fibers

are contained in the white rami of the 2nd and 3rd thoracic anterior roots. The postganglionic fibers to the upper limb may arise from the upper 1st to 4th thoracic, and the inferior and middle cervical ganglia (see also ch 21), those for the lower limb from the lumbar and sacral ganglia. Excision of the inferior cervical or the stellate ganglion when present and the upper three or four thoracic ganglia provides as complete a sympathectomy as it is possible to make of the upper limb, as well as the head and neck. It also will destroy most of the sympathetic nerves to the heart. This operation may fail, however, to remove completely the sympathetic supply to the arm since there may be 'intermediate' ganglia which are not removed in such an operation.

To the Head and Neck

Sympathetic impulses to the structures of the neck, face, scalp and intracranial cavity are conveyed from the spinal cord in the white rami of the upper two thoracic nerves. They ascend to connect with cells in the middle and superior cervical ganglia. From the latter postganglionic fibers are distributed through the internal carotid cavernous and external carotid plexuses as described on page 1295. The sympathetic nervous system as well as supplying the blood vessels, sweat glands and pilomotor muscles of the head and neck also innervates the salivary glands, the dilator pupillae muscles, Mueller's muscle and the smooth muscle component of the levator palpebrae superioris. The spinal center for the dilator pupillae is situated (in man) in the 8th cervical or 1st thoracic segment. The preganglionic fibers are found in the white rami of the first thoracic nerve, and are distributed as already stated through the internal carotid and ciliary nerves.

To the Thoracic Viscera

The sympathetic postganglionic fibers join with the branches from the vagus to form the cardiac, pulmonary and esophageal plexuses.

The cardiac plexus lies in relation to the origins of the aorta and pulmonary artery. It consists of a superficial and a deep portion, and is formed by the interlacement of fibers from the cardiac branches of the vagus (parasympathetic) and sympathetic nerves. The vagus fibers are preganglionic. They terminate around ganglion cells in the walls of the heart (p. 302). The sympathetic fibers derived from the superior, middle and inferior cardiac nerves are postganglionic, their cell stations lying in the corresponding cervical gan-

glia (fig 711, p. 1295). The preganglionic fibers arise from the upper four or five thoracic segments of the spinal cord.

The pulmonary plexuses anterior and posterior, lie in relation to the corresponding aspects of the root of the lung. They are formed from postganglionic fibers of the sympathetic (T 2, 3 and 4) and preganglionic fibers of the vagus. The latter connect with ganglion cells in the walls of the bronchi. Herein is situated an intrinsic nervous plexus consisting of these ganglion cells and medullated and nonmedullated fibers.

The esophageal plexus embraces the lower half of the esophagus. Vagal and sympathetic fibers (from the upper thoracic ganglia and from the thoracic portion of the great splanchnic nerve) enter into its formation. The vagal fibers end around ganglion cells of the intrinsic plexus of Auerbach in the esophageal wall.

To the Abdominal and Pelvic Viscera

The greater, lesser and least splanchnic nerves. These are composed of preganglionic fibers and may be looked upon as elongated white rami. They connect with cells in the prevertebral (colateral) ganglia. The postganglionic fibers after emerging from the latter join the neighboring plexuses. The greater splanchnic nerve arises from the spinal cord from as high as the 4th or 5th thoracic segment, and as low as the 9th or 10th. Its fibers end in the upper part of the celiac ganglion; from here postganglionic fibers are continued into the celiac plexus. The lesser splanchnic and the least (or lowest) splanchnic nerves are much smaller. The former arises from the 9th and 10th or the 10th and 11th thoracic segments and its fibers after passing without interruption through the vertebral ganglia at these levels end in the lower portion of the celiac (or aorticorenal) ganglion. The least splanchnic nerve arises from the last one or two thoracic segments and first lumbar segment; it joins the renal plexus (fig. 713). Postganglionic fibers arising from small ganglia within the plexus are distributed to the kidney and ureter.

The lumbar splanchnic nerves are three or four strands which arise from the second and third lumbar segments. Their fibers pass through the lumbar portion of the sympathetic chain and enter the inferior mesenteric ganglion; here some are relayed, others are continued without interruption and find their cell stations in peripheral ganglia.

THE PLEXUSES OF THE ABDOMEN AND PELVIS

FIG 71.3 Diagram of the nerve plexuses of the abdomen and pelvis. A.R., aortic renal.

The sympathetic fibers form rich plexuses in relation to the aorta and its branches from which filaments pass to the abdominal and pelvic viscera. Parasympathetic fibers also enter into the constitution of these plexuses.

The *celiac* (or *solar*) plexus lies upon the abdominal aorta at the origin of the celiac artery. The *celiac ganglia*, right and left, are embedded within the plexus, which is made up of fibers arising in the ganglion (i.e., postganglionic fibers of the greater and lesser splanchnic nerves) together with preganglionic fibers of the vagus. The lower part of the celiac ganglion is often detached and is then referred to as the *aorticorenal ganglion*. The plexus invests the celiac artery throughout its course and gives rise to several subordinate plexuses—the *hepatic*, *gastric*, *splenic*, *renal*, and *adrenal plexuses*—which invest the corresponding arteries and their branches.

The *superior mesenteric plexus* is continuous above with the celiac plexus. It surrounds the superior mesenteric artery along the branches of which it is prolonged as subsidiary plexuses. The plexus is composed of postganglionic fibers which arise in an aggregation of nerve cells—the *superior mesenteric ganglion*—lying within it of preganglionic fibers derived from the lumbar segments of the cord and from the celiac plexus. It and the other plexuses to be described also contain parasympathetic fibers. The superior mesenteric plexus supplies the pancreas and the small intestine and the large intestines as far as the commencement of the descending colon.

The *aortic* or *intermesenteric plexus* lies upon the aorta between the origins of the superior and inferior mesenteric arteries. It receives fibers from the celiac plexus and from the upper lumbar ganglia. The aortic plexus gives rise secondarily to the *spermatic* and *ovarian plexuses* which supply

the testes and ovary with autonomic fibers. It is connected below with the *inferior mesenteric plexus* which invests the artery of the same name. The *inferior mesenteric ganglion*, a collection of ganglion cells lying within the latter plexus, receives the lumbar splanchnics, this ganglion is not present, as a rule, in the human subject (Learmonth), but a number of smaller ganglia are found scattered through the plexus. The plexus is formed of fibers derived from the aortic plexus from the inferior mesenteric ganglion when this is present. From it secondary plexuses arise which invest the branches of the inferior mesenteric artery and carry sympathetic impulses to the descending colon, iliac colon, pelvic colon and rectum.

The *superior hypogastric plexus* is the downward extension of the aortic plexus. It lies over the lower end of the aorta, and in the angle formed by the aortic bifurcation. Though rarely condensed into a single bundle it is sometimes referred to as the *hypogastric nerve* or the *presacral nerve*. It transmits inhibitory impulses to the pelvic colon and via the pelvic plexuses to the rectum, bladder and other pelvic viscera. It divides below into the right and left pelvic or *inferior hypogastric plexuses*. These lie one on either side of the rectum and are composed of medullated and non-medullated fibers among which are scattered numerous small ganglia which are sometimes referred to collectively as the *hypogastric ganglion*. Parasympathetic fibers enter the inferior hypogastric plexus through the pelvic nerve (sacral outflow). The sympathetic fibers contributing to the pelvic plexuses have their ultimate source in the lumbar segments of the cord. They reach the plexuses via the hypogastric plexuses as well as more directly from the sacral part of the sympathetic chain. Through subsidiary plexuses—*hemorrhoidal, vesical, uterine, vaginal and prostatic*—fibers (sympathetic and parasympathetic) are conveyed from the pelvic plexuses to the pelvic viscera.

THE PARASYMPATHETIC OR CRANIOSACRAL DIVISION OF THE AUTONOMIC NERVOUS SYSTEM

The cells giving rise to parasympathetic fibers are situated at three different levels of the central nervous system—the *midbrain*, the *medulla oblongata* and the *sacral region of the spinal cord*. The axons of these cells leave the central nervous system to connect with ganglion cells lying within or in close relation to the innervated organ (see fig. 711). As in the case of the sympathetic division the axons of the central cells are called *preganglionic*, those of the ganglion cells, *postganglionic*. The former are medullated, the latter nonmedullated. The three levels from which parasympathetic fibers emerge will be referred to

as the *tectal* (or *midbrain*), the *bulbar* and the *sacral* outflows, respectively.

A THE TECTAL OR MIDBRAIN OUTFLOW

The group of cells composing the Edinger-Westphal nucleus of the oculomotor nerve (p. 1416), in the floor of the cerebral aqueduct, are believed to give rise to the tectal fibers.

The autonomic fibers are conveyed in the third nerve as far as the ciliary ganglion where they find their cell stations. Postganglionic fibers emerge from the ganglion in the short ciliary nerves, and terminate in the sphincter pupillae and the ciliary muscles (p. 1410).

B THE BULBAR OUTFLOW

These fibers leave the brain in the *facial, glossopharyngeal and vagus nerves*.

(1) The parasympathetic fibers (secretory and vasodilator) entering the *facial nerve* arise from the *superior salivatory (salivary) nucleus* which lies dorsal and lateral to the lower end of the motor nucleus of the facial. These fibers emerge from the brain in the sensory root of the facial nerve (*nervus intermedius*, ch. 65) and travel with the latter to the facial canal of the temporal bone. Here they leave the facial, (i) in its *chorda tympani* branch which later joins the lingual to be conveyed to the floor of the mouth. At this point some of the chorda fibers (secretory and vasodilator in function) separate from the lingual again to enter the *submaxillary (submandibular) ganglion* from where they are relayed, the postganglionic fibers pass to the submaxillary and submandibular glands, and the mucous membrane of the mouth. (ii) In the great superficial petrosal nerve and nerve of the pterygoid canal (Vidian nerve) to the *sphenopalatine ganglion*. From here postganglionic fibers pass via orbital branches of the ganglion to the lacrimal gland, and to the mucous membrane of the soft palate, nasopharynx and pharynx via the palatine nerves. Vasodilator fibers also leave the facial by the great superficial petrosal nerve, and enter the cranium are conveyed along the middle meningeal artery and its branches.

(2) The parasympathetic fibers (secretory and vasodilator) of the *glossopharyngeal nerve* arise from cells of the *inferior salivatory (salivary) nucleus*. This nucleus lies in the uppermost part of the medulla oblongata immediately below the superior salivatory nucleus, and lateral to the motor nucleus of the glossopharyngeal nerve. The autonomic fibers leave the brain with the latter nerve but separate from it again in its tympanic

* This nucleus is actually in the lowest part of the pons.

branch (Jacobson's nerve) which joins a twig from the geniculate ganglion (g. of facial nerve) and filaments from the internal carotid plexus to form the *tympanic plexus*. From this plexus emerges the *small superficial petrosal nerve* through which parasympathetic fibers are continued to the otic ganglion. From this ganglion postganglionic fibers are conveyed to the parotid gland via the *auriculo-temporal nerve* (p. 589). The tympanic plexus itself sends filaments to the mucous membrane of the tympanic cavity, the mastoid air cells and the Eustachian tube and the internal ear.

(3) The *vagus nerve* contains the greater proportion of the fibers of the bulbar outflow. They arise from the *dorsal nucleus* of the vagus and are distributed through the latter's numerous branches to the thoracic and abdominal viscera (ch. 65). Unlike those in the other two cranial nerves, the preganglionic fibers of the vagus connect with ganglion cells situated within the innervated organs. Thus the vagal fibers to the heart connect with ganglion cells in the cardiac walls; those to the bronchi with the nerve cells of the intrinsic plexus in the bronchial walls; those to the esophagus, stomach and intestine form synapses with the ganglion cells of the *mesenteric plexus* of Auerbach and the *submucous plexus* of Meissner. The preganglionic fibers are therefore quite long, the postganglionic very short. The cells of origin of most of the cardiac fibers of the vagus form a discrete group (*cardioinhibitory center*) lying alongside the dorsal nucleus of the vagus.

C THE SACRAL OUTFLOW

The cells of origin lie in the anterior horns of the 2nd, 3rd and 4th and sometimes the 1st sacral segments of the spinal cord. The preganglionic fibers emerge in the anterior roots of the corresponding sacral nerves. The fibers leave the spinal nerves again and, proceeding peripherally as the *pelvic nerve* (or *nervus erigens*), on each side, enter into the formation of the pelvic plexus. The fibers terminate around ganglion cells lying in close relation to the pelvic organs. They carry motor impulses to the walls of the descending colon, rectum and bladder, inhibitory impulses to the internal anal and vesical sphincters and to the uterus, and dilator impulses to the blood vessels of the bladder, rectum and genitalia.

The Afferent Visceral Nerves

Impulses are transmitted from the viscera by afferent fibers which pass through the various plexuses and reach the central nervous system via the vagus, pelvic, splanchnics and other autonomic nerves.

The afferent fibers of the sympathetic division are the peripheral processes of ganglion cells in the

posterior spinal root ganglia from the 1st thoracic to the 3rd lumbar segments. None arise from sympathetic ganglia. They reach the sympathetic trunk via the white rami communicantes and are distributed to the viscera along with the corresponding efferent fibers (fig. 71-2). Though some of these afferent fibers are nonmedullated, the majority are medullated, and of larger size than the efferent fibers. The ganglion cells of the posterior roots which give origin to the afferent fibers of the sympathetic (or of the pelvic nerve) have not been shown definitely to differ from those giving rise to the ordinary somatic sensory fibers. For this reason the sympathetic system proper is sometimes regarded, though perhaps irrationally, as consisting solely of efferent neurons. The afferent fibers pass to their destinations without interruption in any of the sympathetic ganglia passing directly to the viscera in the splanchnics or the other visceral nerves. A certain proportion also enter the spinal nerves for distribution to the limbs via the gray rami.

The afferent fibers of the vagus are the peripheral processes of cells in the ganglion jugulare and the ganglion nodosum. The central processes of these neurons terminate in the dorsal nucleus of the vagus (ch. 65). Therein connections are made with efferent parasympathetic neurons to complete the reflex arc. The afferent fibers of the pelvic nerve arise from cells in the posterior root ganglia of the 2nd, 3rd and 4th sacral nerves. They pass peripherally with the efferent autonomic fibers.

The *visceral reflex arc*, as pointed out by Gaskell, is formed upon a plan similar to that upon which somatic reflexes are based. The afferent fiber in the latter instance is connected to the anterior horn cell through the intermediary of an intraspinal (internuncial) neuron or a series of such neurons. These are spoken of as connector neurons. In the case of visceral reflexes, the afferent fiber makes contact with a cell in the lateral horn of gray matter. The axon of this cell connects with a ganglion cell of the sympathetic system. This ganglion cell and its postganglionic fiber corresponds to the motor neuron of the somatic reflex arc.

A certain degree of independent reflex activity can be carried out through the intrinsic plexuses, e.g., of the intestine, when these are separated from the central nervous system by division of the main autonomic nerves. It is also true that some independent activity can be carried out through axon reflexes or possibly through some of the more peripherally placed ganglion cells. Other parts of the autonomic system, however, cannot

function apart from the central nervous system. The larger ganglia of the parasympathetic or sympathetic, for instance, do not serve as reflex centers. It is clear from the description of the origin and course of the visceral afferent nerves given above that no anatomical basis for such action exists.

The Functions of the Autonomic Nervous System

The autonomic nervous system governs the activities of cardiac and smooth muscle, of the digestive glands and sweat glands of the adrenal medulla and possibly of certain endocrine organs. It is concerned with those processes which normally are beyond voluntary control and are for the most part beneath consciousness. The term autonomic as applied to this system is not altogether suitable since, as we have seen, it is under the control of centers within the central nervous system, and cannot function as an independent unit.

Through its various activities the autonomic system exercises the important function of maintaining the constancy of the fluid environment of the body's cells: it serves to combat forces, acting either from within or without, which tend to cause variations in this environment. Regulation of the composition of the body fluids, of their temperature, quantity and distribution, is effected through the actions of the autonomic nerves upon circulatory, respiratory, excretory and glandular organs. For example, of glandular structures under autonomic influence, the liver, pancreas and adrenal medulla are of especial importance in the regulation of blood sugar, the sweat glands and in the control of body temperature. The neural lobe of the pituitary is partially under autonomic nervous control. The thyroid gland, adrenal cortex, adenohypophysis and probably also the parathyroid glands are governed by hormones liberated by the pituitary (ch. 56), though it is not improbable that they may be influenced also by impulses received through autonomic paths. The stability of the internal environment (the *milieu interne* of Claude Bernard) which is so characteristic of the healthy body, is spoken of by Cannon as *homeostasis*. According to Cannon, the essential and particular function of the autonomic system is to bring about the internal adjustments upon which this constant state depends. He therefore refers to the autonomic nerves as the *interofective* system. He speaks of the voluntary system (i.e., the central nervous system and the somatic

nerves) as the *exteroffective* system, since through its exteroceptors and effectors a direct relationship is established with the external environment.

The great majority of the effector organs of the autonomic system are innervated by both sympathetic and parasympathetic divisions (see table 71 1), and the effects exerted by the two types of fiber going to a given organ are antagonistic. Thus the heart's action is inhibited by the vagus but augmented by the sympathetic. In the intestine the effects of the two nerves are reversed, the parasympathetic (vagus nerve to the small bowel and upper half of the colon, and the pelvic nerve to the lower half of the latter) are augmentor, the sympathetic is inhibitory. The removal of the effects of one set of fibers, as by section, results, as a rule, in the effects of the other set becoming more prominent. This fact indicates that each type of fiber exerts a constant or tonic action and suggests that the two effects are delicately balanced one against the other. Thus section of the vagus nerves causes an increase in the cardiac rate, and section of the parasympathetic or of the sympathetic fibers to the iris causes, respectively, dilation or constriction of the pupil. See pupillary reactions, (p. 1409).

Taken as a whole the actions of the sympathetic division and its ally the medulla of the adrenal gland (sympathoadrenal system, ch. 58) are directed towards strengthening an animal's defenses against the various dangers which beset it, e.g., extremes of temperature, deprivation of water or the attacks of its enemies. It has been shown by Cannon, however, that the sympathetic system is not indispensable: both ganglionic cords may be completely removed yet the animal remains in good health provided it is kept in the sheltered environment of the laboratory. Sympathectomized cats if kept warm and carefully tended will live indefinitely. Kittens deprived of their sympathetic trunks grow normally, female cats become pregnant and give birth to young, though the mammary glands do not function normally and the maternal instinct is lacking. Sympathectomized animals are, however, incapable of arduous work, sugar is not mobilized from the liver on demand, an increase of circulating red blood cells does not occur during excitement or exercise (p. 68, 69), the usual reactions to cold (elevation of the hairs and vasoconstriction) fail and adrenal medulla is not liberated in an emergency. They are also less able to withstand oxygen lack or hemorrhage than are normal animals. It is evident that the sympathectomized animal could not fend for it-

TABLE 71 1

Organ	Parasympathetic Effects	Origin of Sympathetic Postganglionic Fibers	Sympathetic Effects
<i>Heart</i> (p 302)	Inhibition	Superior middle and inferior cervical ganglia	Acceleration
<i>Vessels</i>			
Cutaneous (ch 21 and 25)	—	Various paravertebral ganglia	Constriction
Muscular (see pp 252-7 and 351)			
Coronary (see p 329)			
Salivary glands (ch 36)	Dilation	Superior cervical ganglion	Constriction
Buccal mucosa	—	Superior cervical ganglion	Dilation
Pulmonary (see p 298)			
Cerebral (see p 344)			
Abdominal and pelvic viscera	—	Prevertebral ganglia	Constriction
External genitalia (pp 1109-1301)	Dilation	Prevertebral ganglia	Constriction
<i>Eye</i>			
Iris (ch 75)	Constriction	Superior cervical ganglion	Dilation
Ciliary muscle (ch 75)	Contraction	Superior cervical ganglion	Relaxation
Smooth muscle of orbit and upper lid (ch 75)	—	Superior cervical ganglion	Contraction
Nictitating membrane (cat and dog)	—	Superior cervical ganglion	Retraction
<i>Bronchi</i>	Constriction	Thoracic ganglia	Dilation
<i>Glands</i>			
Sweat (ch 52)	—	Paravertebral ganglia	Secretion
Salivary (ch 36)	Secretion	Superior cervical ganglia	Secretion
Gastric (p 599)	Secretion	Celiac ganglion	Inhibition [*]
Pancreas (p 629)			Secretion of mucus
Acini	Secretion	Celiac ganglion	—
Islets	Secretion	Celiac ganglion	—
Liver	—	Celiac ganglion	Glycogenolysis
Adrenal (pp 1030-31) medulla	—	No postganglionic fibers	Secretion
<i>Smooth muscle</i>			
Of skin	—	Paravertebral ganglia	Contraction
Of stomach wall (pp 717-18)	Contraction or inhibition	Celiac ganglion	Contraction or inhibition
Of small intestine (pp 717-19)	Increased tone and motility	Celiac and superior mesenteric ganglia	Inhibition
Of large intestine (pp 717-19)	Increased tone and motility	Inferior mesenteric and hypogastric ganglia	Inhibition
Of bladder wall (ch 35) (detrusor muscle)	Contraction	Inferior mesenteric and hypogastric ganglia	Inhibition
Of trigone and sphincter	Inhibition	Inferior mesenteric and hypogastric ganglia	Contraction
Of uterus pregnant	nil	Inferior mesenteric and hypogastric ganglia	Contraction
Of uterus nonpregnant	nil		Inhibition

* With certain exceptions, e.g., those supplying the sublingual and parotid glands and the sphincter pupillae the postganglionic fibers of the parasympathetic arise from cells situated in, or in close proximity to, the innervated organ itself

self, and, in the struggle for existence, would soon succumb to the hazards of the environment. The sympathetic ganglionated chain has also been completely removed in man, thus abolishing all connection of the peripheral sympathetic system with the central nervous system without producing any serious consequences.

Parasympathetic effects, rather than being characterized by a diffuse outburst of activity, as may result from sympathetic stimulation, are more localized in character. It has also been suggested that they are concerned with conservative and restorative processes, and the sympathetic with processes involving the expenditure of energy. Inhibition of the heart, contraction of the pupil for the protection of the eye from intense light and the activities of the digestive tract through which the energy stores of the body are replenished, are frequently given as examples of acts of conservation presided over by the parasympathetic. These apparent differences in the activities of the two divisions have led some (following Gaskell) to speak of the functions of the sympathetic and parasympathetic divisions as *catabolic* and *anabolic*, respectively. It is an interesting but perhaps a too speculative generalization.

A summary of the actions of the autonomic system upon various structures is given in table 71.1

Chemical (Humoral) Transmission of Nervous Impulses¹

Transmission of impulses from neuron to neuron and from neuron to effector cell is accomplished by the elaboration of chemical substances by the nerves. The classical experiments of Otto Loewi, in 1921, first clearly demonstrated the existence of humoral mediators. Two frog hearts arranged in standard fashion for recording contractions were prepared so that the fluid perfusing one heart could come in contact with the second. Upon stimulation of the vagus nerve to the first heart, its rate of contraction was reduced. When the fluid perfusing this heart came in contact with the second it also slowed in rate although its vagus had not been stimulated. Some substance had obviously been released in the first heart which could be carried by the perfusing fluid to the second. Loewi termed this material "*Vagusstoff*." By the same technique stimulation of the cardiac accelerator nerve to the first heart

increased its rate and also the rate of the second heart when the perfusing fluid reached the latter. This response Loewi attributed to the release of "*Acceleransstoff*."

By various techniques, described below, "*Vagusstoff*" has been shown to be acetylcholine, and "*Acceleransstoff*" is identical with or related to epinephrine (adrenalin). In 1933, Sir Henry Dale proposed the terms *cholinergic* and *adrenergic* to describe the nerves which liberated acetylcholine or epinephrine (or related substances). The adjectives are also used to describe agents which cause effects similar to those produced by acetylcholine and epinephrine. Dale has also proposed that cells stimulated by cholinergic or adrenergic nerves be termed *cholinoceptive* and *adrenoceptive* respectively.

Acetylcholine is now recognized as the mediator of impulses at all autonomic ganglia, all parasympathetic postganglionic terminations, sympathetic postganglionic endings at sweat glands, and motor nerve endings at skeletal muscle. In these cholinergic nerve fibers acetylcholine is present in an inactive form (probably bound loosely with a protein or a lipoprotein). Upon stimulation of the nerve the acetylcholine is set free and diffuses down the nerve fiber and from the terminations. These same nerve fibers contain an enzyme, *choline acetylase*, which is capable of synthesizing acetylcholine with great rapidity. Which of these two mechanisms is the more important in releasing free acetylcholine remains unsolved.

Free acetylcholine is unstable, it is readily hydrolyzed to choline and acetic acid. This hydrolysis occurs almost instantaneously in the presence of *acetylcholinesterase*, an enzyme present at the termination of cholinergic nerves.² The enzyme is one of a group of hydrolytic enzymes, often referred to as *cholinesterases*, found in the body. *Acetylcholinesterase*, or *true or specific cholinesterase*, has acetylcholine as its preferred or only substrate, and is most effective when the amount of acetylcholine is small. The other (pseudo- or nonspecific) *cholinesterases* will utilize acetylcholine and other choline and non-choline esters.

¹ Choline acetylase is very widely distributed in the nervous tissues, being found in brain ganglia and peripheral nerves. It is also present in the placenta, but is absent from liver and kidney. For optimal activity this enzyme requires Mg. ⁺ and Ca. ⁺⁺ ions. The concentration of choline acetylase in nerve fibers declines during their degeneration, but some still remains even after the nerve has ceased to conduct.

² *Acetylcholinesterase* is also present in large amounts in erythrocytes, the chief source of the enzyme for experimental studies.

¹ We are indebted to Dr. William C. North of the Department of Anesthesiology of Duke University for the preparation of this section.

as a substrate and are most effective in the presence of large quantities of acetylcholine

Cholinesterases may be inhibited by a variety of substances. Much of the knowledge about acetylcholine and nerve impulse transmission has been obtained only through the ability of these agents to inhibit acetylcholinesterase. Physostigmine (eserine), an alkaloid extracted from the Calabar bean (*Physostigma venenosum*) was the first substance shown to inhibit these enzymes. Subsequently many synthetic inhibitors have been prepared, among them neostigmine (Prostigmin), diisopropylfluorophosphate (DFP) and tetraethylpyrophosphate (TEPP). Physostigmine and neostigmine are reversible inhibitors, the enzyme is inactivated only so long as it is in combination with the inhibitor. As the latter is eliminated by the body, the enzyme once more becomes active. DFP and TEPP combine irreversibly with the enzyme, permanently inactivating it. Hence, for cholinesterase activity to be restored new enzyme must be synthesized.

Such minute amounts of the cholinergic mediator are liberated during impulse transmission, and the mediator is so rapidly broken down by acetylcholinesterase, that the identification of the mediator as acetylcholine is still largely indirect. The experimental methods used to identify acetylcholine are, however, sufficiently instructive to consider briefly. First, the effects of nerve stimulation may be compared with those of acetylcholine administration. Second, a modification of Loewi's original experiment, i.e., stimulation of the autonomic nerve to an organ or ganglion and testing the venous blood leaving it, or the fluid perfusing it for acetylcholine activity on a suitable test preparation. In order to prevent hydrolysis of the acetylcholine after its liberation from the nerve terminals the animal must be given physostigmine or some other inhibitor, or the perfusing fluid must contain it. Five common qualitative tests for the detection of the mediator may be mentioned.

(1) Blood pressure of the cat. Dilatation of the arterioles and a fall in blood pressure. The effect should be annulled by atropine. (2) Inhibition of the perfused frog's heart or rabbit's auricle annulled by atropine. (3) Contraction of the voluntary muscle (rectus abdominis) of the frog. (4) Contraction of the muscle in body wall of the eserinized leech. This test is sensitive to 2 μ g (gamma) of acetylcholine per liter. (5) The active substance should be inactivated by alkali or by blood (which contains cholinesterase). Comparison of the response of the test system (i.e., the

blood pressure fall in the cat) to the perfusion with the response to known amounts of acetylcholine makes it possible to quantitatively estimate the amount of acetylcholine actually liberated. Results of such studies coupled with knowledge that acetylcholine is actually found in cholinergic nerves leaves little doubt that acetylcholine is the mediator.

Summary of Experimental Work Relating to the Role Played by Acetylcholine in the Transmission of Nervous Effects

1 *Stimulation of the chorda tympani nerve, salivary glands.* Babkin and his associates found that when the chorda of one side was stimulated a substance entered the blood which caused a fall in blood pressure and secretion from the denervated salivary gland of the opposite side. These effects were abolished by atropine. Similar results have been obtained by others. During stimulation of the chorda of a perfused salivary gland for example, a substance identical in action with acetylcholine was found by Henderson and Roepke in the perfusion fluid.

2 *The liberation of acetylcholine from parasympathetic endings in the iris.* When a strong light was thrown into one eye, the other eye became shaded. An acetylcholinelike substance was obtained from the aqueous humor of the illuminated eye but not from the darkened eye (Engelhart).

3 *Acetylcholine as an intermediary of parasympathetic effects in the alimentary tract and bladder.* It has been shown that Ringer's solution in which a beating loop of intestine is immersed is capable of augmenting the activity of another similar loop (Weiland). It has also been found that if the vagus nerve to the intestine is stimulated and a loop then removed and suspended in Ringer's solution the contractions of this loop are greater than those of a similar one which had not been previously excited in this manner. These experiments suggest that during intestinal activity a substance is liberated by the vagal endings which has an augmenting effect upon the contractions. Evidence for the liberation of acetylcholine by the vagus has been obtained by Dale and Feldberg. A substance identical in action with acetylcholine was detected in the venous blood leaving the resting stomach or in the eserinated fluid perfusing the wall. During vagal stimulation the quantity of the active material was increased fourfold.

An acetylcholinelike substance has also been identified by Henderson and Roepke in the fluid perfusing the bladder during stimulation of parasympathetic nerves. In the case of the intestine and bladder as in the case of vasodilator nerves, the same discrepancy exists between the action of atropine upon the effects of nerve stimulation and the action of the drug upon the effect

of acetylcholine administration Atropine abolishes the action of acetylcholine when applied artificially to these organs but does not depress the contractions set up by parasympathetic stimulation Henderson and Roepke conclude from the results of their experiments that, whereas the tone of the intestine and of the bladder is dependent upon the liberation of a choline ester, another mechanism is responsible for the phasic contractions Atropine, as is well known depresses the tone of the intestinal and vesical musculatures but exerts no direct effect upon the contractile mechanism

4 *The liberation of acetylcholine from sympathetic preganglionic fibers* Feldberg and Gaddum perfused the superior cervical ganglion with eserinized fluid The inflow cannula was inserted into the common carotid artery, all branches of which had been tied except the one to the ganglion The fluid was collected from the internal jugular vein, all its tributaries except that from the ganglion having been occluded During stimulation of the cervical sympathetic trunk below the ganglion the fluid issuing from the vein was found to possess an action identical with that of acetylcholine When the collected fluid was passed through the ganglion of the opposite side its stimulant action upon this structure was evidenced by a contraction of the nictitating membrane Fluid collected before or after the period of stimulation showed no such activity

5 *Acetylcholine liberation during the discharge of adrenaline* Stimulation of the sympathetic fibers supplying the adrenal medulla causes an acetylcholinelike substance to appear in the blood of the adrenal vein It has therefore been concluded that acetylcholine acts as a chemical transmitter from the nerve terminals to the medullary cells It will be recalled that the sympathetic fibers ending in the adrenal are preganglionic, the adrenal cell itself taking the place of the ganglion cell

6 *Acetylcholine as the transmitter of effects to the sweat glands* Although the human sweat glands are innervated by the sympathetic, their behavior to drugs is similar to that of structures supplied by the parasympathetic, they are unaffected by adrenaline, stimulated by pilocarpine, and paralyzed by atropine An experiment by Dale and Feldberg gives an explanation of these discrepancies, or at any rate brings the mechanism of sweat secretion into the general scheme Excitation of the sympathetic fibers to the foot pads of the cat was followed by sweating and the appearance of acetylcholine in the eserinized fluid perfusing the paw

The chemical identity of the adrenergic mediator is not so well characterized as that of the cholinergic mediator Cannon and Baq, in 1931, demonstrated that stimulation of adrenergic nerves liberated a substance into the circulation

which they called "sympathin" Although many of the effects of sympathetic stimulation could be produced by the administration of epinephrine, Cannon and Rosenbluth were unable to demonstrate complete qualitative and quantitative identity between the two types of stimulation They proposed the "sympathin theory" which is discussed elsewhere (ch 58) Subsequent work has confirmed their idea that there is more than one type of adrenergic effector However, it has been shown that epinephrine is not the only mediator released on sympathetic stimulation

Epinephrine was crystallized from adrenal medullary extracts by Abel in 1901 Since then it has been identified in other nervous tissue and found to be secreted at adrenoceptive effector cells In 1946, Euler reported that adrenergic fibers contained another catechol amine, levarterenol (norepinephrine, noradrenaline), the following year Baq and Fischer found that some adrenergic fibers liberate only epinephrine others only levarterenol, and still others both epinephrine and levarterenol Isoproterenol (isopropyl norepinephrine isopropyl noradrenaline) was found by Lockett, in 1956, in pulmonary venous blood following stimulation of the upper thoracic sympathetic chain

The properties of the first two of these substances, found in the adrenal medulla, are described in chapter 58 The response of the effector cells is the same whether the mediators arrive by way of the circulation or whether they are released by nerve terminal endings on the cells

The mechanisms whereby the adrenergic mediators are formed, or by which they are released are not known However, once released upon stimulation of adrenergic neurons, the mediators are, compared to acetylcholine slowly inactivated At least four possible pathways of epinephrine metabolism have been described (1) An enzyme, *monoamine oxidase*, is present throughout the body which is capable of oxidatively deaminating primary amines Epinephrine and arterenol are substrates for this enzyme, although the reaction proceeds rather slowly (2) Conjugation of epinephrine with glucuronic or sulfuric acid at the hydroxyl groups occurs, primarily in the liver and intestines (3) The phenolic hydroxyl groups of epinephrine are readily oxidized forming a quinone which in turn forms a cyclic structure *adrenochrome* (4) Recently Axelrod has demonstrated that the phenolic group in the meta position is methylated to a considerable extent in the body There is as yet,

however, no evidence that any of these inactivating mechanisms is the one primarily responsible for terminating adrenergic effects

The concept of specific receptors, first proposed by Dale in 1906, aids in understanding the rather complex responses to sympathetic stimulation or epinephrine administration. Noting that epinephrine caused some smooth muscle to contract, while it relaxed others, he proposed that the former had "motor" type receptors while the latter had "inhibitory" type receptors. Ahlquist has divided the adrenergic receptors into two types. Alpha receptors are those associated with vasoconstriction, myocardial ectopic excitation, myometrial contraction, nictitating membrane contraction, intestinal relaxation, iris dilator muscle contraction, pilomotor contraction, and glycogenolysis. Beta receptors are those concerned with vasodilation, cardioacceleration, myocardial augmentation, myometrial relaxation and bronchial relaxation. Furchgott has presented evidence which indicates that with vascular smooth muscle, at least, individual cells may contain both α and β receptors.

Levarterenol appears to stimulate only alpha receptors, isoproterenol only beta receptors, and epinephrine is capable of stimulating both. Epinephrine is 2 to 10 times more potent than levarterenol in stimulating the alpha receptors. Isoproterenol is 2 to 10 times more potent than epinephrine in stimulating the beta receptors and 100 or more times more active than levarterenol. Therefore, although epinephrine is the more potent agent as a vasoconstrictor, levarterenol may produce a greater rise in blood pressure for a given dose, since it has no or little effect on vasodilator fibers.

Euler claims that levarterenol is most commonly found as the mediator in adrenergic nerves. If this is true it readily explains the observed discrepancies between the effects of epinephrine administration and sympathetic nerve stimulation.

From the information now available it is possible to construct the mechanism by which the autonomically innervated effectors are stimulated (fig 71 4). Impulses leave the central nervous system by way of cholinergic preganglionic fibers which terminate at ganglionic cells. In the sympathetic division these neurons are collected in anatomically discrete bodies. The parasympathetic ganglion cells are rarely discrete, being located usually within the organ innervated. In either case, acetylcholine is liberated from the preganglionic terminals where it is free to act upon the

receptor sites of the ganglion cell. This combination of acetylcholine with receptor results in a loss of membrane integrity and the potential difference between the interior and exterior of the cell disappears. The electrical activity associated with this "depolarization" is of sufficient intensity to disrupt the continuity of the adjacent membrane, and the impulse is propagated along the postganglionic fiber. As long as the acetylcholine is bound to the receptor site, the membrane at that point remains depolarized. However, the acetylcholinesterase present at the synapse immediately (less than 1 msec) destroys the acetylcholine and the polarity of the neuronal membrane is restored. By this mechanism each preganglionic impulse liberates acetylcholine which in turn initiates a postganglionic impulse. The limiting factor in rate of transmission seems to be the refractory period of the nerve fiber.

Obviously, substances which will prevent access of acetylcholine to the ganglion cell receptors, or which will cause prolonged depolarization of the nerve membrane will block ganglionic synaptic transmission.

Fig 71 4 Diagram showing the distribution of cholinergic and adrenergic fibers. A, parasympathetic; B, sympathetic; 1, preganglionic; 2, postganglionic. Heavy lines, cholinergic; light lines, adrenergic.

The impulse travels down the postganglionic fiber as described and releases a humoral agent at its terminal. If the fiber is parasympathetic or sympathetic to the sweat glands, acetylcholine is the mediator released. This substance then combines with specific receptors on the effector cell to produce the characteristic response of that cell.

If the postganglionic fiber supplies other sympathetically innervated structures, epinephrine, levaterenol or isoproterenol is liberated from the terminals. The agent liberated is apparently characteristic for a specific neuron. In the case of the adrenal medulla which may be considered to be composed of ganglion cells without axons, the adrenergic mediators are liberated into the blood. The other postganglionic sympathetic neurons liberate the mediator in close proximity to the effector cell. The mechanism whereby epinephrine, levaterenol or isoproterenol stimulate the effector is unknown. Since there is apparently no specific instantaneous mechanism for destroying the substance, its action is probably somewhat different from that suggested for acetylcholine.

Drugs Acting on the Autonomic Nervous System

Many agents are capable of eliciting or modifying responses of the autonomic nervous system. A brief survey of the types of drugs used for these effects may help further to understand the function of the autonomic nervous system.

DRUGS ACTING AT THE GANGLION

The alkaloid *nicotine* was the first compound found to stimulate postganglionic fibers. The delineation of this effect led to the term *nicotinic* used to describe the effect of acetylcholine on the ganglion cell. In recent years a number of synthetic compounds have been found to possess ganglion stimulating properties including *carbamoylcholine*, *decamethonium* and *tetramethylammonium bromide*. Obviously little therapeutic advantage would be obtained from the stimulation of all postganglionic fibers which would result from the administration of such an agent. However, these substances are useful as experimental tools.

The blockade of ganglionic transmission is a more desirable therapeutic end. Again *nicotine* was the first substance known to cause such an effect. The paradox of the same substance causing two opposing effects is resolved when it is understood that far larger quantities of the drug are necessary to block than to stimulate. The mechanism of action in both cases seems to be that nicotine, like acetylcholine, initiates a response in the postganglionic fibers by depolarizing the nerve membrane.

With large amounts of the alkaloid the depolarization is prolonged, preventing repolarization of the neuron and hence preventing subsequent discharges. Even though acetylcholine is released by the preganglionic termination, it cannot initiate transmission in the postganglionic fiber. The dual nature of the action of nicotine, as well as its effect on skeletal muscle, makes it of little clinical usefulness. Its ganglionic actions are responsible for many of the side effects of the use of tobacco.

Tetraethylammonium chloride (TEA) blocks ganglionic transmission by combining with the acetylcholine receptors of the postganglionic neuron without depolarizing the cell membrane. In this instance the liberated acetylcholine cannot gain access to the receptor site to initiate depolarization. Other ganglionic blocking agents, hexamethonium, pentamethonium, pentolinium (Ansoly sen), mecamylamine (Inversine), trimethaphan (Arfonad) and others produce effects similar to those of TEA. There may be minor differences in mechanisms of action, and they may vary in the duration of their action, however, the qualitative nature of their responses is similar.

The effects of ganglionic blockade can be predicted readily. Depending upon the degree of blockade there will be depression to complete paralysis of autonomic function. This will result in such effects as interference with vision (accommodation and pupillary size), postural hypotension, etc. It must be remembered that the autonomic system is composed of two functional units which frequently antagonize each other to varying extent depending upon the demands made upon the body. No response to the administration of a ganglionic blocker may be observed until some demand is placed upon the autonomic system (e.g. hypotension following change from a recumbent to a standing position). On the other hand where there is a great deal of autonomic activity (as in hypertension of sympathetic origin) the administration of a drug such as tetraethylammonium may produce a dramatic and immediate response (in this case a decrease in blood pressure). This is not the result of the drug initiating a response but rather of blocking existing physiological activity.

DRUGS ACTING AT CHOLINOCEPTIVE EFFECTORS

There are relatively few substances which will mimic the effects of acetylcholine liberation at autonomic effectors. The alkaloid *muscarnine* from the poisonous mushroom *Amanita muscaria* was the first such substance isolated. From its effect came the adjective *muscarinic* which has been used to describe the actions of acetylcholine at the effector cells. It is now of only toxicological importance. *Acetyl β methacholine* (Methacholine, Meecholy), possesses the actions of acetylcholine. It is destroyed by acetylcholinesterase but not by

the non-specific cholinesterase. When given in sufficiently large amounts its effects are, therefore, somewhat more prolonged than those of acetylcholine. *Carbaminoyl β methylcholine* (bethanecol, Urecholine) is similar to methacholine in its actions (at cholinceptive effector cells) with the exception that it is not destroyed by cholinesterase. Consequently its actions may persist for hours. *Carbaminoylcholine* (Carbachol, Doryl) also stimulates cholinergically innervated effectors. In addition, as mentioned above, it also stimulates ganglionic cells. Like bethanecol, it is not subject to hydrolysis by cholinesterase. *Pilocarpine*, a naturally occurring alkaloid, was at one time an important therapeutic agent that stimulates cholinceptive effectors directly. Like muscarine, it was of great help in elucidating the dynamics of autonomic function. Despite its long history, relatively little is known of its mechanism of action, and its use today is limited chiefly to its local effects upon the eyes.

Many drugs block the stimulation of effector cells by cholinergic agents. The prototype of the group is *atropine*, an alkaloid found in several species of the potato family. The classical source is *Atropa belladonna* (deadly nightshade). A chemical isomer, *scopolamine*, also occurs naturally and has the same effect upon cholinergic transmission. These two agents are essentially interchangeable both quantitatively and qualitatively in their effects upon the autonomic nervous system. Dozens of synthetic compounds, similar to atropine in action, are available. None is as potent (in terms of amount required to produce a given effect) as the natural alkaloids, and they vary one from another in their duration of action and affinity for certain types of effectors. This permits some selectivity in blocking cholinergic responses.

Atropine and its congeners combine reversibly with the receptor site to prevent access of cholinergic substances to the effector cell. As with the ganglionic blockers, acetylcholine is released from their nerve endings, but no response is elicited. The effects produced by atropine are those of interference with parasympathetic function and sweating. Consequently a patient who has received atropine shows exaggerated sympathetic effects, such as tachycardia, decreased intestinal motility, mydriasis, etc. These are not direct responses to atropine but rather the result of blockade of normal physiological antagonism to sympathetic functions.

DRUGS ACTING AT ADRENOCEPTIVE EFFECTORS

The effects of epinephrine and levarterenol (nor epinephrine) have already been discussed (ch. 58). Unlike acetylcholine, these substances are inactivated relatively slowly and hence may be administered exogenously to produce their characteristic responses. However, the administration of a single

dose of one of these drugs produces, therapeutically speaking, a transient response. Other drugs are available which produce various adrenergic responses for longer duration.

Ephedrine is an alkaloid from the Asiatic plant *ma huang*. It causes many of the cardiovascular effects of sympathetic stimulation, apparently affecting both alpha and beta receptors for it will increase blood pressure, dilate the pupil, relax the bronchioles, etc. Enough differences exist between the actions of ephedrine and epinephrine to suggest that ephedrine may act by some mechanism different from that of epinephrine, but no definitive statement can be made on the basis of information now available. It also produces central nervous system excitation, and is at times used to counteract central depression.

Many other adrenergic compounds have been synthesized. Minor chemical variations in some cases cause marked changes in the nature of the response produced. By making appropriate chemical modifications, drugs have been prepared which have primarily only one or two of the actions of epinephrine. The variety of drugs employed and the relationships involved in their actions is properly the scope of pharmacology and is too extensive a subject for review here.

Certain alkaloids (ergotamine, ergoeristine, etc.) found in ergot were found by Dale early in this century to block the pressor effects of epinephrine. In recent years a number of synthetic cholinergic blocking agents have been prepared. Most widely used of this group are *piperoxan* (Benodamine), *phenoxylbenzamine* (Dibenzyline), *phenotolamine* (Regitene), and *azapetine* (Ildar).⁴

Not all adrenergic effects are blocked by these agents. Vasoconstriction is most readily inhibited by these blockers. On the other hand, no known drug will inhibit sympathetic cardioacceleration. As with atropinelike drugs, the adrenergic blockers do not of themselves initiate responses, but effects are seen following their administration which are the result of disrupting the balance between the two divisions of the autonomic system or reducing excessive sympathetic activity.

Transmission at the Myoneural Junction

The transmission of impulses at the myoneural junction is accomplished in much the same fashion as synaptic transmission. Acetylcholine, liberated from the nerve ending, reacts with the muscle end plate to depolarize it and initiate contraction of the actomyosin fibers (fig. 71.5). Acetylcholinesterase immediately inactivates the acetylcholine, the muscle end plate repolarizes,

⁴ Many other compounds recently introduced into therapeutics produced limited adrenergic blockade which causes "undesirable side effects" at times.

FIG. 71-5 Diagram of the region of the muscle end plate (from Acheson after Couteaux)

and the situation is favorable for reception of another nerve impulse and initiation of another muscular contraction (p 1304-1305)

Evidence that acetylcholine is liberated from the terminals of motor nerves and serves as a transmitter of impulses to the muscle fibers has been obtained by Dale and his associates.

1 Upon rhythmical stimulation of the hypoglossal nerve of the perfused tongue of the cat acetylcholine appeared consistently in the venous fluid. Similar results were secured with the perfused leg muscles of the dog during stimulation of the ventral spinal roots after excision of the lumbar sympathetic chain.

2 The sudden injection of a small dose (2 to 10 μ g) of acetylcholine into the artery supplying the gastrocnemius of the cat during circulatory arrest caused a sharp contraction of the muscle. It is annulled by curare but not by atropine. The direct application of a minute amount (5×10^{-6} μ g) of acetylcholine to the motor end plate of the muscle fiber causes a short sharp tetanic contraction. Ten times this quantity applied elsewhere to the fiber is ineffective (Buchthal and Lindhard).

3 The intravenous administration of eserine (0.2 to 0.3 mg per kg) to a spinal cat caused an increase of 130 per cent in tension of a gastrocnemius twitch provoked by stimulation of the motor nerve. Eserine had no such effect upon the response of denervated muscle to direct stimulation.

DRUGS ACTING AT THE MYONEURAL JUNCTION

Although acetylcholine is the humoral mediator at the junction of motor nerves with skeletal muscle the other choline esters mentioned above, muscarine and pilocarpine have no effect at this site. Nicotine is capable of both stimulating and paralyzing the motor end plate in a manner similar to its action at the ganglia. Neostigmine and edrophonium (Tensilon) are capable of potentiating muscular activity and in larger doses will produce

fasciculations as a result of direct stimulation (depolarization) of the motor end plate. Obviously direct chemical stimulation of muscle fibers is not of therapeutic but only of toxicologic importance.

The inhibitors of myoneural conduction are of more importance. The inhibition may be of two types: a) Tubocurarine and its derivatives as well as the synthetic drugs gallamine (Flaxedil) and Mytalan paralyze skeletal muscle by blocking access of acetylcholine to the motor end plate. Depolarization cannot occur and contraction cannot be initiated. This blockage is reversible and to a limited extent paralysis with these agents can be overcome by the administration of a cholinesterase inhibitor (such as physostigmine or neostigmine) which will permit the released acetylcholine to increase to the point that it will drive the curare molecules from the receptors. Neostigmine and edrophonium in addition to their cholinesterase inhibiting action are direct stimulants to these cholinergic receptors and will reverse curare paralysis directly. A second type of inhibitor or muscle relaxant is exemplified by compounds such as succinylcholine (Anectine) or decamethonium (Syntaurine). These agents combine with the receptor site and cause depolarization. Since the compounds are relatively slowly inactivated the membrane does not repolarize so that impulses cannot be transmitted from the nerve ending even though acetylcholine is being released. There is no way in which this blockade may be reversed other than permitting the drug to be inactivated. Both succinylcholine and decamethonium are rather promptly inactivated by the tissues.

Myasthenia gravis. This condition as its name implies is a condition of profound weakness of the muscles, those of the eyes, face and throat being as a rule involved first. Collections of lymphocytes (lymphorrhages) and degenerative changes occur in the muscles. The disease is accompanied by a high degree of creatinuria and a reduction in the excretion of creatinine. The thymus is frequently enlarged and myasthenia gravis is a frequent accompaniment of thymic tumors. Administered creatine is practically all excreted as such. Death results from involvement of the respiratory muscles. Myasthenia gravis is associated sometimes with thyrotoxicosis in which enlargement of the thymus is also commonly seen.

In 1931 Walker described a dramatic improvement in a case of myasthenia gravis following the administration of eserine. Later prostigmine was found to confer even greater benefit. The effect unfortunately is transient, lasting for no longer than 3 or 4 hours. Other anticholinesterases like diisopropylfluorophosphate (DFP) have since been employed, the latter agent though it has a more lasting effect is otherwise inferior to prostigmine or neostigmine. The first drug to be used with

benefit was ephedrine, introduced by Edgeworth in 1930, who was herself a victim of the disease.

The muscular weakness in myasthenia gravis is not due to any disease of the central nervous system, nerve trunks, or muscles but, as shown by Harvey and his associates, to some defect at the myoneural junction. With regard to the nature of the functional disorder, the action of cholinesterases suggests three possibilities, namely (a) deficiency of acetylcholine production, (b) the presence of excessive amounts of cholinesterase or (c) the production of a substance with a curarelike action. The investigations of Wilson and Stoner point to the last mentioned as the most likely factor. They found no increase in the cholinesterase content of the blood in subjects of the disease, nor any evidence of a failure in acetylcholine synthesis, but the serum of patients suffering from the disease, but not under treatment with prostigmine, caused neuromuscular block in the nerve-muscle preparation of the frog. Serum from patients receiving prostigmine treatment exerted no curarelike action. With the idea that the primary fault originates in the thymus, thymectomy has been resorted to in some instances, with apparently beneficial results.

The Role of Humoral Transmission in the Central Nervous System

There is currently much controversy over the nature of synaptic transmission in the central nervous system. Acetylcholine is involved, but is apparently not the only transmitter. The prevailing concept is that where acetylcholine is involved its mechanism of action is similar to that at the autonomic ganglia. Where acetylcholine is not the transmitter, other substances have been suggested, including levarterenol (or "sympathin"), 5-hydroxytryptamine, histamine and adenosine triphosphate (ATP).

The role of acetylcholine is suggested by the following observations:

1. Feldberg and Vogt found varying concentrations of choline acetylase in different regions of the central nervous system belonging to the same afferent or efferent pathway. They attributed this variation to alternate distribution of cholinergic and noncholinergic neurons. For example, the retina of the dog contains large amounts of choline acetylase, the optic nerve very little, and the lateral geniculate body (where next neuron in the pathway begins) again large amounts.

2. Acetylcholine content of the brain varies with the degree of functional activity. Richter and Crossland have shown that during deep anesthesia the concentration of acetylcholine in rat brains is three times as great as during convulsions. The

concentration returned to normal in 10 seconds after cessation of the convulsions.

3. Acetylcholine has been found in the efferent venous outflow of the isolated cat's brain and in eserinated Ringer's solution which was perfused through the lower end of the spinal cord of the dog. In the latter instance stimulation of the central end of the divided sciatic nerve increased the concentration of acetylcholine during the period of reflex activity (Bülbring and Burn).

4. Acetylcholine is found in cerebrospinal fluid by a variety of techniques and it has been observed to transude from the cerebral cortex. This transudation decreases concomitantly with a decrease in electrical activity of the cortex as the depth of anesthesia is increased. Undercutting of the cortex (leading to a "silent cortex") stops the production of acetylcholine (MacIntosh and Oborin).

The evidence for the existence of noncholinergic chemical transmission is more tenuous.

1. Eccles has demonstrated by intracellular recording, that the electrical activity at synapses can be accounted for only on the basis of a mediator and that this mediator at certain synapses is not acetylcholine.

2. As mentioned, Feldberg and Vogt have demonstrated uneven distribution of acetylcholine in the central nervous system. The cerebellum is notably deficient in both acetylcholine and choline acetylase. Yet extracts of cerebellum injected into the carotid artery have been found to increase electrical activity of the cerebellum. No claim is made that this substance, as yet unidentified, is a mediator, but it seemingly would fulfill the requirements of a central transmitter.

3. 5-Hydroxytryptamine (serotonin) is irregularly distributed in the brain. This agent, as well as drugs which will liberate it and drugs which antagonize its actions peripherally, can elicit pronounced central effects. The objections to its role as a mediator result first from the fact that it is found in those areas also high in acetylcholine concentration, where presumably acetylcholine is functioning as a mediator. Second, drugs which have opposing central effects (such as amphetamine which is a stimulant and reserpine which is a depressant) produce identical quantitative changes in 5-hydroxytryptamine concentrations in the brain.

4. Levarterenol is also irregularly distributed in the brain. Like 5-hydroxytryptamine it is found in highest concentrations in those areas rich in acetylcholine. It has been demonstrated to modify synaptic transmission, but there is little evidence to justify assigning it a primary role in noncholinergic transmission.

No unifying statement may be made of the mechanism of humoral transmission within the

central nervous system That such transmission must exist seems assured Likewise, it must in part be cholinergic The identity of other mediators, or what functions are served by the substances found in the brain which are active elsewhere in the body, remains to be elucidated

Association for Research in Nervous and Mental Disease Vol 9 The vegetative nervous system

mechanism for blue light of the particular wave length used to illuminate the background. When this is done systematically throughout the spectrum with different wave lengths in the background the sensitivity of this part of the red mechanism to all other wave lengths can be plotted. If the red mechanism depends on two or more receptors or pathways then a further rise in the blue background intensity may produce another break in the regular increment threshold curve for a red test flash at the point where the second mechanism begins to be affected by the blue (or other colored) stimulus.

As a result of a detailed analysis made in this manner, in which numerous wave lengths have been used both for the test flash and for the background, Stiles has obtained evidence for five separate mechanisms in addition to the rods. The estimated spectral sensitivities of the three main ones (π_1 , π_2 , π_3) are plotted in figure 73 18. They provide a very important body of concrete information with regard to the color mechanisms in the normal eye. The problem however, remains as to how these curves should be interpreted and how they can be integrated into the other data on color vision.

Stiles is cautious on this subject and prefers to label the curves π_1 to π_3 and to use the word mechanism rather than receptor or even pathway. The point that has been determined in each case is the intensity which is required at each wave length for some process involved in the perception of the test flash to be affected by the conditioning stimulus. On structural and physiological grounds this new process which becomes affected could be (a) the threshold of a new type of receptor, (b) the threshold of a bipolar cell, (c) the threshold of a ganglion cell, or (d) the threshold at which some inhibitory process came into action. There is nothing as yet to indicate which of any of these processes is the effective one in any of the π_1 to π_3 mechanisms. When more information is available, this analysis of increment thresholds will undoubtedly prove of the utmost value. Meanwhile π_1 (blue mechanism), π_2 (green mechanism) and π_3 (red mechanism) agree very well with estimates which have been made of the sensitivity of these color mechanisms from the data obtained by color mixture. π_2 and π_3 are closely similar to the curves obtained from the foveal center and described above. Thus there now seems to be approaching some certainty that the sensitivity of the two mechanisms of the central fovea is very much as has been suggested, but there is still doubt as to what physiological characters determine the sensitivities of these two mechanisms. Among the various possibilities the following may be mentioned: (a) single pigments in single cones, (b) mixed pigments in single cones, (c) single pigments in single cones, but relaying on to combined

FIG. 73 18. Sensitivity curves for the π_1 , π_2 and π_3 mechanisms. The dotted lines represent the P and the D curves from figure 73 17. See text. (After Stiles and Wilmer.)

pathways, or (d) mixed pigments in single cones relaying on to mixed pathways (see figure 73 19). In addition to this simple pattern it could be postulated that other retinal nerve cells could also send information about the difference in responses between the receptors and these nerve cells might have very different thresholds from the receptors themselves. Figure 73 20 indicates one such possibility. The thresholds of cells 1, 2, 3 and 4 might be very different and very differently affected by adaptation and so show up by the increment threshold technique which after all depends on information supplied to the brain by the optic nerve and not necessarily only on the degree of stimulation of the receptors themselves. This hypothesis should be regarded as only a suggestion regarding the manner in which it is now becoming possible to think about retinal physiology, however, since retinal physiology is in a sense, the physiology of the central nervous system its implications are far reaching.

THE BLUE MECHANISM AND π_1 Although some finality appears to be approaching in relation to the identification of the red and green mechanisms, the nature of the blue mechanism remains an unsolved problem. From color mixture data obtained from both normal and color blind subjects and from the increment threshold data of Stiles (the

FIG 73 19 Some possible arrangements for the use of two types of pigment and two types of cone and for the transmission of their photochemical responses to the brain. See text

π_1 curve) it appears to have its maximum sensitivity at about 450 m μ . In several ways, it appears to differ in kind from the other two mechanisms. Some of these differences are listed below.

1 Blue contributes very little to the luminosity of any color mixture, and the responses from the green and red mechanisms (π_2 and π_3) account for nearly all the luminosity of the spectrum.

2 The blue mechanism does not operate with very small fields, and it may actually be absent from the central fovea.

3 The receptive field of the blue mechanism is about 13' in diameter, whereas for the red and the green mechanisms it is of the order of 1'.

4 Extrafoveally, a fairly large field has to be stimulated (or eye movements allowed) in order to allow the mechanism full play.

5 The normal eye can be reduced to a state of monochromatism by sufficient adaptation to violet and blue green, or to violet and red. When this is

done, the eye yields only colorless or very de-saturated sensations in response to subsequent test fields over a large part of the spectrum. If, on the other hand, it is reduced to monochromatism by intense stimulation by yellow light (which, incidentally, has very little influence on color sensations in the central fovea, other than raising their threshold) then all wave lengths from 400-500 m μ subsequently appear as a very saturated violet (which can be matched with 447 m μ). Under these conditions of "violet monochromatism" induced by intense adaptation to yellow light, as distinct from the more usual colorless monochromatisms, intensity discrimination becomes very bad and the visual acuity (see p 1364) becomes very low, black bars on a uniform field have to be separated by more than 7.5' before they can be resolved whereas in comparable "red" and "green" monochromatisms visual acuity is little impaired from the normal (bars can be seen as separate entities when only about 1' apart). This low visual acuity of the blue mechanism is comparable with the low acuity of the rod mechanism, although it is definitely somewhat higher.

6 When the eye is adapted to various colored lights, the effect of the adaptations on subsequent color matches can be recorded and the rate of the recovery of the different mechanisms from the

FIG 73 20 Some possible ways in which receptors could be linked to optic nerve fibers. Cell 1 transmits a , which is some function of A . Cell 2 transmits ab , where fb is some function of B , but not necessarily equal to b , which is the response transmitted by cell 4. Cell 3 transmits ba , where similarly, fa is some function of A but not necessarily equal to a .

FIG. 73 21 Fields for white, blue, red and green for a normal right eye (From Hartbridge)

adaptation can be investigated. It is nearly always found that although the red and the green components in the mixture tend to follow similar and rapid recovery curves, the recovery of the blue mechanism is definitely slower and follows a different time course.

7 The estimated spectral sensitivity curve for the blue mechanism (π_1) has an unique link in it between about 550 $m\mu$ and 600 $m\mu$ which is not found in other sensitivity curves nor in the absorption spectrum of carotenoid protein pigments.

8 Tritanopia (blue blindness) is inherited separately from the other forms of color blindness.

Several features of the blue mechanism suggest that it may be associated in some way with the function of the rods.

1 Neither the blue mechanism nor the rods are present in the foveal center, whereas the blue mechanism, unlike the red and green mechanisms, is in operation almost to the extreme periphery of the eye (see p. 1323), or at least as far out as color is recognized at all (fig. 73 21).

2 The blue mechanism is often the first of the color mechanisms to be affected in cases of retinitis pigmentosa. Tritanopia or failure of the blue mechanism often follows any retinal damage or degeneration which involves the destruction of the rods.

3 When light of any wave length from 400 to 570 $m\mu$ illuminates one half of a divided field (about 4° in diameter) at such a low level of in-

tensity that no sensation of color is aroused, one presumes that only rods are being stimulated. However, the illumination of the other half of the field with light of any wave length between 570 and 700 $m\mu$, of sufficient intensity to arouse a sensation of color in that half, i.e., to stimulate cones, immediately causes the first half of the field to darken and to appear blue. If the divided field is viewed monocularly, the blue can be matched by a spectral wave band centered on 464 $m\mu$ viewed by the unstimulated eye. The suggestion is very strong that rods are involved in this blue sensation.

4 Twilight vision often has a subjective quality of blueness.

There are, equally, several features which argue against the blue mechanism being dependent upon the rods.

1 The spectral sensitivity of the blue mechanism is not that of rhodopsin; it is more nearly that of indicator yellow, although this is not a photosensitive pigment in the ordinary sense.

2 The color mixture data are incompatible with rhodopsin as one of the primary pigments used for color vision if the curves for the other (π_1 and π_2) mechanisms are valid.

3 The visual acuity in violet monochromatism, although low, is higher than that with ordinary rod vision.

4 Trichromatic matches made at photopic levels should not break down at scotopic levels if

rods are involved in both. In practice such matches do sometimes break down.

It is clear from these summaries that, if rods are involved in the blue mechanism, they are acting in some rather different way from their more clearly recognized action. Although man has developed from nocturnal ancestors in whose eyes rods undoubtedly preponderated, it is rather extraordinary that his retina should still possess some twenty rods to every cone if they are of no significance in his apparatus for vision under ordinary daylight conditions, for he has now become such a definitely diurnal animal.

Moreover, there is something very attractive about the 'opponent color theories' that have been developed in various forms by Hering, Houtman, Ladd Franklin, Goethlin and more recently, by Hurvich and Jameson, some of which could well be reconciled with an antagonism between rods and cones. The essence of these theories, all of which vary in detail, is the idea of opposition between blue and yellow, and between red and green. Indeed there are many arguments which can be brought in support of such an interpretation of color vision, particularly if the antagonisms are thought of as not necessarily arising at the receptor level but at some higher level in the neural pathway.

Some of the electrical potentials recorded by Svaetichin and MacNichol (1958) in the horizontal cells (?) of fish in response to stimulation of the photopic receptors by different wave lengths of light suggest that they result from mutually antagonistic events. Negative potentials develop in the blue-green part of the spectrum, positive potentials in the orange-red.

The concept of one neural pathway or mechanism opposing another has much to recommend it as a means of reducing the information entering the central nervous system to manageable proportions and at the same time insuring that the specific qualities of the stimulus are maintained. Redundant information can be eliminated in this manner. For example, and as a pure hypothesis, if both rods and cones are being stimulated, the complete response of the less strongly stimulated together with the excess response from the other provide all the necessary information for recording both luminosity and a limited sensation of hue.

The general hypothesis that the most primitive form of color vision was based on some feature or modification of rod function opposing cone function (or vice versa) and giving rise to sensations of blue when the rod function was dominant and to yellow when the cones were in the ascendant is certainly attractive in its simplicity. It also suggests that the red-green blind (protanopes and deuteranopes) who have the two sensations only, may still possess something akin to this more primitive evolutionary condition of the visual

system. If some of the cones then acquired a second pigment, just as, among the chromatophores, the xanthophores often acquire a red pigment in addition to their normal xanthophyll and become erythrophores, two groups of cones could then result, and the responses from these two groups could provide the means of subdividing the sensation of yellow into one of blue-green and one of orange-red according to which type of cone gave the greater response. This concept is consistent with the restricted retinal fields over which the red and green sensations are evoked in the normal light-adapted eye, whereas the yellow sensation can be evoked, either by green or red light, as far out in the retinal periphery as any color sensations can be recognized (fig. 73.21). However in the dark-adapted eye, red is seen as red in the extreme periphery, yellow and green then generally appear as white because they excite the dark-adapted rods. The physiological interpretation of these receptive fields is presumably to be sought partly in the distribution of the receptors themselves and partly in the distribution of the various bipolar cells and ganglion cells which integrate and code the information provided by the receptors. Protanopia and deuteranopia may in some cases depend on defective transmitting systems rather than defective receptor systems. Two tentative schemes for retinal function could be summarized as follows (see Diagrams I and II). Both have their difficulties but they may help to provide some mental picture of present trends in color vision theory. Future research alone can clarify the position.

Visual Acuity

THE RESOLVING POWER OF THE EYE. The acuteness of vision (or visual acuity) is dependent upon several retinal functions, e.g., the sensitivity to light (intensity threshold), the minimum visible and the ability to recognize the separateness of two closely approximated or parallel lines. The threshold of the latter faculty is commonly referred to as the *minimum separable*¹ or the *resolution threshold*. Visual acuity is the basis of the *form sense*, by which is meant the power of determining by sight the shape, form, outline and minute detail of our surroundings. Visual acuity is customarily expressed in terms of the minimum separable or, to be more explicit, as the reciprocal of the angle subtended at the nodal point of the eye—the *visual angle*—by the space between two points situated at the minimum distance apart at which their duality can be recognized. For example, if the visual angle is 1/321

¹ The minimum separable is analogous to two-point discrimination in cutaneous sensation (p. 1140).

minute, then the visual acuity is $(1/1321 \rightarrow) 0.756$. The average normal eye can resolve two points when the visual angle is 1 minute (60 seconds). The maximum acuity measured with a Landolt C (see below) is about 21. As an object is moved away from the eye its visual angle becomes progressively smaller. Consequently, those details of form and structure which subtend an angle of a minute or more at the nearer point and are therefore visible, gradually become imperceptible with increasing distance. In other words, in order to see an object at a distance as clearly as when it is near the eye, it would need to be increased proportionately in size (see fig 73 22).

In determining the visual acuity, figures such as the broken circle **C** of Landolt or Snellen's prong, **E**, painted black on a white ground and in graded sizes are employed. The subject is seated at a distance of 6 meters (20 feet) and a figure is placed with the gap of the **C** or the prongs of the **E** turned to the right or left, he is asked to say in which position the figure is directed. The width of the lines composing the figures and the gap in the **C**, or the spaces between the prongs of the **E**, subtend angles of various degrees, depending on the size of the figure, when placed at a distance of 6 meters. The width of the whole figure is five times the thickness of its parts. By finding the smallest figure whose position can be recognized the visual acuity of the subject (in terms of the visual angle) is ascertained. In testing the visual acuity for the fitting of glasses Snellen's test type is most commonly employed. This test is devised upon the basis that two points or lines separated by a space having a visual angle of 1 minute can be resolved by the average normal eye. The test type comprises nine rows of block letters printed in black upon a white card. The rows are arranged in descending order of size from above down. The width of the lines forming the letters of the first row subtends an angle of 1 minute at 60 meters from the eye, whereas that of the letters in the other rows, two to nine, have a visual angle of 1 minute at 36, 24, 18, 12, 9, 6, 5 and 4 meters, respectively. The card is placed in a good light, the patient is seated facing it at a distance of 6 meters and asked to read down as many rows as he can. The visual acuity is expressed as a fraction, the numerator being the distance at which the subject is seated from the card and the de-

FIG 73 23 See text

ominator the distance at which the letters could be read by the normal eye. Thus, if he reads the seventh row of letters, i.e., those with a visual angle of 1 minute at 6 meters his vision is $6/6$ or normal. If, on the other hand, he can see distinctly only as far as the fourth row, which the normal eye can read at 18 meters, his vision is $6/18$, if as far as the third row his vision is $6/24$, and so on, for any other row which he is just able to read.

Knowing the distance of the nodal point of the eye from the retina and the visual angle, the size of the retinal image of an object can be calculated (p 1380, 1381). With a visual angle of 1 minute the space on the retina separating two point images is 44μ . The diameter of the space occupied by a foveal cone is given by different observers as between 25 and 40μ . Even if the higher of these figures is taken, then the image of two dots separated by 44μ would fall upon two cones separated by a single unstimulated cone or by one stimulated differently, i.e., by the image of the interspace (fig 73 23).

From such calculations it has been argued that the distance between cone centers is the limiting factor in discriminating two points or thin lines, for obviously with an interspace less than a cone width the two dots would fall upon a single cell, and from what is known of the nerve impulse it cannot be admitted that two parts of a visual receptor, upon receiving simultaneously different types of stimulus, can give rise to dissimilar sensations.

Difficulties stand in the way of so simple an explanation. The eyes, even with the most exact fixation, are constantly executing fine movements (subtending as much as 10°), and this means that the retinal image does not stimulate only one group of cones, but must be constantly shifting its position. This theory must also make the assumption that when the angular distance separating two points is about the diameter of a cone the two images must be dodged about with almost incredible precision, so that they come to lie not on adjacent cones (see fig 73 23) but on two cones separated by an unstimulated cone or by one stimulated differently. Adler concluded from his experiments, in which fixation as exact as possible was secured, that a point image moves over from 2 to 4 cones at least. Furthermore, the size of the image on the retina cannot, owing to the diffusion of light, be calculated with the precision implied by the foregoing calculations (see below). It is true that the smallest visual angle recorded ($25''$) for the space between two visually discrete objects

FIG 73 24 Description in text

would give a retinal image of the same order of magnitude as the diameter of a cone—a fact which fits the theory that the latter is the limiting factor. Nevertheless, it is probable that the correlation is little more than a coincidence.

Wilcox and Purdy suggest that the essential factor is the total illumination of the central cone as compared with its fellow on either side. Thus, in figure 73 24 A, cone 2 receives more light than cones 1 and 3. There is no reason then theoretically why the interspace separating two lines could not be narrower than the width of a single cone and still be recognizable. A limit would be reached, however, when the white interspace was reduced to about half the width of a cone, then all three cones must be illuminated equally. It may be asked, what essential difference is there between the minimum visible (p 1364) and the minimum separable, that the minimum visual angle should be so much greater in the one instance than in the other? Two parallel black lines upon a white surface are recognized as separate because a third white line is seen between them. Why then, provided it is bright enough can it not be seen, even though reduced to an almost infinitesimal width? The difference in the two instances appears to be a matter of the background and may be illustrated by fig 73 24 B. A bright light upon an extensive background illuminates a single row of cones, whereas all cones for a distance on either side are unilluminated. According therefore to the conception of Wilcox and Purdy, no difference exists, in so far as the fundamental retinal process is concerned, between the minimum visible and the minimum separable.

There is one aspect of visual acuity which is probably of far more importance than appears at first sight. It might be supposed that the highest visual acuity would only be obtained if there existed an exactly one to one relationship between each receptor and its optic nerve fiber. It must be remembered, however, that there are, in and around the central fovea, not only midsize bipolar cells but numerous flat and brush types also and that these presumably collect information from numerous receptors. Moreover, ganglion cells may again collect information from several of these bipolar cells. The fields of these cells certainly overlap, which incidentally may have considerable advantage in preventing the development of blind spots or scotomas when individual cells

FIG 73 25 Diagram illustrating the effect of overlapping receptive fields on visual acuity. For explanation see text.

degenerate. The situation is diagrammatically represented in figure 73 25 where the circles represent the overlapping fields of five bipolar cells. A study of this figure shows that the field in question must be covered by at least these five fields, and that it can be subdivided into numerous areas in which from one to five of the receptive fields in question may be affected. For example, a receptor situated at point A would affect four out of the five bipolars, but one situated at point B would affect only one. Thus position on the retina is specified by the particular pattern of bipolar cells which are stimulated. Moreover it has been shown that within any one receptive field the center is generally the most sensitive part and that a greater stimulus becomes necessary to elicit a response from the margins of the field, thus means that a still greater specificity can be achieved in the pattern of response to stimulation of any particular point in the retina. The point A lies on the margins of fields 1, 2, 4, and 5 and therefore stimulates them all rather weakly, but point B affects field 3 maximally and the other fields not at all. Every point stimulated in the area under discussion thus evokes a particular and specific pattern of responses from the bipolar cells both with respect to the grouping of cells affected and also with respect to the frequency of impulses generated, since these depend on the intensity of the stimulus and the position within the receptive field.

As with other faculties of the eye, no absolute and constant value can be given for the minimum separable. It varies greatly with several factors, viz, (a) the intensity of illumination of the test

FIG. 73-26 Relation between visual acuity and illumination (After Hecht)

object, (b) the spectral character of the light, (c) the region of the retina stimulated and (d) the size of the pupil.

The resolving power of the eye for two points increases with the illumination, as illustrated in fig. 73-26. This is a fact difficult to explain. It might be thought that as long as the illumination was above the threshold for a just perceptible sensation, increase in the intensity of the light would be without influence upon the threshold for the minimum separable. Two theories which have been proposed to account for the phenomenon will be mentioned, not because they give any final answer to the problem, but because they bring up some interesting points.

Hartnidge proposes a theory based upon the aberrations of the optical system of the eye and the ability of the retina to discriminate between small differences of light intensity (p. 1341). The retinal image is not clearly defined but is blurred by diffusion circles or bands, caused by the diffraction of light at the pupillary margin and to colored fringes (chromatic aberration, p. 1304). Assuming the pupil to be 3 mm. in diameter and a foveal cone 3.2μ across, he made the following calculations of the light distribution on the retina caused by a white line separating two dark areas. The illumination of the row of cones corresponding to the center of the line image was taken as 100. The illumination of the next row was 31% of the next 9%. The diffusion bands thus virtually increase the width of the image of the white line beyond that indicated by calculations from the visual angle, and encroach upon the dark boundaries. The fine movements of the eyes are continually shifting the image and even the slightest movement will cause the line of junction between the outermost diffusion band and the dark area to move from one row

of cones to another. A row of cones is therefore stimulated at one instant at a different intensity from that at the next. If the difference in light intensity is greater than 10% it is appreciated, and thus a gap between the two dark areas is detected. Now the threshold for discrimination of differences in light intensity varies with the illumination (p. 1342). Consequently, when the illumination is reduced, the difference between the intensity of the outermost diffusion bands and of the dark areas is not perceived, i.e., the shift of the line of junction from one cone to the next causes no sensation. The difference between the illumination of the inner and outer bands may be still detectable but the width of the bright line will be reduced. With further reduction in the illumination and the consequent raising of the threshold for intensity discrimination the white image becomes still narrower and finally, when the angular width is about $1'$, the dark areas fuse across it.

Hecht's theory postulates a change in the "grain" of the retina as a result of variations in illumination. The retina, according to Hecht, is made up of sensitive elements of different intensity thresholds distributed in a statistical manner similar to that of other populations. At low levels of illumination only a proportion of these elements (i.e., rods with the lowest threshold) are excited. The active elements are therefore farther apart and the "grain" of the sensitive surface is relatively coarse. As the light intensity increases the thresholds of more and more elements are exceeded. More rods function, that is, the number of active elements is increased and the "grain" of the retina is finer. As the illumination rises further, cones first those with the lowest thresholds and later less sensitive ones, become active. The maximal effect of increasing the illumination upon the resolving power is reached when the entire rod and cone population is responding (see fig. 73-26). Objections to both of the theories just outlined could be cited, several observations indicate that the threshold for the minimum separable is not dependent entirely upon retinal factors but that central processes play an important part.

The influences of such processes as the lateral inhibition already mentioned in sharpening up edges and increasing contrast between illuminated and unilluminated areas must also be important in determining visual acuity at different brightness levels.

The resolving power of the eye is greater for monochromatic light than for a mixed light source such as daylight when the two have equal illuminating values. This fact is due to the absence of chromatic aberration in the former instance. Monochromatic yellow light ($575 m\mu$) gives the highest value, next in order come green, red and blue.

Theoretically the resolving power must be limited by half the wave length of the light and should therefore be higher in the short-wave end of the spectrum. However, the amount of light visible in the short-wave end falls off very rapidly and as shown on pp 1362-1363 the visual acuity of the blue mechanism is conspicuously lower than that of either the green or the red mechanisms. For these reasons, the middle region of the spectrum in practice shows the highest acuity. Hartnidge has suggested that the visual acuities in white light and in monochromatic lights remain approximately the same, in spite of the fact that there may be blue, green and red sensitive cones, because the cones of the different types may be grouped together in clusters in a more or less random way and the eye tends to fixate the image on the most appropriate cluster.

Three factors are involved in the effect of pupillary size upon the resolving power of the retina. Increase in diameter allows more light to enter the eye and therefore increases the illumination of the retinal image and raises the visual acuity. Diffraction is also reduced by widening the pupillary aperture which will tend to improve the definition of the image. On the other hand, narrowing the pupil diminishes chromatic aberration. The optimum pupillary size lies between maximum constriction and full dilation, namely, at a diameter of about 3 mm.

With ordinary illuminations the visual acuity is some twenty times greater at the fovea than in any outlying part of the retina. In the dark adapted eye (p 1342) the peripheral retina has a much higher value than the fovea.

The illumination of the field surrounding the test object (the surround) has an important influence upon the resolving power of the eye. A uniform increase in the illumination of the surround up to one tenth that of the test object progressively increases visual acuity. Raising the illumination of the surround from this point to equality with the test object causes a slight reduction in visual acuity and when the surround becomes brighter than the test object there is a decided depression. A very bright but small light source situated in the neighborhood of the test object, e.g. a motor head light, causes a very marked lowering of the visual acuity. The effects caused by such concentrated sources of light are referred to as 'glare'. If the small light source is not too bright and especially if the surround is dark little depressing effect upon the acuteness of vision is produced, indeed there may be an improvement due to the accompanying pupillary constriction.

FIG 73-27 See text (After Adler)

THE DISPLACEMENT THRESHOLD ON THE VERNIER ACUITY These terms are applied to the visual faculty of recognizing a break in the contour of a border, a variation in width of a line or the lack of alignment of two straight lines placed end to end. This power of the eye is some ten times greater than its ability to resolve two points. A break in a line subtending an angle as small as $5''$ or even $1''$ can be detected under optimal conditions. It seems quite certain that this visual faculty is not limited by cone diameter, for the break must lie on a single cone and the lines on both sides of the break on the same row of cones (fig 73-27). It is probable that the underlying mechanism is different from that governing the threshold for the discrimination of two points. For example, its threshold is only slightly raised by increasing the illumination (p 1368).

Anderson and Weymouth offer an interesting theory to account for the extraordinary accuracy of the vernier acuity. They suggest that the slight but continuous eye movements shift the line image over the retina, causing successive stimulus patterns. The averaging of the successive patterns gives a sense of position which they call *retinal local sign*. The longer the lines the greater are the number of patterns presented to consciousness and consequently the more accurate is the averaging process. For details of the view of the authors the reader is referred to their original paper.

Hubel and Wiesel have recently (1959) shown by electrical recording from single cells in the visual cortex of the cat that some of these cells respond only to linear patterns of light on the retina and that the orientation of these linear patterns may determine whether a given cell will discharge.

SOME PRACTICAL CONSIDERATIONS WITH REGARD TO LIGHTING Besides reducing visual acuity, glare causes discomfort and one instinctively attempts to protect the eyes by closing the lids or raising the hand as a shield, the pupil constricts. A constant source of glare, even of mild degree results in eye strain. Glare has been classified into three types—veiling, dazzling and blinding. *Veiling glare* is that due to strong light which being uniformly superimposed upon the retinal image, reduces contrast. The light reflected from a printed

page under a bright sky is an example. *Dazzling glare* is due to scattered light in the ocular media which does not form part of the retinal image. Such glare can be produced by a strong light shining into the eye from an angle of about 45° . *Blind glare* results when one looks directly at a very bright light. It is due to an actual reduction of retinal sensitivity.

For moderately fine work, such as reading, sewing, typesetting etc., the illumination of the objects should not be less than from 10 to 20 foot candles. An illumination of 10 foot candles is sufficient for reading ordinary black type on good paper, but the higher illumination is necessary if the printing or the paper is of poor quality. The effect of lighting upon the performance of type setters, mail sorters and others engaged in fine work has been the subject of a number of investigations. Raising the illumination has been found to increase the rapidity and accuracy of the work by from 10 to 16 per cent and to reduce eye strain and general fatigue. The maximum efficiency appears to be reached when the illumination is about 20 foot candles. The lighting should be diffuse and naked bright light sources which could cause glare eliminated. The central field should receive additional lighting so that its illumination will be from 5 to 10 times that of the surround. The constant use of the eyes in poor lighting leads to ocular strain and fatigue with consequent headache. It may cause increase in pulse rate and even nausea, ultimately serious eye defects, especially in the young, may result. The quality of the light is also an important factor. The nitrogen light, being more homogeneous, gives a higher visual acuity than the ordinary electric light bulb; the kerosene lamp lies between the two.

THE PERCEPTION OF MOVEMENT. This is the most primitive of the visual functions; in disease it is the last to fail and is the first to return should any improvement in vision occur. The peripheral (extrafoveal) retina is more specially differentiated for the perception of movement than for other purposes. It is a familiar fact that a slight movement is readily detected even if the moving object is not in the direct line of vision, i.e., when its image falls upon the peripheral retina and the eyes are not fixed upon it. The most sensitive part of the retina is from 10° to 15° from the fovea, but sensitivity diminishes progressively towards the periphery. In the region of maximum sensitivity the angular velocity of a just perceptible movement is from one half to one minute per second, provided that there are stationary objects in the visual field to serve as reference points.

When such are absent the angular velocity must be from 10 to 20 times as great in order for the movement to be perceived. On the other hand, if the angular velocity is very great the movement is not perceived, owing to visual persistence; a very rapidly moving object appears as a stationary streak. The total distance travelled, i.e., the displacement of the object as well as the angular velocity is, of course, a factor in movement perception. The minimum displacement is about 17 seconds of arc, under optimal conditions. The sensitivity of the retina to movement is lower in the dark adapted than in the light adapted eye. Barlow has suggested that the on-off fibers play a large part in the detection of movement.

When the eyes are stationary but the body or head is moved, an *apparent* movement is given to objects in the visual field. To a subject travelling in a train, near objects often appear to move in the opposite direction to the direction of travel whereas those in the background appear to move with the moving vehicle. Apparent movements of surrounding objects also occur when the eye is displaced slightly by pressure upon it with the finger tip or as a result of involuntary contraction of the eye muscles. These apparent movements are attributed to the successive stimulation of groups of receptors as the images move over the retina. When the eyes are moved voluntarily from one object to another in the visual field, images must sweep over the retina in a similar fashion, yet there is no apparent movement of stationary objects. An allied phenomenon and one which offers a similar problem to be solved is seen in cutaneous sensation. We are able, for example, to distinguish between the movement of the finger over a stationary object and the movement of an object over a motionless finger. In both instances receptors are stimulated successively. Conversely, the movement of an object is perceived when it is followed by the eyes, although the position of its retinal image does not alter. It is quite evident that the perception of movement is very complex and cannot yet be explained in all its aspects upon physiological grounds. It is suggested that the absence of an apparent movement of stationary objects when the eyes are turned from one part of the visual field to another is to be explained upon the basis of *attention*. The attention exercised by the observer in changing the fixation of his eyes from the one to the other point compensates, it is believed, for the movements of the images over the retina. In other words, the successive stimulation of visual receptors is ignored because the point to which the eyes are to be turned

engages the attention at the moment that the eye movement takes place, or even before. The perception of the movement of an object pursued by the eyes must also depend upon cerebral processes.

Apparent movement is also produced by the stimulation of closely approximated retinal areas in rapid succession by a series of images of a stationary object. The two main factors determining this so called *stroboscopic illusion* of movement are the time interval between the stimuli and the angular separation of the successive retinal images. A visual sensation of smooth motion is produced when the angular separation is about 1 degree or less and the intervals between the stimuli about $\frac{1}{30}$ second. At intervals of $\frac{1}{30}$ second or less no sensation of movement is produced. The illusion of motion is also lost if the time intervals are lengthened to $\frac{1}{15}$ second or greater, the impressions then becoming discrete.

Irradiation. Owing to chromatic and spherical aberration the images on the retina are not formed of geometrical points of light, but rather of bright points surrounded by diffusion circles. For this reason and also probably as a result of the spread of the effect of the stimulus (*irradiation*) to neighboring neural elements of the retina, or even within the visual area in the brain, a bright area on a dark ground appears larger than a dark one of the same size upon a bright ground. In either instance the image of the bright area encroaches upon that of the black area (see fig. 73 1).

INTERMITTENT RETINAL STIMULATION, FLICKER. When the retina is stimulated intermittently by a series of light flashes as may be produced by interrupting a continuous light by a rotating notched disc or by reflecting light from a rotating disc divided into alternate black and white sectors, a characteristic flickering or unpleasant glittering sensation is experienced when the periodic stimulation reaches a certain frequency. This is due to each light stimulus falling upon the retina during the time of the positive after image (p. 1372) of its predecessor. The suppression of the after image by the second stimulus causes the first sensation to end more abruptly, and, through contrast, to render the succeeding one more brilliant. Upon further increasing the speed of rotation and, in consequence, the frequency (number per second) of the light stimuli, fusion results and the flicker disappears, to be replaced by a continuous sensation having a brilliance equal to the mean of the two (bright and dark) impressions, the frequency at which this occurs is called the *critical fusion frequency* (CFF). If at the instant of fusion the illumination of the bright patch in millilamberts

be designated a , its area designated b , and the total area of the disc, c , then the sensation produced is equal to that which would result from a continuous stimulus having the value $(a \times b)/c$. This is known as the Talbot Plateau law. It accounts for the well known fact that a gray sensation of any depth can be matched by throwing black and white images alternately and at a suitable frequency upon the retina. Similarly, at the critical fusion frequency, white and red images give a sensation of pink, blue and red, a sensation of purple, yellow and green, yellowish green, and so on. These effects are simply explained by *visual persistence*, that is, the sensation evoked by one stimulus has not ceased before the next one is produced, thus a blend of the two sensations in consciousness results. The law holds true only for moderate light intensities.

The value of the CFF is variable, depending upon several conditions the most influential of which is the intensity of the light, the value rising as the intensity increases. That is, a higher rate of stimulation is required for fusion as the intensity of the illumination is increased. The influence of light intensity is embodied in the Ferry (1892) Porter (1906) law which states that the *critical fusion frequency is directly proportional to the logarithm of the light intensity*. Thus, $n = k \log I + k'$ where n equals flashes per second at the instant of fusion, and I the light intensity, k and k' are constants involving the size of the stimulated area and the sensitivity of the observer's eye.²

The Ferry Porter law is valid, however only under certain special conditions. It holds over moderate ranges of illumination of the test object when the image is restricted to the fovea. Above and below this middle range the linear relationship between the logarithm of the intensity and the critical fusion frequency does not hold. When the value of n is plotted against $\log I$ at low and at high intensities the points fall on two straight lines, one at low the other at high intensities. It is believed that these represent respectively rod and cone function, a conception borne out by the results of Hecht and associates and of Lythgoe and Tansley.

Hecht found that with a stimulus restricted to the fovea (cones) the relationship was linear for a middle range of illumination, but above this the curve flattened out, below, it formed a very gentle

² Determination of the critical fusion frequency (CFF) offers an accurate and convenient method for comparing the brightness of differently colored lights. It is especially valuable in this regard because of our natural tendency to confuse the brightness of a color with its hue or saturation.

FIG 73 23 Relation between critical frequency and log I for white light with a 2° field in four retinal locations, at the fovea, and at 5° , 15° , and 20° above the fovea (After Hecht from Hecht and Verriy)

curve. With the image on extrafoveal regions the data form two intersecting straight lines, one at lower the other at higher intensities, the former presumably represents rod function, the latter peripheral cone function (fig 73 23).

Lythgoe and Tansley observed that during dark adaptation the CFF falls in both the fovea and the peripheral parts of the retina when the intensity of the test light was high (6.8 foot candles). At low intensities (0.020 foot candles) the CFF also falls at the fovea, but rises in the peripheral retina. Now, as judged by other criteria, only cones are functioning at high intensities whether the fovea or the peripheral retina is being tested, at low intensities only rods. Also, it was found by Lythgoe and Tansley that when red light was used for testing (rods insensitive), and in a case of night blindness (defective rods) a fall in the value of the CFF occurs during dark adaptation. The fall in the value with high illuminations of the test object is due presumably to the cones, and the rise with low illuminations, to the rods. At moderate illuminations of the test object a fall occurs during the first 5 minutes of dark adaptation (due to cones), (see p. 1142) followed by a rise (due to rods). The critical frequency due to the rods is highest with dark surrounds, that due to cones is increased by bright surrounds, the maximum being reached when the brightness of the latter and of the test object are equal.

A study of the retinal potentials (ch. 72) during intermittent stimulation shows that when a light flash falls upon the retina during the "off effect" of a preceding stimulus, the d wave is interrupted and a pronounced negative dip occurs. This is an exaggerated a deflection. The negative deflection is followed by a large positive swing which, if the

second stimulus occurs soon after the first, is simply the return of the momentarily interrupted "off effect" of the first. If the interval between the two is greater, the upswing is higher, and is then due to the b deflection of the after coming stimulus. Thus, if the light flashes are so timed that each interrupts the "off effect" of its predecessor, a series of regular ripples appears in the electroretinogram which apparently are the cause of the flickering sensation. No negative dip occurs nor do the characteristic ripples appear if a flash falls upon the retina before the "off effect" of the preceding one—a continuous sensation should therefore result.

AFTER IMAGES If the gaze is directed to a bright white light for a moment and the eyes then closed or turned towards a dark surface, an image of the light slowly floats into view, becomes more distinct for a time and then gradually fades. Similarly, if the eyes are stimulated by a colored light or a brightly colored object of any sort, and then darkened, an image of the same color appears. These are called *positive after images*. If, instead of closing the eyes or turning them to a dark surface after looking at a white light, the retinas are stimulated a second time and diffusely by white, e.g., by directing the eyes to a sheet of paper, one then sees a dark image against a white ground. This is called a *negative after image*. If the first stimulus was colored, then this after image is in the complementary color. Negative after images of colored objects are the cause of the phenomenon known as *successive contrast*.

On the basis of Young's theory of color vision, the phenomenon of negative after images is due to adaptation of one or other of the three types of mechanism by the first stimulus. A mechanism which has responded to a given stimulus will not for a time respond as strongly to one of the same type. White light stimulates all three mechanisms. The negative after image which appears upon applying a circumscribed and then a diffuse white stimulus to the retina is, therefore, a dark patch against a white background. When the object looked at is colored and the retina is then stimulated by directing the eyes to a white surface, the image is in the complementary color because those mechanisms which had not been previously stimulated respond more vigorously than the ones stimulated by the colored object. For example, if the object looked at is red, the red mechanism is less excited by a subsequent stimulus of white, those sensitive to green and to violet remain relatively normal and so give a sensation which is the complementary of red, namely, a bluish green.

Positive after images are apparently due to

FIG 73 29 Optical illusion The distance from A to B appears to be greater than that from B to C, they are the same

FIG 73 31 Zollner's lines The long diagonal lines appear to converge, actually, they are parallel

chemucophysical changes in the receptors of the retina caused by and outlasting the stimulus—a form of visual persistence

OPTICAL ILLUSION The brain may be deceived by imitations of certain effects upon which our visual judgments of the size, shape and distance of objects are based. Visual errors of this nature are called *optical illusions* or *optical deceptions*. Some interesting examples are shown in figs 73 29 to 73 31

THE DIOPTRIC MECHANISMS OF THE EYE. CATARACT. OPTICAL DEFECTS. INTRA-OCULAR FLUIDS

Principles of Reflection and Refraction. Definitions and Terminology

Light falling upon a surface undergoes *absorption* and *reflection*, and, if the material is transparent, the rays are transmitted through it, either with or without *reflection*.

The proportions of rays falling upon an opaque unpolished surface which undergo absorption and diffuse reflection, respectively, vary with the character of the surface. A large part of the rays striking an unpolished white surface, e.g., a sheet of paper, are reflected but, being thrown off at different angles to the perpendicular, they do not meet at a focus in front of, or, if continued backwards, behind the surface. The light reflected from such a surface is said to be *diffuse*.

The greater proportion of the light striking a polished surface (e.g., a mirror) is reflected, but the incident and reflected rays are always in the same plane and the angles (angles of incidence and of reflection) which they make with the perpendicular are equal. This statement is true for any polished surface whatever its shape (fig. 74 1).

Reflected rays from a plane mirror are divergent, if continued backwards they would meet at a point situated at the same distance behind the mirror as the object emitting the light lies in front of it. The eye placed in the path of the reflected rays projects them to this point, where a full sized erect image is formed (fig. 74 2). Since the rays do not actually meet at this point but only appear to do so, the image is called *virtual*.

THE FORMATION OF IMAGES BY SPHERICAL MIRRORS. A spherical mirror is the segment of a sphere, its reflecting surface may be *concave* or *convex*, its center of curvature is the center of a sphere of which the reflecting surface forms a part. The middle point of the curved surface is called the pole of the mirror, and a line passing through the pole and the center of curvature is termed the principal axis. The radius of the mirror is the distance from the pole to the center of curvature. Since the latter may lie on the same side as the source of light (concave mirror) or on the opposite side (convex mirror) the radius may be *positive* or *negative*, respectively.

Rays of light coming from a distant object, i.e.,

from infinity, are parallel (1 and 2, fig. 74 3), if they fall upon a concave mirror they are reflected as converging rays and meet in front of the mirror at a point (F) on the principal axis (p o). This point (F) is the *principal focus* and the distance from it to the reflecting surface is the *focal length* or *focal distance* of the mirror. It lies in the principal axis, midway between the center of curvature and the surface of the mirror. A real inverted image of the object and smaller than it, is formed in front of the mirror at the principal focus, that is, in space. The rays from a near object are divergent, the reflected rays are therefore less strongly convergent than when the incident rays are parallel. If the object is at the center of curvature (C) of the mirror then the rays are reflected back to this point. When the object is at a point between the center of curvature of the mirror and the principal focus the rays meet beyond the center of curvature at A, when the object is at A the reflected rays meet at a. These two points are therefore reciprocally related and are called *conjugate foci*. An object placed between the mirror and its principal focus emits rays which upon reflection are widely divergent and cannot be brought to a focus in front of the mirror. Projected backwards they meet at a point behind the mirror where a virtual erect and greatly enlarged image is formed.

Parallel rays striking a convex mirror are reflected as divergent rays which if continued backwards would meet behind the mirror at the principal focus. To the eye they therefore appear to come from this point. Here a virtual erect image, smaller than the object, is formed (fig. 74 4).

The position of an image formed by a concave mirror can be found from the construction in figure 74 5. The object AB is situated beyond the center of curvature C. The rays AP and BO parallel to the principal axis MN after reflection meet and cross at the principal focus F. The images of the points A and B, therefore, lie somewhere on the lines PQ and OL. Now, if lines AD and BH be drawn to pass through C, these lines, known as secondary axes, will cut lines PQ and OL at a and b respectively. Thus, a small inverted real image ab is formed. The image is called real because the rays actually pass through a and b. The construc-

tion of an erect virtual image by a convex mirror is shown in figure 746. The rays from the object AB diverge after reflection and appear to come from F (dotted lines), the image ab is formed at the intersection with the secondary axes AC and BC.

REFRACTION Rays of light in passing obliquely from one transparent medium to another of a different optical density (e.g., from air to glass) are bent or refracted. If one medium is surrounded by the other (e.g., glass in air) the ray is refracted twice. In passing from the medium of lower to the one of higher optical density the rays are bent towards the perpendicular, in the transition from the denser to the rarer medium the bend is away from the perpendicular. With any two media the greater the obliquity of the incident rays the greater is the degree of refraction, rays perpendicular to the surface between the two media are not refracted. The ratio of the angle made by the incident ray (i.e., the ray falling upon the surface of the second medium) with the perpendicular (*angle of incidence*) to that made by the emergent ray (*angle of refraction*) is termed the *index of refraction*. The *refractive index* is the index of refraction when the incident rays enter a substance from a vacuum. In practice air is considered to be of the same optical density as a vacuum. The refractive index is expressed as the ratio of the sine of the angle of the incident ray (i) to the sine of

FIG 747 The oblique ray (A) is refracted upon entering and leaving the block of glass. The emergent ray has the same direction as the entering ray but is not in the same line. P represents perpendicular. The ray B which strikes the glass surface perpendicularly is not refracted.

Fig 74 8 ABC is a prism with the apex at A, the base BC, and the sides AB and AC. The angle of the prism is BAC. A ray of light DEFG is refracted at E and F as in figure [747]. The total amount of refraction, that is the difference in direction between DE and FG, is represented by the angle DKH (the angle of deviation). If the eye is at G, the source of light, D, will appear to be at H. When the ray passing through the prism (EF) is parallel to the base (BC), the ray is said to traverse the prism symmetrically.

the angle of refraction (r), thus, refractive index = $\sin i / \sin r$. The refractive index is a measure of refractive power, it is 1.52 for crown glass and 1.66 for flint glass.

Refraction by plane surfaces. Oblique rays striking a medium with plane parallel surfaces, such as a sheet of glass, are refracted to an equal degree upon entering and emerging, but in opposite directions, i.e., towards and away from the perpendicular, respectively. The incident and emergent rays are therefore parallel though not quite in the same straight line (fig 74 7). A prism has its sides inclined towards one another. Since a ray is refracted upon entering at one surface of the prism and again upon emerging at the other, and is bent so as to run more nearly perpendicular to the glass surface in the former instance and away from the perpendicular in the latter, it will be refracted each time towards the base of the prism (fig 74 8).

Lenses are of two main types: spherical whose surfaces are the segments of spheres and cylindrical.

Fig 74 9 Cross sections of lenses A, planoconvex, B biconvex, C planoconcave, D, biconcave, E, convexoconcave, F, concaveconvex

Fig 74 10 See text

drical. There are six varieties of the former—*planoconvex*, *biconvex*, *planoconcave*, *biconcave*, *convexoconcave* and *concaveconvex* (see fig 74 9). Many modern spectacle lenses are made in the *convexoconcave* or *concaveconvex* form in order to reduce distortion of the visual field when the wearer looks through a peripheral portion of the lens. Lenses of these two forms which also include a cylindrical element are described as *toric lenses*.

Convex lenses may be looked upon as a great number of truncated prisms with their bases directed towards the lens center. Concave lenses, on the other hand, are as a number of prisms arranged with their bases towards the periphery (fig 74 10). It follows then that a symmetrical biconvex lens will bend rays in the same degree at equal distances from its center and bring them to a meeting point or focus, whereas concave lenses will cause divergence of the rays. In either instance the rays are bent towards the bases of the constituent prism.

Refraction by convex lenses. A line passing through the centers of curvature of the lens is termed the *principal axis of the lens*. Any other line intersecting the principal axis within the lens (i.e., a diagonal line) is called a *secondary axis*. The radius of curvature of the lens is the radius of a sphere of which the refracting surface forms a part. Rays passing through the principal axis are not refracted, for the incident and the emergent ray strike each surface perpendicularly and the two surfaces at these points are parallel (see above). Moreover, rays in the secondary axes undergo only very slight refraction, and the incident and emergent rays through not quite in a continuous line are parallel, for again the surfaces which they pierce are parallel. The point where the principal axis is intersected by the secondary axes is termed the *optical center* or *nodal point* of the lens. In a biconvex lens with symmetrical surfaces the actual and the optical centers coincide but in other biconvex lenses the nodal point may be situated nearer to one or other surface.

Light rays from a distant object, i.e. from infinity, are parallel (fig 74 11). The point F where parallel rays meet after refraction is called the *principal focus*. The distance of this point from the lens is called the *focal length* or *focal distance of the lens*. The rays of a light placed at the prin-

Fig 74 11 See text

FIG 74 12 See text

incipal focus traverse the same path but in the opposite direction, and emerge as parallel rays

A near object emits divergent rays. If the source of light (fig 74 12, B) is on the principal axis a little beyond the principal focus, an image is formed at a distance on the other side of the lens greater than its focal length (at C), when the object is placed in the second position (C) an image is formed at the first (B). These points therefore, in respect to an object and its image are interchangeable and are termed *conjugate foci*. If the object is situated at a distance exactly double the focal length of the lens the conjugate foci are at equal distances on the two sides of the lens. In all these instances a *real inverted image, smaller than the object*, is formed. If the source of light (D) lies between the lens and its principal focus, the rays after passing through the lens are widely divergent. To the eye placed in the path of the emergent rays they appear to come from a point (V) at a greater distance behind the lens than the actual A. A *virtual, erect and enlarged image* is formed.

Light rays in passing through a *biconcave lens* are diverged (fig 74 13) therefore a *true image* is not formed. The eye in the path of the rays takes no account of refraction and the rays, in consequence are projected backwards as straight lines which meeting at a point on the other side of the

FIG 74 13 See text

FIG 74 14 Formation of an inverted image by a biconvex lens

FIG 74 15 Formation of a virtual erect image by a concave lens

FIG 74 16 1, refraction by a convex cylinder. A point of light is brought to a focus as a line after refraction through a cylinder. 2 refraction of light by a concave cylinder. Rays of light striking the cylinder perpendicularly to the axis A'A' are diverged and appear to be brought to a virtual focal line F F' (After Duke Elder)

lens, from a *virtual erect image, smaller than the object*.

The formation of an image by a *biconvex lens* is shown in figure 74 14. AB is an object. The rays AH and BE lying parallel to the axis MN meet and cross at the principal focus F. The image of the point A will be at the intersection of the secondary axis AC with AHDF and that of B at the intersection of BC with BEGF. Thus, a small inverted image is formed at ab. The formation of an image by a concave lens is shown in figure 74 15. Rays AHDK and BEGL from points A and B of the object AB are diverged in passing through the lens and appear to come from the principal focus F, as shown by dotted lines. The image of A is formed at a and of B at b, where these lines are intersected by the secondary axes.

Cylindrical lenses (fig 74 16) have one plane surface the other may be *convex* (convex cylindrical lens) or *concave* (concave cylindrical lens). A convex cylindrical lens may be regarded as a section of a cylinder sliced down its long axis, its horizontal meridian is convex. Rays transmitted through it at right angles to its vertical axis are converged as they would be by a convex spherical lens. Light traversing its long axis is not refracted the lens acting in this axis as a plate with parallel sides. A lens of this type may be looked upon as an infinite series of prisms arranged base to base in tiers. In the other type of cylindrical lens the horizontal meridian is concave, rays passing at right angles to the vertical axis are diverged.

The dioptr. The converging or the diverging power of a lens depends upon the curvature of its surfaces (the greater the degree of curvature, the greater the refracting power) as well as upon the

refractive index of the material of which it is composed. The focal length of a lens varies inversely with the refractive power and is therefore a convenient measurement for expressing the strength of a lens. The standard focal length is taken as 1 meter. The refracting power is expressed as the reciprocal of the focal length (given in meters), the unit being the *diopter (D)*. Thus, the strength of a lens with a focal length of 1 meter is 1 diopter, of one with a focal length of 2 meters, $\frac{1}{2}$ diopter, of one having a focal length of $\frac{1}{2}$ a meter, 2 diopters and so on. The symbols + or - (+1 D, +2 D, -1 D, -2 D, etc.) are used respectively for a converging and a diverging lens. For example if a concave lens has a refracting power of -1 D, a small virtual image of a distant object will be focussed 1 meter from the lens and on the same side as the object. A convex lens of a corresponding power (+1 D) will bring parallel rays to a true focus 1 meter behind the lens. The power of a cylindrical lens is expressed in a similar fashion.

THE REFRACTING MEDIA OF THE EYE These are the cornea, the aqueous humor, the crystalline lens and the vitreous body. The refractive indices are given in the following table

Cornea	1.37
Aqueous humor	1.33
Crystalline lens (whole)	1.42
Vitreous body	1.33

It will be noticed that the refractive indices of the cornea and of the aqueous humor and vitreous are approximately the same, for practical purposes they may be taken as identical and the eye then taken as having two refracting surfaces, (a) the anterior surface of the cornea in contact with

air, and (b) the lens surrounded by a common medium in so far as refraction is concerned. The greatest refraction occurs at the corneal surface (42 diopters), of less importance is refraction at the surfaces of the lens (19 diopters with accommodation relaxed and 36 diopters in full accommodation). The whole eye has a refracting power of between approximately 60 and 65 diopters. The value in the table above for the refractive index of the lens is calculated from the refractive power of of the lens as a whole, as though it were a homogeneous structure, but such is not the case. On the contrary, the lens consists of an almost spherical nucleus with a high refractivity (1.41) surrounded by a zone called the *cortex* of lower optical density (1.38). The surrounding cortex is composed of a series of concave meniscus lens, as shown in figure 74-17. The peculiar structure of the lens accounts for the paradox that the mean value of the refractive indices of its parts (1.39) is less than the refracting power of the whole. Several important advantages are derived from this peculiar structure of the crystalline lens, it diminishes spherical aberration (p. 1393), tends to prevent the scattering of light within the eye and enhances the power of the lens to alter its converging power during accommodation (p. 1356).

THE CONSTANTS OF THE EYE Knowing the curvatures of the refractive surfaces of the eye and the distances between them as well as the refractive indices of the media, the path taken by the rays of light can be determined and the image constructed. The values of the *constants of the eye* are given in the following table

Position of anterior surface of cornea	0
Position of posterior surface of cornea	0.6
Position of anterior surface of lens	3.6
Position of posterior surface of lens	7.2
Position of retina	24.1
Radius of anterior surface of cornea	7.7
Radius of posterior surface of cornea	6.8
Radius of anterior surface of lens (distant vision)	12.0
Radius of posterior surface of lens	6.0

The refractive indices of the media have been given above.

Construction of the image from the foregoing data is a very laborious proceeding. To start with, the image formed by the first refracting surface is constructed, this image now serves as the object

FIG. 74-17. Showing structure of the crystalline lens (diagrammatic)

FIG 74 18 The cardinal points of the eye ϕ' , The anterior focus, 15.7 mm in front of the cornea ϕ' , The posterior principal focus 24.13 mm behind the cornea—that is, upon the retina H, H' , the principal points, in the anterior chamber KK' , the nodal points, in the posterior part of the lens (After Duke Elder)

for the next refracting surface, the second image in turn is the object of the third surface and so on. The matter is very much simplified, however, by constructing the *diagrammatic or schematic eye* by the application of the theorem of Gauss. This states that every optical system composed of spherical surfaces with their centers on the principal axis has three pairs of cardinal points. These are two *principal points* (K and K' , fig 74 18), an *anterior* and a *posterior focal point* (ϕ and ϕ') and two *nodal points* (N and N')

The *first and second principal points* lie close together in the anterior chamber 2 mm behind the cornea. Planes passing through the principal points and perpendicular to the axis are termed the *first and second principal planes*, an object in the first principal plane forms an erect full sized image in the second and vice versa. The first and second principal points correspond, therefore, to the conjugate foci of a single lens.

The anterior focal point (ϕ) is situated 15.7 mm in front of the cornea. Rays from this point in the axis would, after passing through the system, emerge as parallel rays. Parallel rays entering the system are focussed at ϕ' which is situated on the retina. ϕ and ϕ' therefore correspond to the principal foci of a single lens.

The nodal points (K and K') also lie close together on the axis and near the posterior surface of the lens. They correspond to the optical center of a single lens. Rays passing through the nodal points are not refracted. A ray entering the system and passing through K appears to come from K' and emerges along a line parallel to that along which it entered. The following table for the schematic eye gives the distances of the six cardinal points from the anterior surface of the cornea.

	mm
Anterior surface of cornea	0
First principal point, H	1.7
Second principal point, H'	2.0
First nodal point, K	7.0
Second nodal point, K'	7.3
Posterior focal point, ϕ'	24.1
Anterior focal point, ϕ	15.7

FIG 74 19 Illustrating the inversion of the retinal image (schematic eye), F_1 , first focal point, H_1 and H_2 , first and second principal points, N_1 and N_2 , first and second nodal points, AB , object, ah , image

The two nodal points lie so close together that no significant error is entailed if they are taken as one, the same may be said for the principal points. Thus the compound optical system of the eye can be simplified to the so called *reduced schematic eye of Listing*. This has a single ideally refracting surface situated in the anterior chamber 13.5 mm behind the cornea and with a radius of 5.7 mm. The nodal point or optical center of the reduced eye lies 7.03 mm, the principal point 2.3 mm and the posterior focal point 24.13 mm behind the anterior corneal surface. The anterior focal point is 15.7 mm in front of the cornea. The distance of the nodal point from the retina, i.e., the focal length of the eye, is $(24.13 - 7.03 =) 17.05$ mm. The refracting power is therefore $(1000/17.05 =) 58.65$ diopters.

By means of an X ray beam, which is not refracted, projected into the eye Goldman and Hagen have measured the length of the globe in the living human subject. The value obtained (23.4 mm) agrees closely with that of the schematic eye. The value for the total refractive power of the normal human eye, as determined by these observers, is also in close agreement, namely, 59.22 diopters.

THE FORMATION OF THE IMAGE ON THE RETINA
Knowing the foregoing measurements, the paths taken by the light rays can be drawn and a construction of the image upon the retina readily carried out. The formation of the retinal image is illustrated in figure 74 19. The large arrow $A-B$

represents an object emitting divergent rays which are converged and brought to a focus to form the image represented by the small arrow $a-b$. The retinal image, it will be observed, is smaller than the object and inverted. For the sake of simplicity only a few rays are shown, two from a point at either end of the object and one from its center, but of course the surface of an object consists of an infinite number of points, each of which emits divergent rays. One of each pair of rays in the figure (solid line) passes unrefracted through a secondary axis (i.e., through the nodal point N), the ray from the upper part of the object to the lower part of the retina and vice versa. The other ray of each pair undergoes refraction and meets the corresponding unrefracted ray. Similarly, rays from a point on one side of the object will fall upon the retina as a point of light in the opposite part of the image. Thus, it is seen how the image on the retina becomes inverted. Of course we see objects in their true position. Reversion is a cerebral function developed, probably, through the association of visual sensations with those of touch. If inverting spectacles are placed before the eyes, so as to produce an erect image of the environment on the retina, the visual world appears upside down for some time. But after a period of confusion lasting several weeks the visual environment appears the correct way up. On removing the spectacles only a short period of confusion results.

The idea that the retinal image is inverted was at first difficult to believe. Kepler (1604) inferred from his optical studies that this must be so, but it was Scheiner (1625) who furnished the proof by observing the back of an excised eye from which the sclerotic and choroid coats had been removed. The inverted image of an object was clearly visible upon the translucent retina. The inversion of the retinal image may also be demonstrated during life in persons of blonde complexion because their choroid contains little pigment. The subject is examined in a darkened room, the eye being turned towards a lighted candle placed well to the temporal side. An inverted image of the flame may be seen showing through the inner side of the wall of the globe.

The size of the retinal image is dependent upon the angle $a N b$, (fig. 74 19) this—the angle subtended at the nodal point of the eye by an object in the visual field—is called the *visual angle*. The size of the image can be calculated if one knows the distance of the nodal point of the eye from the object and from the retina and the size of the object. Thus in the figure $A B$ is the object and

$a b$ its image. The triangle $A N B$ and $a N b$ being symmetrical then

$$\begin{aligned} a b / A B &= b N / B N \\ a b &= A B \times b N / B N \\ b N &= 17.05 \text{ mm} \\ i &= 17.05 \times O / d \end{aligned}$$

i is the size of the image, O the size of the object and d its distance from the nodal point of the eye ($17.05 =$ distance of retina from nodal point see p. 1380). An object which subtends one minute of angle at the eye forms an image on the retina of size approximately 4.5 microns. The full moon subtends about $1\frac{1}{2}^\circ$, and its image on the retina would therefore be about 0.135 mm. diameter.

THE OPHTHALMOSCOPIC EXAMINATION OF THE EYE. Under ordinary circumstances we cannot see within the eye of another person because only a limited quantity of light enters his eye through the relatively small pupillary aperture. It is like trying to look through a small window into a darkened room. Furthermore of the light which enters the eye, a large part is absorbed by the pigment layer of the retina. Even when a light is brought close to the eye under observation one is unable to see the retina because the pencil of parallel rays which emerge do not enter the examiner's pupil unless his eye is directly in its path, and when he attempts to bring his eye into the proper position either his head comes between the light and the subject's eye or the light (if between himself and the subject) dazzles his sight.

These difficulties are overcome by means of the ophthalmoscope. This instrument consists of a small mirror with a central perforation through which the observer views the subject's eye. Light furnished by an electric lamp placed above the head of the patient is reflected from the mirror and the pencil of rays emerging from the subject's eye passes through the aperture of the mirror to the examiner's eye.

The invention of the ophthalmoscope is commonly attributed to Helmholtz (1851) but a crude device based upon the same principle was used by Babbage two years previously. The modern oph

FIG. 74 20 Showing the two extreme pencils of parallel rays arising from the edges of the illuminated area of the fundus in an emmetropic eye. S subject, O , observer. Vertical dotted line indicates the position in which the extreme ray pencils will enter the observer's eye. (After Duke Elder.)

FIG 74 21 Emergent rays from hypermetropic eye. A virtual erect image is formed at $x'y'$ (After Duke Elder)

FIG 74 22 Emergent rays from myopic eye which cross at $x'y'$ and then diverge, a real inverted image is formed at $x'y'$ (After Duke Elder)

thalmoscope consists of a small electric tungsten lamp associated switch and battery, an optical system forms a beam of light which may be reflected from a small mirror into the patient's eye. The mirror has a small central aperture to permit the examiner to look through the mirror down the beam of light. Most ophthalmoscopes also have a chain of small lenses ranging from +20 D to -20 D between the aperture and the examiner's eye position, each of which may be brought into position to correct refractive errors both in the patient and in the examiner. The examiner seats himself 1 meter from the subject, adjusts the collimating optical system so that a divergent beam of light enters the subject's eye and looks through the sight hole in the mirror. If the observed eye is emmetropic (i.e., of normal refraction) a uniform red glow—the *red reflex of the fundus*—caused by reflection from the retina is seen lighting up the pupil. No detail, e.g., optic disc or retinal vessels, is visible. This is because the rays emerge from the subject's eye as diverging pencils of parallel rays. In order for an image of the subject's fundus to be formed upon the examiner's retina, rays from many pencils must enter his eye simultaneously. At a distance of 1 meter this is impossible, but can be effected if the observer brings his eye quite close to the patient's eye (see fig 74 20). When the subject's eye is hypermetropic the rays composing the emergent pencils are *divergent*, it is therefore possible at a distance of 1 meter for many pencils to enter the observer's eye. The rays appear to meet behind the subject's eyes where a

FIG 74 23 Path of the light from the eye in the indirect method of ophthalmoscopy in emmetropia, hypermetropia and myopia (After Duke Elder, *Text Book of Ophthalmology*)

virtual erect image is formed (fig 74 21). When the observer moves his head the image moves in the same direction. In myopia, the emergent rays *converge*, they meet and cross in front of the eye. Again, diverging rays from several fundus enter the observer's eye and form a *real inverted image* in front of the subject's eye (fig 74 22), it moves in a direction opposite to that of the examiner's head.

After this preliminary examination one or other of two methods of ophthalmoscopy—the indirect or the direct—may be employed. In the *indirect method* a separate biconvex lens with a focal length of 7.5 cm (about 13 D) is held in front of the eye of the examinee. The observer seats himself 1 meter away and holds the lens in the path of the beam from the mirror and a short distance in front of the eye under observation. The subject turns his eye a little inwards in order to bring the optic disc into view, being directed, for example, to look at the observer's left ear if his left eye is being examined. The rays from the ophthalmoscope are converged upon the hand lens which converges them to the eye. They are more sharply converged by the refracting media and come to a focus in the vitreous. The retina is diffusely illuminated. By moving the hand lens toward or from the patient's eye his retina is brought into focus and the optic disc (Plate III) is clearly seen. The rays reflected from innumerable points of the patient's retina and after refraction emerge from his eye to form an image, the position of which differs according to the refractive state of the eye. The rays emerging from the emmetropic (normal) eye are parallel (fig 74 23). They are converged

PLATE III

Normal Human Fundus (From May's *Manual of Diseases of the Eye* by permission of the author)

by the hand lens and form a real, magnified and inverted image in the air between the hand lens and the examiner. This is focused on the examiner's retina. In *hypermetropia* the rays issuing from the patient's eye are divergent, and appear to come from a magnified erect image behind the eye. The hand lens converts this into a small, inverted image in front of its principal focus (fig. 74-23). In *myopia* the emergent rays converge and form a large inverted real image, this is converted by the lens into a smaller image between it and its principal focus.

In the *direct method* a field of smaller area but of higher magnification is seen. The examiner brings the instrument as close as possible to the subject's eye, no hand lens being interposed. He views the subject's fundus with his own right eye, and the subject's left fundus with his left eye. In this position rays from both emergent pencils enter the eye of the observer, and, therefore, except when the observed eye is highly myopic, the details of the fundus can be seen. The image is always erect. The light, after coming to a focus on the retina, emerges from the emmetropic eye as parallel rays which are brought to a focus upon the observer's retina. If, however, the subject's eye is hypermetropic (as described above) the emergent rays will be divergent and can only be focused by the examiner if he accommodates his eye or interposes a convex lens, if the observed eye is myopic the reflected rays are convergent, the examiner must then use a concave lens in order to focus the image upon his own retina. By the use of a concave or a convex lens which will just bring the image of the fundus into clear focus, and the refractive power of the lens required being known, the refractive error of the patient can be measured.

RETINOSCOPY, SKIASCOPY OR THE SHADOW TEST
This is a reliable objective method for determining the refraction of the eye. It is of special value in children and others for whom the reading of test type is impracticable, and for the detection of malingers. The method depends upon the fact discovered by Bowman (1859) that the direction of the rays emerging from the eye varies with its state of refraction. Cugnet (1873) elaborated upon this discovery and brought the method into general use in the study of refractive errors. A retinoscope consists of a plane or concave mirror with a central aperture through which the examiner can look and inspect the pupil of the subject. A light source is placed several feet away and the mirror is used to reflect a beam of light into the pupil of the subject. Electric self-luminous versions of the retinoscope are also available. When the rays are reflected from a plane mirror they form a virtual image behind the reflecting surface. Tilting the mirror to one or the other side causes this image to move in the opposite direction. If a

FIG 74-24 Retinoscopy shadow (After Duke-Elder)

FIG 74-25 Illustrating the movements of the shadow in retinoscopy. A in myopia. When the mirror is in the position AB the image is at D in the highly myopic eye, and at C in the less myopic eye. When the mirror is in the position A'B', the respective images are in the positions d and c. Since Dd is less than Cc, the lower the degree of myopia, the larger the excursion and the quicker the movement of the shadow. B in hypermetropia. When the mirror is in the position AB the image is at D, in the highly hypermetropic eye and at C in the less hypermetropic eye. When the mirror is in the position A'B' the respective images are at d and c. (After Duke Elder, *The Practice of Refraction*.)

concave mirror were used the image, being formed in front of the mirror, would move in the same direction as the tilt of the mirror. Consequently, when a reflected light is thrown into the eye by means of a plane mirror owing to a double reversal of the movement taking place (i.e., a movement of the mirror image which now serves as the luminous object in one direction and of the retinal image in the other), a change in the inclination of the mirror causes the illuminated area upon the retina to move in the same direction as the tilt. This movement of the illuminated area on the retina in relation to the tilt of the mirror is the same whatever the refractive state of the eye. But the rays from the illuminated area on the retina are directed back through the eye and after undergoing refraction emerge through the pupil, the direction of the movement of the illuminated area as it appears to an observer depends upon the

direction of the emergent rays, that is, upon the state of refraction of the eye. The eye is examined with the retinoscope at a distance of 1 meter, in a dark room, a mydriatic, e.g. atropine or homatropine is usually employed.

If the subject is hypermetropic or myopic a pink glow fills his pupil except for a dark semilunar shadow on one side (see fig. 74 24). In the emmetropic eye light reflected from the illuminated area on the retina issues from the pupil as diverging pencils of parallel rays (p. 1377). The rays meet and cross at the far point (punctum remotum), which for the normal eye is at infinity, that is, behind the observer. In a certain position of the mirror one or other of the pencils of rays (see fig. 74 25) enters the observer's eye. The subject's eye appears filled with a pink glare bounded on one side by a very faint shadow, when the mirror is tilted so that the interval between the pencils is in line with the observer's pupil, the subject's pupil is dark. Thus in emmetropia the subject's pupil is either nearly uniformly bright or entirely dark. A bright area and a pronounced shadow are not seen together. In myopia the rays leaving the eye are convergent (fig. 74 22). If the myopia is greater than 1 D they meet and cross at the far point which lies somewhere between the subject and the observer. Therefore when the mirror is tilted, up or down, or to one or other side, the shadow moves against it, i.e., in the opposite direction. If the myopia is less than 1 D the far point is behind the observer and as in emmetropia, only a faint shadow is seen, it moves with the mirror. If the myopia is 1 D the far point is at the surface of the observer's eye and the subject's pupil appears, according to the tilt of the mirror, either completely dark or completely bright, that is without any shadow. In hypermetropia the emergent rays are divergent and the far point is virtual, the rays appear to come from a point behind the mirror and therefore do not meet between the subject and observer. The shadow moves with the mirror.

In applying these facts to the correction of refractive errors, the movement of the shadow is noted and convex or concave glasses according to whether the eye is hypermetropic or myopic, respectively, are placed in front of the subject's eye until the pupil as in a myopia of 1 D, appears uniformly bright or dark. This state when the shadow disappears is called the point of reversal. If the refractive error is even slightly overcorrected a shadow appears which moves in a direction opposite to that of the original movement. Now, when the point of reversal is reached, the far point of the subject's eye is at the surface of the observer's eye, i.e., 1 meter away. The subject therefore, as mentioned above, has still a myopia of 1 diopter. This must be taken into account in calculating the refractive power of the correcting

lenses required. If the eye is hypermetropic and, say +4 D brings it to the point of reversal, then a +3 D lens will be sufficient for correction. If the eye is myopic -1 D must be added to the refraction which was required to bring the eye to the point of reversal.

Papilledema (choked disc, optic neuritis) and **optic atrophy**. In conditions accompanied by high intracranial pressure, e.g., brain tumor, hydrocephalus and uremia, the optic disc loses its natural translucency and becomes reddened and swollen. The central vein is engorged and tortuous and the venules and capillaries dilated. Small hemorrhages may be seen. The swelling of the disc is due to the transudation of fluid from the engorged vessels and its collection in the anterior layers of the lamina cribrosa and between the nerve fibers. The physiological cup becomes gradually filled up, and may eventually be elevated above the general level of the surrounding retina. The circumference of the disc appears blurred or 'woolly'. The disc is enlarged and its lateral spread causes the retina to be thrown into folds or ridges. In the older terminology these changes were referred to as choked disc, optic neuritis or papillitis. The condition is now called **papilledema**. The separation and stretching of the nerve fibers their compression where they penetrate the lamina cribrosa and the overgrowth of glial tissue set up by the presence of the edema fluid leads to nerve atrophy—secondary optic atrophy. The disc in this condition is a grayish or dead white, due to the obliteration of capillary vessels by the overgrowth of glial tissue. The optic cup is deepened as a result of the degenerated nerve fibers. The outline of the pale disc is clearly defined against the surrounding retina. The retinal veins are engorged but the arteries are narrower than normal.

It is now widely accepted that mechanical factors, e.g. changes in intracranial or intraocular pressure are mainly concerned in the production of papilledema. The optic nerve it will be recalled is invested by prolongations of the cerebral meninges—the pia, arachnoid and dura. The spaces between these three layers of the nerve sheath—the subarachnoid and subdural spaces—are continuous, as was first shown by Schwalbe (1870) with the corresponding spaces within the cranium. The dura and arachnoid of the nerve sheath, however, are in close opposition there being only a potential subdural space in this situation. But the intracranial subarachnoid space is in free communication with the corresponding space of the nerve sheath and the intracranial pressure is transmitted through the cerebrospinal fluid to the intravaginal space right up to the lamina cribrosa. The central vein of the retina with its companion artery makes an almost right angled bend as it leaves the optic nerve and, crossing the intravaginal space, pierces the arachnoid and dura a short distance behind

FIG 74 26 Description in text

the eyeball (fig 74 26) Any marked rise in intracranial pressure distends the sheath, for the dura in this situation differs from that within the cranium in being unsupported by bone (Macdonald) The elevated pressure thus transmitted to the sheath tends to compress the vein in its course across the intravaginal space and to impede the venous return, as well as to block the lymph channels situated in the adventitia of the central vessels Little or no interference is offered to the blood flow in the artery owing to its more resistant wall and to the higher arterial blood pressure The venous pressure rises and the intraocular part of the vein and its branches become engorged since they are beyond the influence of the intracranial pressure

Papilledema is therefore comparable with an edema which may occur in almost any situation as a result of obstruction of the venous and lymphatic channels while the arteries remain pervious No evidence that papilledema is inflammatory in nature can be found upon histological examination (Holmes and Paton)

Atrophic changes in the disc occurring unpreceded by papilledema are referred to as *primary optic atrophy* The main causes of primary optic atrophy are pressure upon the nerve within the cranium as by a tumor, certain nervous diseases (tabes, general paralysis of the insane and disseminated sclerosis) and toxic substances, e.g., wood alcohol, quinine, lead and salicylic compounds Since the optic nerve fibers have their cell bodies in the retina (ganglion cell layer) the atrophy of the section between the point of pressure and the retina is in the nature of a retrograde degeneration (p 1118) As already mentioned, the optic nerve fiber is devoid of a neurilemma, regeneration therefore never occurs In tabes and general paralysis of the insane the atrophy is probably the result of a syphilitic meningitis which affects the nerve secondarily The toxic substances mentioned exert their action apparently directly upon the ganglion cells of the retina

BIOMICROSCOPY—THE SLIT LAMP By means of this instrument an intense narrow beam of light is thrown obliquely into the eye and a small section of the cornea, anterior chamber, iris, lens or an

terior part of the vitreous observed stereoscopically through a binocular microscope The beam passes through an adjustable slit which when narrowed to minimum width concentrates the beam of light upon an area as small as 0.05 mm in diameter The illuminated section is in the form of a prism, or more correctly of a parallelepiped The tissues within this section may be magnified some 25 diameters Under this method of examination ocular structures which ordinarily appear homogeneous show a definite pattern, and any abnormality is readily recognized by one familiar with the appearance in health For example, the anterior and posterior epithelial layers of the cornea are seen as bright lines bounding the less luminous substantia propria, and any pathological condition, e.g., erosions, small opacities, keratitis, etc., are easily detected The laminated structure of the lens is clearly revealed The central nucleus and the cortical layers are marked by luminous boundaries, the lens sutures appear as darker lines

ENTOPTIC PHENOMENA Visual sensations may arise from images of objects situated within the eye itself The most familiar of these are the *muscae volitantes* (L. flying flies) which are seen as faint specks projected some distance in front of the eye They are due to shadows cast upon the retina by small semi-opaque particles in the vitreous body, such as epithelial cells, small coagula or embryonic rudiments Particles lying close to the retina are most likely to give rise to these sensations Lying behind the axis of rotation of the globe such particles cast shadows which move downwards over the retina when the eye is turned upwards but, since the direction of any movement on the retina is reversed in consciousness, they appear to move upwards This upward movement is followed by a slower downward movement When any attempt is made to fix one's sight upon the specks they dart away, from which fact their name was derived These *muscae volitantes* are usually noticed while viewing a bright uniform field, such as the clear blue sky, for then the pupil is small and sharper shadows are cast on the retina Some of the reports on the sighting of "flying saucers" could be accounted for in this way

Ordinarily the retinal vessels which, it will be recalled, lie outside the fovea and superficial to the retinal layers, are not perceived Helmholtz thought that the sensitivity of the retina underlying the vessels was greater than elsewhere, so that the light reaching the retina through them, though reduced in intensity, caused as great an effect as light falling in unshielded regions When light is thrown into the eye at such an angle (e.g.,

FIG 74 27 Description in text

obliquely through the sclera) that the shadows of the vessels fall upon a retinal region unaccustomed to receive them, they become visible. If, while his eye is being illuminated in this way in a dark room, the subject looks towards a wall, and the light falling on the sclera is given a slow circular movement, he sees a highly magnified image projected against the uniform surface. The vessels appear as an intricate branching pattern against a bright ground and are known, after their discoverer, as *Purkinje figures*. A method which any one can employ himself to make the extrafoveal capillaries visible is to look at a uniformly bright surface through a pin hole in a card held close to the eye while he oscillates the opening quickly (about once per second) from side to side and thereby shifts the shadows from point to point in the retina.

Mueller (1855) made use of Purkinje's observation (1811) to prove that the light sensitive elements are the rods and cones. Moving the source of light causes the images to change their positions on the screen. If we measure the distance of this shift (fig 74 27, A-B) and the distance between the two positions of the light (a b) then, knowing the distance of the nodal point of the schematic eye (N) from the retina and from the screen, the position of the shadow (α - β) relative to the vessels (v), i.e., the distance α v, can be calculated. This was found to be from 0.17 to 0.36 mm, which is by actual measurement the approximate distance of the vessels in front of the rod and cone layer.

FIG 74 28 Showing interior of anterior half of the eyeball

The corpuscles moving in the retinal capillaries can be observed if the eye is directed to a uniformly illuminated surface. The best way to perform this experiment is to look at the sky through a dense blue violet glass plate. The blood cells then appear projected upon the plate. It is actually possible to calculate the speed of the corpuscles from the distance between their positions at the beginning and end of a given time interval. Vuerodt (1873) was the first to make such an estimation. Knowing the distance of the nodal point of the eye from the retina and from the glass screen, the magnification of the travelled distance can be determined.

Other entoptic phenomena which should be briefly mentioned are the colored halos seen around bright lights, especially in dark surroundings. The halos consist of a series of concentric rings of rainbow colors—from blue to red from without in. Actually they are diffraction spectra, due to the structures of the eye acting as diffraction gratings. There are two kinds of halo—*lenticular* and *corneal*. The first is attributed to the radial fibers of the lens and is the larger. The corneal type is believed to be due to the epithelial and endothelial cell layers of the cornea.

The Accommodation of the Eye

ANATOMICAL SKETCH

Before giving an account of the physiological mechanism of accommodation, the structures concerned, e.g., the ciliary body and the crystalline lens will be briefly described.

THE CILIARY BODY When the interior of the anterior half of the eyeball is exposed by a transection through its equator, a transparent disc—the *crystalline lens*—is seen occupying the center of the bowl shaped structure (fig 74 28). On the wall of the globe some distance behind the circumference of the lens lies the dentate border of the retina proper known as the *ora serrata* (p. 1316). The ciliary body is a circular zone of tissue extending forwards from the ora serrata to a short distance from the circumference of the lens. It is covered on its inner aspect by the pigment layer of the retina, which we have seen (ch. 72) is continued forwards (as the *pars ciliaris retinae*) from the point of termination of the neural layers. The ciliary body consists of three parts, the *orbiculus ciliaris*, the ciliary processes and the ciliary muscle. The *orbiculus ciliaris* immediately adjoins the choroid, of which it may be considered the direct continuation. It is a band about 4 mm broad encircling the eyeball and presents on its inner aspect a number of radially arranged ridges. The *ciliary processes* appear as some seventy triangular elevations on the inner aspect of the ciliary body, they project towards the axis of the eye and form a series of radial fringes (*corona ciliaris*) which

Fig 74 29 Showing structures in the region of the angle of the iris

Fig 74 30 Showing arrangement of circular fibers of the ciliary muscle (After Fincham)

completely encircle the equator of the lens, but are separated from it by a very short interval. The great bulk of the ciliary body is composed of the ciliary processes and the ciliary muscle. The fibers of the ciliary muscle are arranged in two sets, an outer meridional and an inner circular. The meridional fibers arise from the scleral spur (p 1400), they run backward to be attached to the ciliary processes and to the orbiculus and through the latter to the choroid. The circular fibers are fewer, in meridional sections of the globe they appear as a small triangular hunk of cross sectioned fibers lying behind the angle of the iris (fig 74 29). As a matter of fact, these fibers are not uniformly circular in direction but take different courses and interlacing with one another, form a reticulated ring shaped band (fig 74 30). Taken as a whole this part of the ciliary muscle constitutes a sphincter (*sphincter muscle of Mueller*) situated in front and to the outer side of the ciliary processes. The fibers composing the margin of the central opening are mainly circular and are attached to a band of elastic tissue situated at the angle of the iris, the outer circumference of the sphincter is connected to elastic fibers which are continuous with similar fibers of the choroid. The muscle is thus anchored by two elastic attachments.

THE CRYSTALLINE LENS is a transparent, biconvex, circular structure about 11 mm in diameter and between 3.6 and 3.9 mm thick at the center. It is situated with the center of its anterior surface coinciding with the center of the pupil, the pupil

lary margin lies in contact with this surface. The center of the anterior surface is termed the *anterior pole* of the lens, the center of its posterior surface, the *posterior pole*. An imaginary line joining the poles is called the *principal axis*. The two surfaces meet at the circumference in a rounded edge termed the *equator*. The posterior surface in the young adult is decidedly more convex than the anterior (see table, p 1350), this difference diminishes somewhat with age. The lens is enclosed in a structureless highly elastic capsule. The latter is not of uniform thickness, being thinner over the posterior than over the anterior surface, and the part covering the central region of each surface is thinner than the corresponding peripheral parts. The values in ascending order of thicknesses are center of posterior surface (av 22μ), peripheral part of posterior surface (av 13.7μ), center of anterior surface (av 15.7μ), peripheral part of anterior surface (av 18.2μ) (see fig 74 31). A single layer of columnar epithelial cells covers the anterior surface of the lens immediately beneath the homogeneous capsule. The latter is formed as a secretion of these cells. The substance of the lens consists of a series of ribbon like fibers which arise from the region of the equator and are actually greatly elongated epithelial cells (fig 74 32). By careful examination of the lens, from the more central part of the anterior surface to the region of the equator the gradual transition of the columnar cells into the attenuated cells of the lens substance can be traced. The fibers proceed from the equator towards the lens center and, abutting against fibers coming from other segments of the periphery fuse along well defined lines—the *lens sutures*. These are seen in the adult lens as a series of faint irregular lines radiating from the center to form what is known

Fig 74 31 Showing the regional variations in thickness of the lens capsule (After Fincham)

Fig 74 32 Meridional section of the lens (From Wolff after Poirier and Becker)

as the *lens star*. On section, the lens shows a series of concentric laminae with a nucleus of extreme convexity and high refractive index, and a less refractive cortex. The optical advantages of this construction have been pointed out (p 1379). The nucleus is also of much firmer consistency than the cortex which is relatively soft and pliable.

THE MECHANISM OF ACCOMMODATION

The interval between the ciliary processes and the equator of the lens is occupied by a circular membranous band, this is the anterior part of the *zonula ciliaris* (*zonula of Zinn*). The precise origin of the fibers of the zonula is disputed but they appear to arise as a system of transparent fibers from the anterior part of the hyaloid membrane 1.5 mm. or so in front of the ora serrata. Passing forwards they form a series of bundles which occupy grooves between the ciliary processes, and then bridge the gap, as just mentioned, between the ciliary processes and the lens. Near the lens circumference the zonula splits into an anterior and a posterior lamina, the former is the thicker of the two and blends with the lens capsule a little in front of the equator, and constitutes what is

generally known as the *suspensory ligament* of the lens. The space between the two layers of the zonula is called the *canal of Petit*. Slits in the layers of the membrane establish communications between the canal of Petit and the anterior chamber and the region behind the lens (postlenticular space, p 1399).

Light rays from an object at infinity, which is taken as any point more than 20 feet (6 meters) distant, are parallel and are brought to a focus (principal focus) on the retina of the emmetropic eye. Rays from a near object are divergent, but they too are brought to a sharp focus. This adjustment of the dioptries of the eye whereby it is able to focus the image of both far and near objects is called *accommodation*. That the refracting power of the eye does actually undergo a change when it is turned from a far to a near object or vice versa was shown by Scheiner (1619) by a simple experiment. A card with two pin holes separated by a distance less than the diameter of the pupil is held before one eye. The eye is focussed upon a needle held in front of the card and perpendicular to a line joining the two holes. The needle appears single, but it appears double if the eye is focused upon an object placed either beyond it or between it and the eye. The explanation will be evident from fig 74.33.

There are at least three possible means by which accommodation of the eye could be brought about. The retina might be moved towards or away from the lens, i.e., the eye might be elongated or shortened so that divergent rays in the one instance or parallel rays in the other would be accurately focussed. This mechanism is actually made use of in the mollusc pecten. That it is not the method followed by the human eye was proved by Young (1801). A second possibility is that the distance between the retina and the lens is altered by a movement of the lens, this is the method used in photography, the distance between the film and the lens can be nicely adjusted for the focus of near objects. In the bony fishes accommodation is effected in such a manner.¹

FIG 74.33 Scheiner's experiment. Upper cut O, position of needle, PP, pinholes in card, SS screen with image of needle focussed at o. When the screen is moved forward or backward (S'S' or S''S'') the two pencils of light are intercepted before they have reached a focus in the first instance, and after they have met and crossed in the second. Two images are formed at o' and o' or at o'' and o''. In the case of the eye (lower cut), any difference in its focus must be due to changes in the lens since the retina is stationary. When the needle is viewed with one eye through the peep holes, and brought into focus one image is seen, but two blurred images appear if the eye is focussed upon a nearer or a more distant object. If when the eye looks at an object near than the needle, and the needle is moved a little nearer to the eye, the two images approach one another, when the needle is moved farther away they become more separated. When the eye is accommodated for far vision, changes in the distance of the needle cause converse movements of the images, becoming farther apart as the needle approaches the eye, and coming closer together as it is moved farther away. The continuous lines represent rays from the needle, the interrupted lines rays from a nearer point in focus.

¹ These fish are myopic when the eye is at rest i.e., the eye is adjusted for near vision, accommodation for far vision is an active process consisting of contraction of a structure called the *campanula* which moves the lens backward. In some birds the central part of the anterior surface of the lens moves forwards into the pupillary aperture and as a result of pressure against the rigid margin of the iris becomes highly convex. In other avian species the cornea consists of two lamellae, the posterior being drawn backwards during accommodation for far vision. In others again (owls and hawks) the curvature of the cornea is increased during near vision.

FIG 74 34 Illustrating the mechanism of accommodation of the eye for near vision. The horizontally shaded lens and the unshaded iris show the position of the parts when at rest, the vertically shaded lens and iris show the position during accommodation for a near point. C ciliary muscle, S.L. suspensory ligament (Redrawn from Landolt)

Variations in the convexity of the crystalline lens and consequently of its converging power is the third possibility (fig 74 34). This is the method first suggested by Young for the human eye, the conception was later elaborated by Helmholtz. That such is the mechanism adopted by mammals in general is now almost universally accepted. A change in the convexity of the anterior surface of the lens during accommodation is a well-established fact and one which can be demonstrated by the following experiments. A lighted candle is held to the outer side and a little in front of the eye of a subject in a darkened room. Three images (Purkinje-Sanson images fig 74 35) within the subject's pupil will be seen by an observer, one bright and erect reflected from the cornea, another larger, erect and dimmer from the anterior surface (epithelial layer) of the lens which like the cornea, acts as a convex mirror. The third image is inverted, bright and smaller than the other two, it is reflected from the posterior (concave) surface of the lens. The subject is directed to gaze into the distance while the positions of the images are

FIG 74 35 Purkinje-Sanson images. A, during far vision. B, during accommodation for near vision (Redrawn and modified from Williams)

noted, he then looks at a near object when a change in the size and position of the reflection from the anterior surface of the lens will be observed. It becomes smaller and moves towards the corneal image which, of course, remains stationary, as does also the inverted image from the posterior surface of the lens. The change in size and position of the large erect image must mean that the anterior surface of the lens has become more convex. Now, if one knows the radius of curvature of the cornea, which can be measured by means of an instrument known as an ophthalmometer, then the radius of curvature of the surfaces of the lens and the changes in their curvature during accommodation can be calculated from careful comparative measurements of the sizes of the images from the cornea and lens. The average values for the radius of the anterior surface of the lens in five subjects examined by Fincham were 12.2 mm for the resting eye and 6.8 mm during accommodation for near vision. The change in curvature of the posterior lens surface was slight (about 0.5 mm). The average increase in thickness of the central part of the lens was 0.47 mm, while the equatorial diameter diminished by 0.5 mm. The center of the anterior surface moved forward by from 0.3 to 0.4 mm. In general terms the change in shape of the lens during accommodation for near vision can be summed up as follows. The central part of the anterior surface becomes more convex, the posterior surface shows little change. The peripheral region of the anterior surface actually becomes somewhat flatter, this surface taken as a whole therefore assumes a hyperbolic form.

The manner in which the change in shape of the anterior surface of the lens is brought about was explained by Helmholtz as follows. When the eye is accommodated for distant vision the suspensory ligament which, as we have seen, is attached to the lens capsule, is drawn taut as a result of the pull of the elastic structures, e.g. the ciliary body and choroid. The peripherally directed traction exerted upon the lens capsule through the suspensory ligament results in flattening of the curvature of the anterior surface of the lens. Focussing the image of a near object is accomplished by contraction of the ciliary muscle which, by drawing the choroid forward, permits the ciliary processes to move forward and inward, thus reducing the diameter of the ring (corona ciliaris) which they form. The suspensory ligament and lens capsule are thus relaxed, and the lens, by virtue of its inherent elasticity, assumes a more convex form (figs 74 34 and 74 36). The convex lens, i.e., one

FIG 7436 Diagram to illustrate the mechanism of accommodation C, ciliary muscle, relaxed (left), contracted (right), S, spring representing the elastic choroid, L, lens, left section, for far vision, right for near vision, Z, zonula

released from the restraint of surrounding structures, is therefore at its maximum convexity. Helmholtz's conception is supported in its main tenets by modern work. The movement inward of the ciliary processes during accommodation for near vision has been observed in the living human eye, and in an eye from which the lens substance had been adsorbed as a result of injury, tightening and slackening of the empty capsule was seen during the corresponding phases of accommodation. Yet the curvature assumed by the anterior surface of the lens is, as mentioned above, *hyperbolic*, whereas one would expect it to assume a spheroidal form were the lens substance itself elastic and the change in shape due simply to its recoil when released from restraint.

The details of the mechanism with respect to this point have been elucidated by the work of Fincham. According to this observer, the change in shape of the lens during accommodation is explained by the high degree of elasticity possessed by the lens capsule and by the regional variations in its thickness (p 1387), together with the pliable nature of the cortical part of the lens as compared with the nucleus. When the lens is accommodated for distant vision, its substance is confined under tension within the capsule and, as a consequence, distends the latter to the greatest degree where it is weakest, (i.e., thinnest) namely, on the posterior surface. The convexity of this surface is therefore near its maximum when the eye is adjusted for distant objects and little further change can occur during accommodation for near vision. Upon contraction of the ciliary muscle and the consequent slackening of the suspensory ligament the recoil of the elastic capsule moulds the plastic cortex, the peripheral part of the anterior surface is thus pressed back by the relatively thick capsule but the thinner central part of the latter permits the lens substance, chiefly the highly convex nucleus, to bulge forwards. That is, the anterior surface of the lens becomes somewhat "conoid" (Fincham).

THE VISUAL AXES AND PUPILLARY DIAMETER DURING ACCOMMODATION. The complete set of

TABLE 741

Pupil Diameter in mm	Depth of Focus (D)	Depth of Field when Focused on		
		Infinity	Hyperfocal distance	25 cm
1	± 0.85	α to 1.18 m	α to 0.59 m	31.8 to 20.6 cm
2	± 0.44	α to 2.27 m	α to 1.13 m	28.1 to 22.5 cm
3	± 0.30	α to 3.33 m	α to 1.67 m	27.0 to 23.3 cm
4	± 0.24	α to 4.17 m	α to 2.08 m	26.6 to 23.6 cm
5	± 0.20	α to 5.00 m	α to 2.50 m	26.3 to 23.8 cm
6	± 0.18	α to 5.56 m	α to 2.28 m	26.2 to 23.9 cm
7	± 0.16	α to 6.25 m	α to 3.12 m	26.0 to 24.0 cm

Depth of field of the eye based on the detection of ± 0.3 D with a 3 mm diameter pupil and corrected for the retinal direction effect.

accommodation for a near object comprises, besides an increase in the convexity of the anterior surface of the lens, *convergence of the eyes and constriction of the pupil*. The constriction of the pupil which occurs during accommodation serves three purposes. The narrowed aperture of the iris (a) reduces lateral chromatic and spherical aberration, thus increasing visual acuity, (b) diminishes the quantity of light entering the eye and (c) increases the *depth of focus*.

The depth of focus of any lens system is defined as the greatest distance through which an object may be moved and still be sharply focussed. When a clear image is formed by a lens, each point in the object is, as a result of diffraction, a series of small concentric circles of light, rather than a geometrical point. When the distance from the lens is increased the image is formed in front of its previous position (that is, in front of the surface, such as a photographic film or retina), if the distance is reduced, the image is formed behind. In either case the rings of light upon the surface become larger. If they are of such a size as to still remain confined, each to a particle making up the grain of the surface, film or retina, the image is sharp and appears in true focus, if they are large enough to spread to neighboring particles the image of the object is blurred. In the case of the fovea the "grain" is determined by the cones. The

FIG. 74-37 The amplitude of accommodation at different ages. A. The lowest physiological values. B. Average values. C. Maximum values (After Duane.)

depth of focus of the eye is, therefore, given as the greatest distance through which a point can be moved while its image remains restricted to a single cone. The depth of focus of the eye varies with the diameter of the pupil. The values given in table 74-1 are based on measurements of the sensitivity of the eye to out-of-focus blur and are corrected for the retinal direction effect of Stiles and Crawford. If, for example, the observer has a pupil diameter of 3 mm, a change in the refractive power of the eye of ± 0.3 diopter will just be detected, but with a 6 mm pupil a change of ± 0.18 D will be detected. These powers may be translated into distances. Thus, if the observer has a 3 mm pupil and his eye is focussed on infinity, all objects from infinity down to 3.3 m will be seen sharply. This near point—the hyperfocal distance—is the reciprocal of half the depth of focus when expressed in diopters. If the eye is focussed on the hyperfocal distance then all objects from infinity to 1.67 m will be in focus. Similarly, it may be calculated that if the eye is in focus for a point 25 cm away, objects within the range 27 to 23 cm will be perceived sharply. The depth of focus decreases as the distance from the eye is reduced. This tendency is, therefore, counteracted by the constriction of the pupil which occurs as part of the mechanism of accommodation of the eye for near vision.

The range and amplitude of accommodation. The farthest point from the eye at which an object can be seen clearly is called the *far point* or *punctum remotum*. The corresponding point nearest the eye is termed the *near point* or *punctum proximum*. In the emmetropic eye the far point is at infinity, i.e., at a distance of over 20 feet (6 meters) and the near point at from 7 cm to 40 cm, depending upon age (fig. 74-37). The difference between the far and the near point distances is termed the

range of accommodation. The difference between the refracting power of the eye when accommodation is completely relaxed for the far point and fully displaced for the near point is called the **amplitude of accommodation**. The far point is conjugate to a point on the retina, i.e., parallel rays entering the eye come to a focus on the retina and rays from the latter upon emerging from the eye are parallel and would meet at infinity. Similarly, in the accommodated eye the near point is conjugate with a point on the retina. The focal length of the eye in each state of accommodation therefore corresponds, respectively, to the far and near point distances. It will be recalled that the refractive power is expressed as the reciprocal of the focal distance, the unit being 1 meter and called a diopter. The reciprocal of the far point distance is termed the *static refraction* (designated R) of the eye and that of the near point distance, the *dynamic refraction* (P). The difference between the two (P-R) gives in diopters the amplitude of accommodation. In the emmetropic eye, since the far point is at infinity the static refraction is taken as zero. When the near point is at 10 cm the dynamic refraction is $\frac{100 (1 \text{ meter})}{10} = 10 \text{ D}$. The

amplitude of accommodation in such an emmetropic eye is therefore 10 D.

The amplitude of accommodation diminishes progressively from childhood to about sixty years of age being 16 D at twelve years, 6.5 D at the age of thirty and only about 1 D at sixty. In other words, with advancing years the near point gradually recedes from the eye and at sixty years of age an object must be 1 meter distant in order to be clearly focussed upon the retina (see *presbyopia*). This phenomenon is due mainly to physical changes in the properties of the lens and its capsule (reduced plasticity of the one or diminished elasticity of the other), there may also be a concomitant weakness of the ciliary muscle.

THE METABOLISM AND COMPOSITION OF THE LENS. The lens, devoid of a blood supply, must obtain all the necessary nutrients for growth and metabolism from the surrounding aqueous and vitreous humors. The aqueous humor is believed to be the main source of supply. The vitreous, aqueous and lens all contain glucose and this appears to supply the main source of energy, both by aerobic and by anaerobic metabolism. The oxygen tension of the aqueous humor of the rabbit is about 40 to 50 mm Hg compared with about 72 mm Hg in arterial blood, but the oxygen has to diffuse over a considerable distance to reach the inner layers of the lens. The rate of metabolism of the lens may be readily determined for it may be removed from the body and maintained in a tissue culture medium containing glucose. In one such experiment Merriam and Kinsey (1950) found that a rabbit lens used about 3.4 mg of glucose per 24 hours and

that it produced about 20 mg. of lactic acid. Rabbit lenses use about 10 to 20 μ l. of O_2 per hour and have an R.Q. near to 1. It appears that glucose metabolism in the lens is mainly anaerobic. This anaerobic breakdown of glucose to lactic acid appears to be similar to that found in other tissues, that is, the sequence of reactions in the Embden-Meyerhof scheme. Cytochrome oxidase and flavoproteins have been found in the epithelium of the lens which suggests that this tissue may be responsible for some at least of the small oxygen consumption. The high concentration of glutathione in the lens and of ascorbic acid in the lens and aqueous humor has led to the speculation whether a hydrogen acceptor other than oxygen might be playing a role as both these substances may be reversibly reduced and oxidized, but there is no evidence of their action in lens metabolism. The metabolic function of ascorbic acid remains obscure. Glutathione may be required in the synthesis of the lens proteins and it may be significant that the highest concentration of glutathione is found in the cortex where the new lens fibers are formed.

Four types of protein have been identified in the lens substance: (a) a *euglobin* or "albuminoid" (17 per cent) which is water-soluble, and two water-soluble proteins—*pseudoglobulins*, (b) α *crystalline* (11 per cent) and (c) β *crystalline* (6 per cent), together with (d) a small quantity of albumin (0.2 per cent). The albuminoid is present mainly in the nucleus α crystalline chiefly in the superficial part of the cortex and β crystalline in the deeper parts. The two crystallines are particularly rich in the sulfur-containing amino acids cystine and cysteine. The lens proteins as first shown by Uhlenhuth are *organ specific* not species specific, thus differing in their immunological behavior from red cells (p. 63) and blood serum. For example, a solution of lens protein when injected into an animal of the same or of another species causes the production of an antibody—a *precipitin*. This antiserum has then the power to precipitate a solution of lens protein from wherever derived, i.e., from a species other than the one which supplied the antiserum, from the same species or even from the same animal.

The lens substance contains a high concentration of potassium—400 mg. per 100 grams of wet weight—as compared with about 3 mg. per cent in the aqueous and 20 mg. per cent in serum. The concentrations of calcium (5 mg. per cent), sodium chloride (300 mg. per cent), magnesium and silicates are relatively low. The total salt concentration is between 0.7 and 0.8 per cent. Cholesterol and phosphatides amount to about 200 mg. per cent in young lenses, but are from two to four times this value in older specimens. (Consult Pirie and van Heyningen.)

CHANGES IN THE LENS WITH AGE—CATARACT

The loss of plasticity and elasticity of the lens with age as a result of a gradual sclerosis, and the effect such changes have on the mechanism of accommodation are referred to on page 1391. Some alterations in lenticular color may accompany the sclerosing process, amber tinting, or even a reddish or brownish discoloration of the lens with consequent filtering of the shorter rays, is of common occurrence.

Cataract is the name given to any partial or complete opacity of the lens. In the commonest variety no ocular or general disease which can be held responsible precedes the development of the opacity, and this, since it appears to be simply a manifestation of age, is termed *senile cataract*. The process leading to the opacity is degenerative in nature, not inflammatory, for the lens is, as just stated, avascular. The opacity commences usually in the deeper part of the cortex and does not, as a rule, involve the nucleus. The lens swells as a result of accumulation of fluid between the fibers, the anterior chamber becoming shallow. So long as the superficial layers of the cortex are clear the cataract is called *immature*. It is said to be *mature* when the opacity has extended to include the superficial layers. The water content of the lens has by this time returned to normal. The mature stage is followed by disintegration of the cortex which becomes softened into a pulsatous mass, this is the stage of hypermaturity, drying and shrinkage of the lens finally result.

The essential change in the cataractous lens is a progressive coagulation of the lens proteins. According to the most generally accepted explanation, such a process is due to the prolonged action of ultraviolet light, and in some instances, to the thermal effect of infrared rays. The lens as already pointed out, by absorbing a large proportion of the rays below λ 350 $m\mu$ and 400 $m\mu$, protects the retina from their injurious effects. Wave lengths below 295 $m\mu$ are absorbed by the cornea. The rays absorbed by the lens are not without their effect upon the lens substance itself, it is these which cause the physical change in the lens proteins. Two stages are recognized in the coagulation process: (1) *denaturation of the lens proteins*, consisting presumably of a molecular rearrangement, by light or heat which renders them susceptible to (2) *aggregation (agglutination) of the protein particles* into a flocculent mass—coagulation. This ultimate result occurs only in the presence of certain salts and is enhanced by some organic substances, e.g. dextrose and acetone. The theory that radiant energy is responsible for denaturation of the lens proteins is in accord with many observations. For example, the absorption by the lens of the shorter rays increases with age. The opacity commences in the lower quadrant of the lens which receives the most intense light. In tropical coun-

tries, e.g. India and Egypt, cataract is much commoner than in temperate latitudes, it is also less frequent in the latter than in Arctic zones, presumably as a result of the high content in actinic rays of the light reflected from snow and ice. It is also stated that on this continent the incidence of cataract increases from temperate zones to the equator, and that it is also higher in those who work in the fields than in city dwellers. Burge's experiments and the more recent ones of Clarke show convincingly the effect of light upon the development of lenticular opacities. Burge found that whereas exposure of a solution of lens protein to ultraviolet light for 100 hrs. did not cause coagulation, this occurred if CaCl_2 , MgCl_2 , dextrose or acetone were added. Moreover the exposure of the eye of a living fish or frog to short light waves was without effect if the animal had previously been kept in tap water, but definite opacity of the lens followed a few hours exposure, if the fish or frog had been for some days in water containing 0.8 per cent calcium chloride, 0.1 per cent dextrose or 0.1 per cent sodium silicate. Clarke found that heat enhanced the action of the light rays upon solutions of lens proteins, and that opacity could not be produced in the absence of calcium.

The incidence of cataract is much higher in diabetics than in normal persons, it is usually of the ordinary or so called senile type, but it occurs at an earlier age. The opacity is attributed to the action of dextrose and possibly of acetone bodies in rendering the lens proteins more readily coagulable by light. Duke Elder believes that as a result of the high blood sugar, the osmotic relationships between the lens and the surrounding fluids are disturbed, and the nutrition of the lens thereby interfered with.

Though the factors outlined above appear to be the main ones concerned in the production of the common or senile type of cataract, opinions differ considerably as to the details of the mechanism involved, as well as in regard to the production of other types of lenticular opacity. It is suggested, for example, that the action of ultraviolet rays in inducing denaturation of the lens proteins is due to the reduction of the glutathione and β crystal line content and the consequent depression of the autooxidative mechanism. Such an effect of ultraviolet radiation has been shown experimentally, it has also been established that the content of the lens in glutathione and in the thermostable protein residue diminishes with age. The power of the lens to fluoresce upon exposure to short wave radiations (p. 1330) and the disposal of the surplus energy by converting them into long waves, is considered by Burge to be an important factor in ameliorating the effect of light upon the lens, fluorescing bacteria for example are much less readily killed by ultraviolet light than are other types. It is of some considerable interest therefore

FIG. 74.38. Spherical aberration. Outer rays meet at 1, inner rays at 2.

that the power of the lens to fluoresce diminishes with age.

In glass blowers' cataract, infrared rays would appear to play an important auxiliary rôle. Early cataract has also developed in a few atomic physicists and in some of the Japanese atomic bomb victims. Much research has since been undertaken on the effect on lens metabolism of γ ray and fast neutron radiation. Young animals develop cataract more readily than older animals when irradiated in this way. A latent period of some weeks or months may elapse after the exposure before opacities in the lens appear.

An interesting type of cataract is that following parathyroidectomy, disordered calcium metabolism would appear to be in some way concerned in its production, the calcium content of the lens is increased, whereas that of the blood is reduced. There is no definite evidence, however, to connect ordinary senile cataract with parathyroid deficiency, but there seems little doubt that calcium is concerned in some obscure way with cataract development. A favorite method of producing cataract for experimental study is by the injection of naphthalene, opacities form only if the animal is on a low calcium diet. In rats, lenticular opacity is readily produced by a diet containing a high percentage of lactose or galactose, the former sugar increases the absorption of calcium, but whether this fact has any bearing upon the development of the cataract is difficult to say, it does not dovetail with other observations in respect to calcium and the development of cataract.

The composition of the cataractous lens shows marked differences from the normal. There is an increase in the insoluble albuminoid and a decrease of the soluble proteins and of glutathione, the oxygen uptake is much reduced. Of the inorganic constituents calcium shows a relatively enormous increase (up to 140 mg. per cent). The concentration of magnesium, sodium and silicates is also raised whereas that of potassium is greatly reduced.

OPTICAL DEFECTS

SPHERICAL ABERRATION. Rays traversing the peripheral parts of an ordinary convex lens are refracted more strongly and therefore come to a

FIG 74 39 Chromatic aberration

focus nearer the lens than do those transmitted through more central regions. In other words, the outer and inner rays cross in front of the retina and a blurred image is formed (fig 74 38). This is an inherent defect of convex spherical lenses and is called *spherical aberration*. Spherical aberration is corrected to a certain extent in the crystalline lens, the nucleus having a higher refractive power than the periphery (see p. 1379). The iris, since it covers the outer part of the lens and shuts off the peripheral rays, also serves to correct this defect.

CHROMATIC ABERRATION. The colors composing white light are refracted to different degrees according to their wave lengths. The violet rays are refracted most, the refractive power diminishing progressively from the violet to the red end of the spectrum (fig 74 39). For this reason a series of fringes, colored from violet to red from within outwards, borders the image formed by a simple cheap lens. *Chromatic aberration*, as this defect is called, is corrected in camera and microscope lenses by cementing a biconvex lens of crown glass to a concave one of flint glass. Such a lens is called *achromatic*. The eye is only partially corrected for chromatic aberration. The yellow rays are focused upon the retina, but the short blue rays being more acutely bent meet in front, while the longer less strongly refracted red rays come to a focus behind the retina. Other rays are bent similarly in accordance with their wavelengths. Furthermore, the fovea being on the temporal side of the optical axis, the blue rays fall upon the retina nearer to the point (*axial point*) where it is cut by the optical axis. This, of course, will obtain in both eyes, and lines projected outwards from the axial points will meet as shown in figure 74 39. The blue rays will therefore appear to come from a point farther away than the point emitting the red rays, the image formed on the retina by the shorter blue rays will also be smaller than that formed by the red rays. These effects of the unequal refraction of the different colors are called, respectively, *chromatic stereoscopy* and *chromatic difference of magnification*. In ordinary vision the

colors surrounding the images on the retina are not perceived.

Diffraction and the scattering of light within the eyeball. Light is diffracted by the pupillary margin and by the lens fibers and corneal epithelium, as a result of this and of spherical aberration the retinal image is not made up of points of light but of diffusion circles (blur circles), i.e., a bright central disc surrounded by light rings which diminish in intensity by almost imperceptible gradations towards the periphery. The relative size of the central bright area varies inversely with the diameter of the pupil and directly with the wave length of the light. The opposite effects of changes in the size of the pupil upon this defect and upon chromatic aberration have been pointed out.

None of the ocular media is perfectly homogeneous, owing to their colloidal nature a certain proportion of the light entering the eye is scattered (Tyndall phenomenon), that is, it is not focused upon the retina but is deflected from the course which it would follow according to the laws of refraction if the contents of the globe were perfectly transparent. The colloidal particles have a size of the order of the wave length of light. The quantity of scattered light is directly proportional to the square of the size of the particles, and inversely proportional to the fourth power of the wave length (Rayleigh). Thus the greatest scattering within the eyeball occurs with violet and ultraviolet light and the least with red (see Le Grand).

✓ **PRESBYOPIA** (Gr *presbos*, old, *ops*, the eye) is the term given to the gradual reduction in the amplitude of accommodation which goes hand in hand with advancing years.

EMMETROPIA AND AMETROPIA. The four optical defects just described may be regarded as physiological, the first three being inherent to some extent in optical systems in general, the fourth is a natural accompaniment of age. Two other defects of frequent occurrence are due to incongruity between the length of the eyeball and its refracting power and must be classed as definite abnormalities.

The refractive state of the normal eye, which has its far point (p. 1391) at infinity, i.e., at a distance greater than 6 meters (20 feet), is called *emmetropia*. Parallel rays entering the emmetropic eye are brought to a clear focus on the retina without any effort of accommodation. The static refraction of such an eye is therefore zero. If the far point is not at infinity the eye is *ametropic*. There are two forms of ametropia—myopia and hypermetropia (fig 74 40).

In *myopia* (Gr *myo*, I blink or half close the eye, *ops*, the eye) or *short sight*, the eyeball is too

long relatively to its refracting power (fig 74 40-B). Obviously, such an eye will bring parallel rays to a focus in front of the retina, i.e., in the vitreous. After meeting, the rays cross and form a blurred image or a diffusion circle upon the retina, just as a camera which is extended too far forms an indistinct image upon the film. In order to form a clear image on the retina of the myopic eye the rays must be, not parallel but divergent, such as are emitted by a near object. The far point is therefore at a finite distance, and in extreme instances may be only a few centimeters from the eye. Accommodation, of course, is relaxed for the far point as in the emmetropic eye for, obviously, increasing the converging power of the lens will only cause greater blurring of the image. The far and near points being close together, the range and the amplitude of accommodation (p 1391) are reduced. Myopia is corrected by means of concave (diverging) lenses. If, for example, an object can be seen clearly no farther away than 1 meter, the myopia is -1 D, i.e., a concave lens of this power is required.

In *hypermetropia* (Gr *hyper*, above, *metros*, measure, *ops*, the eye) or *long sight* (fig 74 40C) the eye is too short for its refracting power. Therefore parallel rays after refraction fall upon the retina before they have come to a focus, and form an image blurred by diffusion circles. The rays as they emerge from the eye are divergent. The far point is *virtual*, i.e., it is behind the eye at the point where the rays would meet if continued backwards through the retina. The hypermetrope must accommodate when he views distant objects in order to focus the parallel rays upon the retina. The range of his accommodation (p 1391) is the same as that of the emmetrope but the amplitude is greater. Suppose, for example, that the near point is 0.10 meter in front of the eye and the far point is 0.25 meter behind, i.e., negative (-0.25). Then the dynamic refraction is $100/10 = 10$ D, and the static refraction is $-100/-25 = -4$ D, the amplitude of accommodation is therefore 10 D $- (-4$ D), or 10 D $+ 4$ D = 14 D. Hypermetropia is corrected by means of a convex lens, the distance of the far point behind the eye giving the measure of the strength of lens required, if this is -0.25 meter then a $+4$ D lens would correct the defect (see p 1384).

Although it is customary to account for myopia and hypermetropia in terms of variations in the axial length of the eye and to assume that the power of the cornea and lens is constant, recent studies suggest that this view is inadequate. If the

FIG 74 40 A emmetropia, B myopia C hypermetropia

optical constants of a large number of eyes are measured it is found that the power of the cornea varies from 39 to 47 D and that of the lens from 14 to 25 D. The axial length may range from 22 to 26 mm. Although hypermetropic eyes tend to have a shorter axial length than myopic eyes it is only in the severe degrees of these defects (over $+4$ or -4 D) that the axial length falls outside the normal statistical limits. The refractive errors in a population are so distributed that the three variables cornea, lens and axial length cannot be distributed in a random fashion, for inspection of figure 74 41 indicates that there is an excess number of emmetropes in the population. A correlation mechanism must be postulated to maintain something like emmetropia during the period of growth of the eye from its newborn length of 16 mm to that of 24 mm in the adult state. Most of the growth in length occurs during the first few years of life although myopia often first declares itself at adolescence when the axial length has become stable. Nothing is known about the nature of the process which leads to such a high proportion of emmetropes in the population. Genetic factors are almost certainly involved for refractive errors can often be inherited.

ASTIGMATISM (Gr *a*, privative, *stigma*, a point) In this condition as its name implies, rays of light are not brought to sharp points upon the retina, but form short lines. The defect is present in all eyes to a certain degree, when moderate it is therefore physiological. Only when the fault seriously reduces visual acuity is it abnormal. It must be remembered that rays of light pass through all meridians of a lens, in converging to a focus they therefore form a cone of light, not simply a flat pennantlike beam. If all meridians of a lens have the same curvature, then rays in all planes will be refracted to the same degree and come to a focus together. If, on the other hand,

FIG 74 41 The distribution curve of ocular refraction of 194 eyes. The continuous lines indicate the actual observations and the dotted line indicates the fitted normal curve. As the former is more peaked than the latter it may be concluded that whereas the individual optical components may vary over a wide range in an individual eye these components are usually so correlated that emmetropia results (After Sorsby Benjamin Davey Sheridan and Tanner)

FIG 74 42 Refraction by an astigmatic lens. VV the vertical meridian of the refracting body is more curved than HH the horizontal meridian. A B C D E F G show different sections of the beam after refraction. At B the vertical rays are brought to a focus. At F the horizontal rays are brought to a focus. From B to F is the focal interval.

the curvatures differ, the rays transmitted through a meridian with the greater curvature will be refracted more strongly and brought to a focus in front of rays passing through other meridians. For example, should the vertical meridian be more curved than the horizontal, then when the rays passing through the vertical meridian are in focus, those in the horizontal will form not a point, but an ellipse, a circle or a line. Thus

there are two foci and the distance between two lines—the *focal interval*—is a measure of the degree of the astigmatism (see fig 74 42). Such inequalities of curvature in the meridians of the cornea or, less commonly, of the crystalline lens are the cause of what is known as *curvature astigmatism*. The greater curvature may be in either the vertical, horizontal or an oblique meridian. But in physiological astigmatism (which is due most probably to the pressure of the upper lid upon the eyeball during growth) the greater curvature is in the vertical meridian. In pathological types also this meridian has most commonly the greater curvature. When the refractive power though unequal in the various meridians is the same throughout any meridian and the maximally and minimally curved meridians (*principal meridians*) are at right angles to one another, the astigmatism is called *regular*. In *irregular astigmatism* not only is the refractive power unequal in the different meridians but it is not uniform throughout a meridian and the principal merid-

ians are not at right angles to one another. Astigmatism may result from inequalities in the refractive indices between different parts of the lens, this is termed *index astigmatism*. Slight inequalities of this nature in the refractive indices may also contribute to physiological astigmatism. An oblique or other malposition of the lens is sometimes a cause of *astigmatism*. When the subject of astigmatism looks at a clock face the straight lines in the vertical numerals XII and VI may be clearly seen while the horizontal lines in IX and III are blurred, or vice versa. Or the diagonal numerals may be out of focus while the vertical and horizontal are sharply defined. A chart such as is shown in figure 74 43 is employed to detect the meridian or meridians in which the corneal curvature is abnormal.

Astigmatism is corrected by the use of spectacle lenses convex in the meridian corresponding to that of the cornea (or crystalline lens) having the lesser curvature. Thus if the curvature of the cornea is greater in the vertical meridian the subject is fitted with a cylindrical lens which, it will be recalled, refracts in a single plane having its convexity in the horizontal meridian.

The young emmetrope becomes myopic by 1 to 2 D when viewing a scene in dim lighting such as twilight. There is evidence that some of this 'twilight myopia' is caused by the increased effects of spherical aberration resulting from the dilation of the pupil in dim lighting. However, some of the effect is also due to a small and variable amount of near accommodation of the lens system. Even in bright viewing conditions when the pupils are small and spherical aberration is minimal the emmetrope may become myopic to the extent of 0.25 to 1 D when viewing a scene devoid of visual detail such as a clear blue sky. This day myopia is due to the lens system accommodating for near. It is not known why the accommodation mechanism does not remain focussed at infinity in the absence of a suitable visual stimulus. This condition may cause difficulty in high altitude aircraft when searching for approaching aircraft.

Contact Lenses

The contact lens consists of a thin cuplike shell of glass moulded to fit the cornea and sclera and ground to the required curvature. It is applied directly to the eye and therefore moves with it. Contact lenses are employed for the correction of various types of refractive error e.g. myopia and hypermetropia and those due to abnormalities in the form of the cornea (astigmatism or conical

FIG 74 43 Chart used in testing for astigmatism. One eye being closed the patient is asked to say which of the groups of lines are blackest and most distinct and which are lightest and indistinct.

FIG 74 44 Contact lens

cornea) or to absence of the lens (*aphakia*). Before being applied the concavity of the lens is filled with saline solution and when in position is separated from the cornea only by a thin film of the solution. The refractive indices of the cornea and the saline are approximately the same. The two therefore constitute a single refracting medium moulded as it were by the posterior surface of the glass shell into a normal form. Light rays are refracted at the anterior surface of the cornea in contact with the air and are strongly at the posterior surface but undergo no further refraction until they reach the crystalline lens (fig 74 44).

The Intraocular Fluids

THE INTRAOCULAR PRESSURE The pressure within the chambers of the eye of a living animal is from 15 to 20 mm Hg and from 8 mm to 10 mm Hg in the excised but intact globe. It also falls to the latter level immediately after death or after arrest of the ocular circulation. The difference between these two sets of values is due to the pressure of the blood in the vessels of the globe. This will be clear from figure 74 45. The vascular bed of the eyeball lies between the relatively resistant sclerotic on the outside and the incompressible intraocular contents on the other. It is evident that blood pumped into the vessels of the choroid will raise the intraocular pressure above

FIG. 74-45 Showing the distribution of volume pressure in the eye with (1) a collapsed blood pressure, (2) in the normal state, and (3) with raised blood pressure and capillary dilatation (After Duke Elder, *The Nature of the Intraocular Fluids*)

that of a bloodless eye. The intraocular pressure runs closely parallel with that of the blood in the choroidal capillaries. A rise or fall in general arterial pressure therefore may cause a corresponding change in intraocular pressure, though it will be much less in degree. The pulse beat causes a variation in intraocular pressure of from 1 to 2 mm Hg, and the respiration one of from 3 to 5 mm Hg. However, since it is the pressure in the capillary bed of the eye rather than that in the larger ocular vessels which is the determining factor and the former pressure can vary as a result of local changes in caliber of the minute vessels, the intraocular and arterial pressures do not necessarily change in the same direction. Thus arterial hypertension, in which the capillary pressure is not raised (p. 388), does not cause a rise in intraocular pressure; amyl nitrite, on the other hand, causes a fall in arterial pressure as a result of the peripheral vasodilation, accompanied by a rise in intraocular pressure (due to the dilation of the capillaries of the eye and the consequent increase in capillary pressure). The intraocular pressure therefore follows very closely the venous pressure, tying the vortex veins, for example, increases capillary pressure and causes a rise in intraocular pressure of from 50 to 60 mm Hg. The pressure of 8 or 10 mm Hg which, as mentioned above, exists within an eye immediately after its circulation has been arrested, may be looked upon as representing the balance struck between the production of intraocular fluid and its removal through the drainage channels.

Other factors which affect the intraocular tension are, pressure from without by the action of

the eyelids and of the extrinsic muscles of the eye. The effect exerted by the eye muscles in ordinary movements is negligible, but maximally strong convergence of the eyeballs may raise the pressure by from 4 to 10 mm Hg. Movements of the lids have a greater influence, strong contraction of the orbicularis oculi causing a rise of 50 mm Hg or more. Exposure of the eye to light causes a fall, and dark adaptation a rise in pressure which is attributed to constriction and dilation respectively, of the ocular capillaries. Contraction of the ciliary muscle causes no change in the intraocular pressure, nor does the state of the pupil. A change in pressure does not occur therefore upon accommodation of the eye provided that the associated convergent movement is prevented.

THE VITREOUS BODY The vitreous body occupies the segment of the globe lying behind the lens and the ciliary processes. In front it presents a saucer shaped depression—the *hyaloid fossa*—which lodges the posterior convexity of the lens. A narrow space (*postlenticular space*) filled with fluid separates the lens from the concave surface of the vitreous. The *hyaloid canal* (which lodged the hyaloid artery in the embryo) runs from the posterior pole of the lens to the center of the optic disc. The structureless *hyaloid membrane* surrounds the vitreous, anteriorly it is strengthened by radial fibers which have already been referred to as the *zonula ciliaris* (p. 1386). In this region it shows a series of grooves which lodge the ciliary processes. The vitreous body is a jellylike material possessing no obvious structure, but it is claimed that by the use of special fixatives (e.g. a weak solution of chromic acid) a series of superimposed lamellae arranged concentrically around the hyaloid canal and composed of very thin flat cells can be demonstrated. The spaces between the lamellae contain fluid almost identical in composition with the aqueous humor. Though some maintain that the lamellae are fixation artefacts and that the vitreous body is a homogeneous gel there seems little doubt that a framework does exist. If the vitreous body is examined with the phase contrast microscope a network of fibers of various sizes can be demonstrated and a clear cut hyaline membrane which encloses it. The human vitreous adheres firmly to the retina in the region of the macula and optic disc. Less firm adhesions also occur at the equator and this appears to lend support to the hypothesis that some retinal detachments are caused by traction of the vitreous fiber on the retina. Examination of the vitreous structure with the electron microscope has revealed three types of fibers: (1) fibers without cross striations of diameter 15 to 30 μ , this type being commonest, (2) fibers showing cross striations of period 61 μ and diameter 15-30 μ , (3) fibers showing cross striations similar to collagen (61 μ) and diameter 50 to 80 μ .

THE AQUEOUS HUMOR is a clear watery fluid occupying the anterior and posterior chambers of the eye. It has a refractive index of 1.33, it is alkaline in reaction (pH 7.1 to 7.3) and has a specific gravity of from 1002 to 1004. The composition of the aqueous humor closely resembles that of an ultrafiltrate of plasma. The main difference between the composition of plasma and aqueous lies in the very low protein content of the latter (10 to 20 mg, 100 ml in man). The aqueous contains a lower concentration of glucose and a higher concentration of lactic acid than does plasma. This may be due in part to the metabolism of glucose by the lens and cornea. The ascorbic acid concentration of the aqueous is some 10 to 50 times greater than that in the plasma, and it is thought to be passed into the fluid by the ciliary body. This high concentration may be connected with the metabolism of the avascular tissues such as the cornea, lens and vitreous body. The ascorbic acid content of the aqueous has been shown to fall dramatically in scorbutic guinea pigs but no ocular defects occur in prolonged scurvy in either guinea pigs or man.

The Formation of the Intraocular Fluids

Owing to the importance of the subject to glaucoma, the formation of the intraocular fluids has been investigated most diligently, especially by Duke Elder and his associates. But the precise mechanism involved has not yet been established. There have been three theories of the process proposed, namely, that it is one of (1) ultrafiltration, (2) dialysis or (3) secretion. None of these theories alone fits all the known facts. The principal process appears to be one of ultrafiltration, and involves those factors, capillary blood pressure and colloid osmotic pressures, which have been described elsewhere in connection with the interchange of water and substances in solution across capillary membranes (chs 3 and 13). The high capillary pressure required for ultrafiltration into the interior of the eyeball has been shown to exist (owing to the relatively high hydrostatic pressure therein), the mean pressure in the capillaries derived from the retinal artery and the posterior ciliary arteries is 50 mm Hg which is much higher than that in the capillaries of most other regions. Nevertheless, ultrafiltration is not a complete explanation of the formation of intraocular fluid, for when the concentrations of the constituents of plasma and of the aqueous humor are compared, it is evident that the latter is not simply an ultrafiltrate like the fluid in Bowman's capsule, for example. It is therefore thought that dialysis plays a part, though there are discrepancies here which

do not permit the formulation of a theory based upon simple dialysis alone. There is also some evidence that certain substances, e.g., sodium are secreted.

The surface of the ciliary body and the posterior aspect of the iris are believed to constitute the membrane interposed between the aqueous humor and the blood. That diffusion occurs across both these surfaces is indicated by the following observations. When the pupillary aperture is occluded either experimentally or as a result of disease, aqueous fluid accumulates behind the iris. On the other hand, fluid is formed after excision of the iris or when it is congenitally absent. In certain fish not possessing a ciliary body and in the congenital absence of the latter in man, normal aqueous humor is present, it has also been found in a cyst of the iris itself.

THE CIRCULATION OF THE INTRAOCULAR FLUIDS
THE DRAINAGE SYSTEM OF THE EYE. Intraocular fluid is probably reabsorbed to some extent from all parts of the interior of the globe. A small proportion of the dialyzed fluid passes from the posterior chamber through the zonule and down the hyaloid canal to the lymphatics of the optic nerve. However, less than 1 per cent is reabsorbed in this way, or indeed from any region of the eye lying posterior to the iris. The chief exits for the fluid are at the angle of the anterior chamber (angle of the iris or filtration angle) and from the anterior surface of the iris. It will perhaps be of advantage to the reader if the main structural features of this region are recalled.

On the deep aspect of the sclera at its junction with the cornea and in front of the angle of the anterior chamber lies an annular venous sinus—the canal of Schlemm (sinus venosus sclerae) (fig 74.29). The sinus completely surrounds the corneal margin and in meridional sections of the eye appears as a small oval gap or cleft lined by endothelium. The inner or posterior wall of the canal is separated from the anterior chamber by a zone of trabecular tissue formed by the breaking up of the posterior elastic lamina of the cornea and termed the pectinate ligament; the intervals between the trabeculae are termed the spaces of Fontana. The trabecular tissue of the pectinate ligament is continued around the iridial angle its fibers terminating in the tissue of the iris. Schlemm's canal is fed by an afferent arteriole derived from the ciliary arteries and drained by an efferent venule which empties into the episcleral venous plexus (Friedenwald). The spaces of Fontana communicate with the anterior chamber, but there is no direct communication between the former and the lumen of Schlemm's canal, the

canal cannot be injected for example, with a colloidal solution introduced into the anterior chamber

The *scleral spur* is the term applied to a small triangular projection of the sclera on the posterior aspect of the sclerocorneal junction. It lies immediately behind the outer part of the posterior wall of Schlemm's canal and gives attachment to the meridional fibers of the ciliary muscle. Contraction of the muscle, by pulling upon the spur, is said to dilate the canal and thus favor the drainage of fluid from the anterior chamber.

Movement of the intraocular fluid from the posterior to the anterior chamber and from the latter to the filtration angle is brought about largely through intermittent variations in intraocular pressure occasioned by the several factors already discussed (e.g., pulsatile and respiratory variations in blood pressure and actions of the eyelids, etc.). Temperature differences between the superficial and deeper parts of the anterior chamber (thermal factor) cause convection currents to be set up which also play an important part in the movement of fluid. At the angle of the iris the fluid percolates into the spaces of Fontana whence it is absorbed across the posterior wall of the canal of Schlemm.

Friedenwald and Pierce have demonstrated a differential absorption between the water, crystalloids and protein constituents of the aqueous. From their experiments which involved the introduction of substances into the anterior chamber, these observers conclude that crystalloids and a small quantity of water are reabsorbed from the anterior surface of the iris, passing by diffusion through the walls of the capillaries. Colloids are removed by the phagocytic action of the surface layer of epithelial cells. A part of the protein is hydrolyzed by the action of enzymes present in the fluid and reabsorbed as amino acids. Water is absorbed chiefly through the spaces of Fontana and the canal of Schlemm. The rate of passage of fluid through the wall of the canal is governed apparently by hydrostatic and osmotic forces. The pressure of blood in Schlemm's canal (or rather in the small veins leading from it) is stated to be equal to or about 1 mm. higher than that of the fluid in the anterior chamber, but after the absorption of crystalloids one would expect the osmotic pressure of the aqueous to be considerably lower than that of the serum, under such circumstances an uptake of fluid would occur, provided the blood flow through the canal did not fall below a certain level. Slowing of the circulation would tend (as a result of the dilution of serum

colloid dilution by the reabsorbed fluid and consequent reduction in osmotic pressure) to reduce the rate of reabsorption, an increase in blood velocity to increase it. Such a relationship was actually observed by Friedenwald and Pierce. Increase in intraocular pressure would quite evidently increase reabsorption; the pressure would thus tend automatically to be restored to its original level.

According to some authorities (Maggiore, Duke Elder) the canal of Schlemm contains blood only when the ocular venous pressure is inordinately high, being filled under usual circumstances with an aqueous fluid (with an osmotic pressure around that of the fluid in the anterior chamber). Since as mentioned above the pressure of blood in the small veins leading from it is higher than the normal intraocular pressure the canal could not serve as a pathway for the continued reabsorption of fluid, it is claimed that reabsorption can occur only if the intraocular pressure rises above the normal level. This conception attributes a safety valve function to the canal. I.e., it is called into play presumably only in an emergency.

GLAUCOMA OR OCULAR HYPERTENSION Persistent elevation of the intraocular pressure occurs as an accompaniment of several diseased states of the eye and may then be due to blockage of the drainage channels at the iridial angle or to the excessive production of fluid. The latter effect may result from mechanical irritation of the ciliary processes (e.g., by displacement of the lens) or obstruction of the venous channels with consequent rise in capillary pressure. Ocular hypertension associated with some such obvious disease of the eye is referred to as *secondary glaucoma*. When the intraocular pressure is persistently elevated above 35 mm. or so and no abnormality of the eye exists to account for the hypertension it is termed *primary glaucoma*. At the outset it may be said that though primary glaucoma has been the subject of much speculation its cause remains obscure.

The excessively high intraocular tension causes compression of the vessels and in time serious disturbances in the nutrition of the eye result, namely optic atrophy, excavation (clipping) of the disc, blindness and ultimately disintegration of the optical mechanism. Owing to the readjustments which take place in the ocular circulation the hypertension may exist for some time before any of these effects make their appearance. The pressure as it gradually rises first compresses the venous channels but as a result of the opening up of the arterioles and capillaries, a larger proportion of the arterial pressure is transmitted to the venous side, the compressing force is thus overcome and the circulation maintained. This stage in the progress of the condition is referred to as *compensated glaucoma*. A point will be reached,

however, at which the pressure of the intraocular fluids approaches equality with that in the ophthalmic artery, then further compensation becomes impossible and the structural changes just mentioned supervene. The condition is then termed *inflammatory or decompensated glaucoma*.

The possible factors which have been suggested in explanation of the elevated pressure will be briefly considered. Mechanical obstruction at the filtration angle due to reduction in the depth of the anterior chamber and the consequent adhesion of the periphery of the iris to the cornea, is frequently present in decompensated cases, but this is secondary and not primarily related to the hypertension. It is not improbable that some abnormality in the nervous control of the vascular bed of the globe is fundamentally responsible. Friedenwald suggests that the reabsorption of water through the mechanism of Schlemm's canal (p. 1398) as a result of sclerosis and narrowing of the afferent vessels may be the essential factor concerned. Reduction in the caliber of these vessels would tend, by slowing the blood flow through the canal, to reduce the reabsorption rate. Spasm of the vessels feeding the sinus would have a similar effect. On the other hand, the reduced depth of the anterior chamber in decompensated glaucoma suggests that the increased pressure originates in the posterior chamber of the eye, and the theory has been advanced that swelling of the vitreous is responsible. From the gelike nature of the vitreous body one might expect its water content to vary with changes in its inorganic constituents or in pH. It has been found, however, that the chemical changes necessary to cause any significant increase in volume of the vitreous are far greater than any that could occur in the body. Finally, a vasodilator toxin of the histamine type has been suggested which supposedly, by causing dilation of the intraocular capillaries and an increase in the permeability of their walls, would lead to overproduction of intraocular fluid. The aqueous in decompensated glaucoma has a higher protein, and lower chloride content and osmotic pressure than normal, this fact lends some force to the theory of increased capillary permeability. The

abnormal permeability would also, by reducing the effective osmotic difference between the contents of the anterior chamber and the blood, tend to diminish reabsorption. Nevertheless, analysis of the aqueous humor in compensated cases shows no significant departure from the normal and therefore lends no support to the idea that a change in capillary permeability is the fundamental factor in the development of glaucoma.

There is no causative relationship between arterial and ocular hypertension.

THE VISUAL FIELDS AND PATHWAY. MOVEMENTS OF THE OCULAR MUSCLE. STEREOSCOPIC VISION

THE VISUAL FIELDS The visual field of one eye is the part of the external world which is seen by that eye at any given moment, i.e., when its gaze is fixed in one direction. It may be likened to a portion of a great hollow sphere—a bowl—upon the interior surface of which the images of the external world are projected. Traquair pictures the visual field as "an island of vision surrounded by a sea of blindness", carrying the simile further, the surface contour of this imaginary island is described in terms of visual acuity, the highest point corresponding to the fovea, a deep (bottomless) pit to the blind spot and a gradual slope toward the peripheral retina. The visual field of each eye subtends an angle of about 160° in a horizontal and 145° in the vertical meridian. The visual field on each side is divided by a line passing vertically through the fixation point (p. 1417) into two unequal parts, an outer or *temporal* and an inner or *nasal*. The latter is smaller owing to the shadow of the nose, its diameter being about 60° whereas the diameter of the temporal part is around 100° . Similarly a line passing horizontally through the point of fixation divides the field into an upper and a lower part, the former being restricted by from 5° to 10° by the upper lid and orbital margin. Rays of light from the outer or temporal half of the visual field fall upon the nasal (inner) half of the retina, those from the inner or nasal half of the visual field fall upon the temporal half of the retina (fig. 757, p. 1408). Although an image is formed upon each retina the two are fused in consciousness into a single impression (see p. 1412). In most animals the visual fields of the two eyes overlap, that is, certain parts of the outside world are seen by both eyes at the same instant—*binocular vision*. In animals with eyes placed laterally in the head overlap of the visual fields must obviously be very small in extent, the visual fields being almost completely separate—*monocular vision*. The extent of overlap of the visual fields of the monkey and of man, whose eyes are placed in the front of the head, is large (120° horizontal diameter) and the monocular field of vision, that

is, the field which can be seen by one eye but not by the other, is relatively small (35°) (figs. 751 and 755). Rays of light entering the eyes from an object in the binocular field of vision fall upon the nasal half of one retina and upon the temporal half of the other. If, however, the object is well to the right or to the left of the line of vision, i.e., in the outer part of either temporal field, the rays then fall upon the nasal half of the peripheral retina of the nearer eye (right or left) but not upon the other retina which is shaded by the nose. So the monocular field of vision consists in man of a crescentic area (35°) at the outer limit of the temporal field of each eye.

When one looks directly at an object the eyes are turned so as to bring an image of the object upon the most sensitive area of each retina, i.e., upon the nasal and temporal halves, respectively, of the foveae. The horizontal diameter of the entire visual field, that is, of the area of overlap of the two fields plus the monocular fields on each side is about 200° .

We shall see when the arrangement of the fibers conveying visual impulses is considered that fibers arising from the nasal halves of the retinas cross in the chiasma, whereas the temporal fibers remain uncrossed. Thus it is that the occipital cortex of one side receives impulses from the nasal half of the opposite retina and from the temporal half of the retina of the same side, that is, those retinal halves which receive impressions from the opposite halves of the visual fields (fig. 757, p. 1408). Loss of vision in one half of each eye is called *hemianopia*. When the blindness affects the right or the left halves of both retinas, i.e., the nasal half of the left retina (temporal half of visual field) and the temporal half of the right (nasal half of the visual field) or vice versa, the *hemianopia* is said to be *homonymous*—left or right respectively. If the blindness is in the left half of one retina and in the right half of the other, i.e., in either both temporal retinal halves (nasal halves of visual fields) or in both nasal retinal halves (temporal halves of visual fields) the *hemi-*

FIG 75.1 Showing monocular (white) and binocular (black) fields of vision. Upper rabbit, lower monkey (or man). (From Parsons, after Brouwer and Zeeman)

anopia is *crossed* or *heteronymous* and is referred to as *binasal* or *bi-temporal*, respectively. It will be noted that the qualifying terms refer to the affected halves of the visual fields and not to the retinal halves. In other instances a quarter only of each visual field is affected, when the term *quadrantic hemianopia* is employed. It may be the upper or the lower quadrants of the nasal or of the temporal fields which are involved, or homonymous quadrants may be affected, i.e., a quadrant in the nasal field of one eye and in the temporal field of the other. The type of hemianopia is further specified by the use of the word "superior" or "inferior" (fig 75.2). Thus, a superior nasal quadrantic hemianopia is one in which the eyes do not see objects in the upper nasal

quadrants of the visual fields (blindness of lower temporal retinal quadrants)

Isopters. The sensitivity of the retina from the periphery to the fovea can be explored by using a series of test objects of graduated sizes with the perimeter, and determining in different meridians the distance from the fixation point (p 1417) at which each object is just perceptible. The points so determined are marked upon the perimeter chart and lines drawn through each set. Thus a series of boundary lines roughly concentric with the fovea are constructed which indicate the thresholds for the perception (minimum visible, p 1364) of the different test objects, and therefore demarcate levels of retinal sensitivity. Each is called an *isopter of sensitivity*, they might be compared to the contour lines indicating elevations on a detailed geographical map.

THE BLIND SPOT. The entrance of the optic nerve since it is devoid of rods and cones is completely blind. An object whose image falls upon it is therefore invisible (see fig 75.3). Not even a sensation of blackness results, for when the eye is fixated upon the cross, as described in the legend of the figure, and the book moved until the optic disc is occupied by the circle the latter simply disappears, no sensation whatever being experienced to indicate its existence. Ordinarily this "hole" in the visual field causes no inconvenience because, in any position of the eyes, should one

FIG 753 The blind spot. Close the left eye, hold the figure about 6 inches in front of the right eye and look steadily at the cross. Move the book slowly toward the eye until the circle disappears. When this occurs the image of the circle has fallen upon the entrance of the optic nerve from which rods and cones are absent; it is therefore insensitive to light. Figure on the right shows the blind spot projected 6 inches in front of the right eye as mapped out by means of perimetry. (After Helmholtz.)

FIG 754 Perimeter. *e*, position of the patient's eye; *c*, chin rest, further description in the text.

image of an object fall upon the blind spot, a sensitive part of the opposite retina receives the other image. Even when one eye is closed or blind, we are not aware of the blind spot in the seeing eye unless it is specifically demonstrated. Patients who have had portions of their peripheral retina destroyed some time previously by localized disease are often unaware of the presence of the blind areas until they are demonstrated to exist by means of perimetry.

Perimetry is the term applied to the procedure of mapping out the visual fields. The instrument employed is called a *perimeter*. It comprises a metal band or arm, shaped in a large arc of a circle with its concavity directed towards the subject

(fig. 754). A holder sliding in the arc carries the test object which can be moved centrally or peripherally as required. The arm itself is pivoted at the center, enabling it to be rotated to any angle. The subject's head is supported on a chin rest. One eye is covered; the eye under examination is placed at the center of the sphere of which the perimeter arm forms the arc, and made to fix a point straight ahead in the center of the arm. The latter is rotated by degrees through a full circle, and at each new position the test object is moved centrally until it is just perceived by the subject. This point and corresponding points at the various positions of the arm are marked upon a perimeter chart, and the contour of the visual field outlined through them. The chart (fig. 755) is ruled in circles (comparable to latitudes on a geographical map) to indicate degrees from the point of fixation and in radiating lines (longitudes or meridians). The mapping of the blind spot and of the sensitivity of the retina in isopters has been referred to. The reader should consult texts on ophthalmology for a more detailed description of perimetry. A simple but rough method of perimetry (*confrontation method*) which will reveal a major limitation of the visual fields is the following: The observer stands facing the subject and about two feet in front of him. One eye of the patient is covered while the other, which he fixes upon the opposite eye of the examiner, is being tested. The examiner holds his finger midway between himself and the patient but outside the limit of his own visual field and then brings it slowly toward the midline. The observer compares the position at which he first sights his finger with that at which it is first seen by the patient. The procedure is

repeated from various directions, above, below and from either side

The Visual Pathway

The optic nerve The ganglion cells of the retina (ganglion cell layer) whose central processes constitute the optic nerve, are the secondary neurons of the visual pathway (ch. 72). The primary neurons are the bipolar cells of the inner nuclear layer, the peripheral processes of the latter connecting with the visual receptors—the rods and cones. Tertiary neurons complete the pathway from the lateral geniculate body to the visual cortex. The fibers of the ganglion cells as they enter into the formation of the optic nerve are arranged in groups corresponding, in their relative positions, to the quadrants of the peripheral retina from which they arise. That is, fibers from the upper and lower temporal quadrants of the retina are found in the upper lateral and lower lateral regions of the nerve, respectively (fig. 75.3). Those from the nasal quadrants are situated in the inner sections of the nerve, the fibers from the upper quadrant lying above those from the lower. In the distal part of the nerve the macular or foveal fibers are in a lateral position, being wedged between the upper and lower temporal bundles, but again, fibers from the upper half of the fovea lie above those from the lower half.¹

The optic chiasma The fibers from the temporal halves of the peripheral retina continue uncrossed into the corresponding optic tracts, while the fibers from the nasal halves cross in the chiasma to the optic tract of the opposite side.² In the chiasma the temporal fibers lie in its lateral angle. Those of upper retinal origin lie above those arising from the lower retinal quadrant. In the crossing of the nasal fibers those from the upper quadrants lie upon the upper aspect, those from the inferior quadrants upon the under aspect of the chiasma, the macular fibers lie in between.

The Optic Tracts and Primary Optic Centers

The visual pathway from the chiasma to the primary optic center consists of compact bundles

¹ There is some evidence that centrifugal fibers may be present in the optic nerve. Grant has recently succeeded in demonstrating centrifugal effects from the mesencephalic reticular activating system in the cat's retina. These centrifugal signals may adjust the peripheral sensitivity of the retina, although much more work will be required to establish their function. (See Grant.)

² The proportion of the fibers which cross in the chiasma varies in different mammalian forms. In the opossum example $\frac{4}{5}$ cross to the opposite optic tract, whereas in the ferret $\frac{3}{5}$ cross, in the rabbit also the uncrossed fibers are few in number

of fibers—the optic tract. In the optic tract, fibers from the upper quadrants of the peripheral retina tend to lie ventro-laterally, those from the lower quadrants ventro-medially. The foveal fibers lie dorso-laterally. The optic tract passes backwards and outwards between the tuber cinereum and the anterior perforated substance to the cerebral peduncle around which it turns as a flattened band to reach the lateral (external) geniculate body. In this, the primary visual center, the great majority of the optic fibers make connection. A smaller number are continued to the superior colliculus (superior corpus quadrigeminum) but none of these are of foveal origin.

The projection of the retina upon the external geniculate body has been studied by Brouwer and Zeman in monkeys. These observers produced localized lesions in the retina and examined the geniculate body histologically after time had been allowed for degeneration of the optic fibers. It was found that the retinas were not projected diffusely throughout the primary optic center, but showed localization of their different regions to definite sections. Thus the upper parts of the peripheral retinas, both nasal and temporal, of the two eyes were projected to the radial parts of the geniculate body. The lower parts of the retinas were represented in the lateral part (fig. 76.3, E). Dorsal to these regions and wedged between them was an extensive area wherein the macular fibers terminated. Binocular and monocular types of vision have separate representations. In the monkey the area which receives fibers from only one eye is very small, occupying a small rim on the ventral aspect of the primary center. In the rabbit, on the other hand, the monocular projection occupies almost the entire geniculate body, binocular vision being represented by a narrow area on the medial aspect of the geniculate body.

The cells of the lateral geniculate body with which the visual fibers synapse are disposed in six well defined laminae which have been numbered 1 to 6 from the surface inwards by Le Gros Clark. One set of three (1, 4 and 6) receive crossed fibers, i.e., fibers from the nasal half of the opposite retina. The other set (2, 3 and 5) are cell stations for the uncrossed fibers, i.e., from the temporal half of the retina of the same side.

The superior colliculi The superior colliculi are the chief centers for visual reflexes, and constitute as well the highest visual centers in submammalian forms. In the latter they are very prominent structures, in fishes and birds they are as large or larger than the cerebral hemispheres.

But in higher animals, they are much reduced in size, and in man, are relatively inconspicuous structures, their visual functions having been taken over by the cerebral cortex. The superior colliculi of mammals receive afferent impulses from (a) the retina through the *optic tracts*, (b) the *occipital cortex* (visual area) and (c) the *spinal cord* via the *spinotectal tract*. Their efferent connection is with the medulla and the spinal cord through the *tectobulbar* and *tectospinal tracts*.

The reflexes centered in the superior colliculi serve to correlate eye movements with the movements of the head, or with the trunk and limbs. The chief of these visual reflexes are, (a) turning the eyes in order to keep them fixed upon a stationary object when the head is turned in the opposite direction (compensatory reflexes), (b) movement of the head with the eyes so as to keep a moving object in view, and (c) movements of the limbs, neck or trunk as in avoiding a moving object or in fending off a blow threatening the eyes. Closure of the lids to protect the sight occurs simultaneously.

The *optic radiation* (*geniculocalcarine pathway*). The visual fibers after leaving the external geniculate body pass through the posterior extremity of the internal capsule, and curving forward and outward into the temporal lobe sweep backward in relation to the outer aspect of the posterior horn of the lateral ventricle to reach the *area striata* (area 17) of the occipital cortex (pp. 1249 and 1408). The optic radiation also contains descending fibers which end in the superior colliculus and the external geniculate body.

The *visual cortex*. This comprises that part of the cortex referred to above as the *area striata*,² which forms the walls and lips of the calcarine fissure on the mesial aspect of the occipital lobe. The different retinal areas in their projections upon the cortex show definite localization. There is a point to point projection on to the striate area. The cortical cells, for example, are conceived as receiving individually impulses from single cones to form a pattern corresponding to that of retinal organization.⁴ The homonymous halves of the peripheral retinas are represented in the anterior part of the visual area, the upper

quadrants in the upper wall and lip, the lower quadrants in the lower wall and lip. In other words, the nasal half of the right retina and the temporal half of the left are projected on to the left occipital cortex—the projection of the upper quadrant in each case lying above that of the lower quadrant. Similarly, the nasal half of the left retina and the temporal half of the right are projected onto the right striate area. The macular representation occupies the posterior part of the striate area reaching backwards to the occipital pole, but it also spreads forwards to overlap the projection area of the peripheral retina (fig. 75-6). As in the case of the peripheral retina, the upper and lower parts of the macula (fovea) are projected to the upper and lower halves, respectively, of this part of the striate area. The cortical projection of the macula is possibly bilateral, i.e., represented in its entirety in both hemispheres, since the retention of macular vision in both eyes after an extensive lesion of an occipital lobe is not infrequent. Indeed sparing of macular vision has been reported after apparently complete ablation of one occipital lobe. It has been supposed by those who believe that the macula is represented bilaterally that fibers pass from the lateral geniculate body of one side through the posterior part of the corpus callosum to join the optic radiation of the opposite hemisphere. In the monkey, however, excision of one occipital lobe is followed by retrograde degeneration of *all* cells of the corresponding lateral geniculate body, which would not be the case if some of its cells sent fibers to the opposite hemisphere. In so far as man is concerned the question is unsettled.

The subject of hemianopia may be quite unaware of his defect of vision. He compensates sometimes to a considerable extent for his half blindness by turning his eyes more toward the blind side of the visual field so as to bring the image on to the sound part of the retina. Compensation is also in part psychological, that portion of the image of a familiar object which falls upon the blind half of the retina is visualized mentally. Thus the image is completed subjectively. Normally, when an object is seen with one eye that part of the image which falls upon the blind spot is filled in mentally so that no gap is apparent.

The Effects of Lesions at Different Levels of the Visual Pathway (see also p. 1405)

(1) A destructive lesion of one optic nerve will result in total blindness of the corresponding eye

² The histology of the striate area is described in ch. 67.

⁴ Though the existence of point to point projection of the retina upon the striate area has been definitely established the cortical representation is not rigidly fixed and circumscribed by anatomical paths, but is capable of considerable functional adaptation and modification under changed conditions (See Hubel and Wiesel.)

FIG 756 Diagram showing the projection of the retina on the calcarine cortex. Right hand figure is temporal half of right visual field (From Holmes, redrawn and slightly modified)

(fig 757) Increased intracranial pressure may cause atrophy of the optic nerves and a gradual concentric reduction of the visual fields of both eyes

(2) A lesion involving the chiasma will result in visual defects whose nature will depend upon the fibers destroyed (a) Pressure upon the uncrossed fibers in the outer angle of the chiasma, as by an aneurysmal dilatation of the internal carotid artery, may produce blindness in the temporal part of the retina of the same side. If

these fibers on both sides are affected, the sight in the temporal half of each retina (nasal half of the visual field) may be lost (*bi-nasal hemianopia*). According to Cushing a dilated third ventricle may, by pressing from above, force the angles of the chiasma against sclerosed internal carotid arteries and so produce a *bi-nasal hemianopia*. (b) Pituitary tumors, owing to their position, are likely to involve the nasal fibers at the point of their crossing and thus cause *bi-temporal hemianopia*. Since the nasal fibers from the lower ret-

FIG. 75.7 Diagram to show the effects upon vision and pupillary reactions resulting from interruption of retinal impulses at various levels. 1, Optic nerve, blindness of corresponding eye, direct reaction of this eye and consensual reaction of sound eye lost. Consensual reaction of blind eye and direct reaction of sound eye retained. Near reflex unaffected. 2, Chiasma, bitemporal hemianopia. Wernicke's pupillary reaction. 3, Optic tract, homonymous hemianopia (blindness in nasal half of right retina and temporal half of left). Wernicke's pupillary reaction. 4, Optic radiation, homonymous hemianopia. Light and near reflexes retained. 5, At synapses in the oculomotor nucleus. Light reflex lost, near reflex retained (Argyll Robertson pupil, see also p. 1412). The lesion is usually bilateral (as in tabes, disseminated sclerosis, etc.).

nasal quadrants lie ventral to those from the upper, the lower are likely to be involved first in pituitary tumors, *superior temporal quadrantic hemianopia* will result. Lesions (e.g., tumors) pressing from above tend first to cause defects in the lower temporal quadrants of the visual fields. Dilation of the third ventricle or a tumor of the pituitary stalk may produce such an effect.

(3) Lesions of the optic tract, of the primary visual center or of the optic radiation will result in *homonymous hemianopia*. The right halves of the two eyes (left halves of the visual fields) being effected in right-sided lesions and the left halves in left-sided lesions. An abscess or tumor of the temporal lobe may, by involving the optic tract or optic radiation, cause a homonymous hemianopia. When the optic radiation is pressed upon by a temporal lobe lesion the hemianopia is very

often incomplete, i.e., quadrantic. The ventral fibers of the radiation are likely to be implicated by a tumor in the lower part of the lobe, and a superior quadrantic hemianopia result. Injury to the dorsal fibers tends to cause a defect confined at first to the lower homonymous quarters of the visual fields.

(4) *Lesions of the occipital cortex.* A lesion involving the area striata of one hemisphere or the optic radiation before their termination therein results in an homonymous hemianopia, right or left, depending upon the side of the brain affected. Quadrantic homonymous hemianopia will result when the lesion is restricted to the upper or lower part of the striate area. Owing to the large cortical area representing the macular region, or perhaps to the fact that the macula is bilaterally represented, extensive unilateral occipital lesions

or excision of a large part of this area often leave acute (central) vision intact, the blindness then involving only the peripheral half of each retina. In man, bilateral destruction of the visual cortex causes total blindness.

The Pupil

Pupillary reflexes. Reflex changes in the size of the pupil occur under the following conditions: (a) Constriction or dilation occurs in response to changes in light intensity (*light reflex*). When light is thrown into the normal eye the pupil of that eye constricts promptly, this is the *direct pupillary reaction*. But the pupil of the opposite eye, though shaded, also narrows, thus, the *indirect or consensual pupillary reaction*, is dependent upon fibers which cross to the pupillary-constrictor center of the opposite side. (b) Constriction occurs as a part of the mechanism of accommodation to near vision (*pupillary reaction of accommodation*). With it are associated convergence of the eyes and accommodation of the lens. These three reactions are appropriately grouped under the term *near reflex or accommodation reflex*. (c) Dilation follows stimulation of the skin of the neck (*carotid reflex*). (d) Irritation of the eyelid or conjunctiva causes dilation followed by constriction of both pupils (oculo-sensory reflex). The afferent fibers of this reflex are contained in the ophthalmic division of the trigeminal nerve. (e) Closure of the eyelid, or an effort made to close the lid while it is forcibly held open causes slight pupillary constriction (lid or orbicularis reflex). (f) Pupillary dilation may occur during certain emotional states (e.g., fear), as a result of acute pain or a sudden sound. (g) Finally, stimulation of labyrinthine receptors causes changes in the diameter of the pupil (ch. 64). For example, rapid rotation of the body around its long axis causes dilation of the pupil and large rhythmical changes in its diameter (*hippus*). Even in a constant environment the pupil area is constantly fluctuating by about 10 per cent of its total area. These movements are called *physiological unrest*. These fluctuations are identical in amplitude and phase on both sides and, therefore, must originate central to the iris muscles.

THE IRIS

The iris is the most anterior part of the vascular tunic of the eye. It is a thin contractile disc perforated a little to the nasal side of its center by the pupil. The pupillary margin rests upon the anterior surface of the lens. The space between the lens and the cornea is divided by the iris into a larger

anterior and smaller posterior chamber, the two chambers communicating through the pupil. The periphery (root) of the iris is attached to the anterior surface of the ciliary body and is continuous through the pectinate ligament (p. 1399) with the posterior elastic lamina of the cornea. The following five layers from before backwards compose the structure of the iris, (a) the anterior epithelium, (b) the anterior limiting membrane, (c) the stroma, (d) the posterior membrane and (e) the posterior epithelium. The anterior epithelium consists of a single layer of flat endothelial like cells. Near the pupillary margin of the iris there are many small pits—the *crypts of Fuchs*—over which the epithelium is absent. The stroma is composed of loose connective tissue. It transmits the vessels and nerves and holds numerous branched cells which in dark eyes contain pigment granules. The iris contains two involuntary muscles—the sphincter pupillae and the dilator pupillae. The sphincter pupillae is embedded in the stroma and comprises a band of circular fibers about 1 mm broad surrounding the pupil. When these fibers contract the pupil is constricted. The dilator pupillae constitutes the fourth layer of the iris, i.e., the posterior membrane, mentioned above. It consists of a thin layer of smooth muscle fibers which converge towards the pupillary margin where they bleed with the fibers of the sphincter. At the root of the iris the dilator fibers pass into the ciliary body from which they take origin, when they contract they draw upon the pupillary margin and thus dilate the pupil. The posterior epithelium comprises two layers of deeply pigmented cubical cells, it is the continuation anteriorly of the pars ciliaris retinae (p. 1386). The arteries of the iris which are loosely coiled form two vascular circles, one near the pupillary margin—the *circulus arteriosus minor*, the other near the root of the iris—the *circulus arteriosus major*. The two circles are connected by vessels which, arising from the larger circle, converge towards the pupillary margin where they form the smaller circle.

Blue or gray eyes owe their appearance to the pigment in the posterior epithelial layer as seen through the unpigmented stroma and other layers of the iris. The pigment cells of the stroma are responsible for the color of dark eyes, the shade varying with the quantity of pigment present. In the white races nearly all newborn babies have light colored irides because pigment does not develop in the stroma until some weeks after birth. But Negro babies and others belonging to the dark races have brown eyes, the stroma pigment being well developed at birth.

The functions of the iris. The iris has three important functions, (a) it serves as an opaque screen, like the diaphragm or "stop" of a camera, to adjust the quantity of light reaching the retina.

under different intensities of illumination, (b) it prevents light from passing through the periphery of the lens and thus reduces spherical and lateral chromatic aberration. The image is thus more clearly defined by restricting the transmission of light through the central part of the lens, and (c) when the pupil constricts the depth of focus of the eye is increased (p. 1413).

The visual system operates over a very wide range of illumination (10^{12} times). Over this range the pupal area only alters by a factor of 16 times and therefore, the pupil cannot maintain the retinal illumination at a constant level. The pupil light reflex probably adjusts the aperture of the eye so as to obtain the optimum visual acuity at each light level.

Pupillo-constrictor Pathways

It is generally believed that the receptors of the light reflex are the same as those mediating visual sensations. Wagman and his associates have made the interesting observation that in dim light the curve of pupillary size at different wave-lengths agrees closely with the scotopic luminosity curve. The most effective wave-length in causing pupillary constriction of the dark adapted eye is, therefore, around 510 m μ , in the light adapted eye, it is about 560 m μ . Thus, the pupillary reaction shows a difference in sensitivity at high and low light intensities corresponding to the Purkinje shift.

The afferent fibers of the light reflex travel with the visual fibers and with the afferent fibers of the dilator response as far as the lateral geniculate bodies. Here they part company from the latter two sets of fibers. They do not enter the lateral geniculate body, but pass into the brachium of the superior colliculus. They then proceed to a group of cells in the pretectal region—the *pretectal nucleus*—where they make their first synaptic contacts. The impulses are finally conveyed by secondary neurons to the oculomotor nucleus on both sides of the brain, but mostly to that of the opposite side. The superior colliculus itself is not interposed in their path, for Ranson and Magoun did not observe pupillary constriction when this part was stimulated. The partial decussation of the afferent fibers, occurs, Ranson and Magoun believe, in the posterior commissure. An earlier crossing of some fibers occurs also in the optic chiasma. The fibers to the same side pass caudally and ventrally along the side of the central gray matter. Though under ordinary circumstances reduction in the tone of the pupillo-dilator center occurs reciprocally with activation of the pupillo-

constrictor center, the light reflex can be carried out through the latter alone. The reflex is therefore retained after section of the cervical sympathetic (which conveys the dilator fibers). Since the afferent fibers mediating the light reflex separate from the visual pathway at the level of the lateral geniculate body, lesions of the optic pathway beyond this point do not interfere with the light reflex.

The efferent fibers subserving the light reflex belong to the parasympathetic division of the autonomic nervous system. They originate in the oculomotor nucleus (probably the Edinger Westphal nucleus) and are conveyed to the iris (sphincter pupillae) via the third nerve, ciliary ganglion and short ciliary nerves (fig. 75/8). The *near reflex* is dependent upon cortical centers. Impulses pass by association fibers from the occipital to the frontal cortex (frontal eye field) and thence via the internal capsule to the nucleus of the third nerve. Constriction of the pupil which accompanies accommodation of the lens is brought about through fibers which probably pass directly to the pretectal region from the occipital cortex adjacent to the visual area. The efferent path from the oculomotor nucleus is the same as that for the light reflex. The afferent pathway is via the visual fibers, i.e., lateral geniculate body and optic radiation, not through the superior colliculus. The reflex is bilateral, i.e., it occurs in both eyes when one is covered and the other directed to a near object.

The Pupillo-dilator Pathway

The dilator muscle of the pupil receives sympathetic fibers which arise from the first and second thoracic segments of the spinal cord and sometimes from the eighth cervical or the third thoracic. They issue by the white ram and pass via the cervical sympathetic to the superior cervical ganglion. From here postganglionic fibers are conveyed along the internal carotid artery into the cranial cavity. Entering the trunk of the nasociliary branch of the first division of the fifth nerve, they are transmitted to the iris in the long ciliary nerves. Some fibers also pass without interruption through the ciliary ganglion into the short ciliary nerves. These fibers supply in addition the smooth muscle of the orbit which lies in relation to the capsule of Tenon (fascia bulbi) and in the "check ligaments" of the ocular muscles. The smooth muscle forming the deep layer of the levator palpebrae superioris also receives innervation from the sympathetic.

FIG 75 8 Diagram to illustrate pupillary reflexes. Interrupted lines indicate the dilator reflex, plain lines the constrictor reflex and visual pathway to the level of the lateral geniculate body; hatched lines show path of near reflex from lateral geniculate body to the cortex and nucleus of the third nerve

The afferent pathway of the pupillo-dilator reflex accompanies the pupillo-constrictor fibers as far as the lateral geniculate body. From here on their course has not been clearly defined, but they presumably descend through the tegmentum of the midbrain, and the reticular formation of the pons, medulla and spinal cord to reach the ciliospinal center.

A higher pupillo-dilator center is situated in the hypothalamus which, in turn, is probably connected with the cortex of the frontal lobe. It sends fibers through the midbrain which according to the researches of Beattie, pass ventrally by the posterior commissure to enter the superior colliculus.

The pupillo-dilator reflex involves reciprocal inhibition of pupillo-constrictor tone. This is the paramount factor in the dilator reflex, for after section of the sympathetic pupillary fibers, the pupil dilates in the dark or in response to a painful stimulus or emotional excitement in an almost normal fashion. Another factor in the dilation of

the pupil by sympathetic stimulation may be the constriction of the vessels of the iris.

When the sympathetic fibers are paralyzed the pupil is narrowed as a result of the unbalanced action of the constrictor fibers, and the dilation of the pupil which normally follows the application of a stimulus, such as a scratch or pinch, to the skin of the neck (ciliospinal reflex) fails to occur. The pupil, however, still reacts to light. Drooping of the upper lid (ptosis) will result from paralysis of the smooth muscle of the levator palpebrae superioris and there may be recession of the eyeball (enophthalmos) from paralysis of the unstriated muscle of the orbit.

An investigation of the pupillary reactions may give valuable information concerning the site of a lesion in the brain (see fig 75 7, p 1408). (a) A lesion destroying one optic nerve, since it interrupts the afferent pathway but leaves the efferent intact, abolishes the direct but not the indirect (consensual) reaction on the blind side. The direct

reaction on the sound side is, of course, retained but the indirect is lost. That is to say, a light thrown into the sound eye causes a response in this eye as well as in the blind eye, but a light thrown into the blind eye is without effect upon either eye. The near (accommodation) reflex is not abolished. Blindness due to destruction of both optic nerves results in the loss of the reflexes for light as well as of those for accommodation.

(b) Hemianopia due to a lesion of the chiasma, or of the optic tract, results in the loss of both the direct and indirect reactions to light thrown upon the blind half of either retina. Light falling upon the sound halves of the retinas causes the normal response. This is known as *Wernicke's hemianopic pupillary reaction*. However, owing to the difficulty of confining a beam of light to the blind half of the retina it is not an easy matter to demonstrate this reaction. (c) Loss of the light reflex (both direct and indirect reactions) with retention or even exaggeration of the accommodation-convergence reflex is known as the *Argyll Robertson pupil*. The pupil is also, as a rule, smaller than normal (myosis) and does not dilate to a painful stimulus nor fully to atropinization; the vestibular reflex is frequently absent as well. The abnormal pupillary responses occur quite apart from any defect of vision. Though usually bilateral the Argyll Robertson pupil is sometimes confined to one side. It is most commonly seen in syphilitic degeneration of the central nervous system (e.g., tabes), but occurs occasionally in other conditions as well. The site of the lesion responsible for the Argyll Robertson pupil is not known precisely. Merritt and Moore give evidence for placing it in the region of the posterior commissure where presumably, the neighboring dilator pathway is also interrupted, but the pathway for the accommodation reflex from the cortex to the oculomotor nucleus would be spared. Scala and Spiegel believe from the results of their experiments that the disease involves the synapses between the afferent and efferent neurons of the light reflex, that is, in the oculomotor nucleus itself. But the oculomotor nerve supplies both pupils and a lesion here is difficult to reconcile with the unilateral loss of the light reflex which sometimes occurs. Langworthy and Ortego conclude, after a careful study, that the lesion is peripheral—due to changes in the iris itself involving sympathetic, parasympathetic and sensory nerves as well as the muscle cells of the sphincter. This theory can account for the irregularity of the pupil, and perhaps, if the sympathetic innervation were injured in greater degree than the parasympathetic, for the myosis,

but it cannot explain the preservation of the accommodation reflex. (d) Destruction of the oculomotor nucleus or of the efferent pathway abolishes all light and accommodation reactions on the same side. The direct and indirect reactions are retained on the contralateral side. (e) Lesions involving the visual pathway after the separation of the visual and pupillary fibers, e.g. lateral geniculate body, optic radiations or occipital cortex, leave the light reflex unaffected. (f) A bilateral lesion implicating the pathway from the cortex to the center for accommodation in the oculomotor nucleus will cause a loss of the near reflex and leave the light reflexes intact. This is the converse of the Argyll Robertson pupil, and is sometimes seen in postdiphtheritic paralysis.

The Effects of Drugs upon the Pupil and Ciliary Muscle

Dilation of the pupil is spoken of as *mydriasis*; constriction as *miosis*. Drugs which cause pupillary dilation are therefore called *mydriatics*, those which cause constriction *miotics*. Paralysis of the ciliary muscles is known as *cycloplegia*; drugs which cause this effect are called *cycloplegics*. Mydriasis is caused by drugs which

(a) Paralyze the peripheral constrictor (parasympathetic) mechanism such as atropine or homatropine. Atropine is also cycloplegic; homatropine much less so.

(b) Stimulate the dilator (sympathetic) mechanism e.g. adrenaline, cocaine, hydroxyamphetamine, hydrobromide. These drugs have little effect upon accommodation.

Myosis is caused by drugs which

(a) Stimulate the peripheral constrictor mechanism e.g. pilocarpine, physostigmine, muscarine. Di-iso fluorophosphate is a powerful anticholinesterase and produces myosis in small doses. These drugs also cause spasm of the ciliary muscles.

(b) Diminish the inhibition of the constrictor center e.g. morphine. The action of this drug upon the pupil depends largely upon the intensity of the illumination. It appears therefore to exert its effect mainly by increasing the sensitivity of the light reflex.

(c) Stimulate the constrictor center e.g. picrotoxin.

CORRESPONDING RETINAL POINTS

When the gaze is directed to an object, an image is formed by each eye and impulses are conveyed to both sides of the brain, yet perfect fusion of the two images occurs in consciousness and only one image is seen. This characteristic of *binocular vision* is explained upon the theory of *corresponding retinal points*. The corresponding

points in the retinas (foveas) which when stimulated simultaneously cause a single visual sensation, lie in the nasal half of one retina and the temporal half of the other. When the eyes are converged, the retinas are turned so that the images fall upon these corresponding parts. If, as a result of unequal action of the ocular muscles, this cannot be brought about, the separate images are not fused in consciousness and an object appears double. This abnormality of vision is known as *diplopia*.

The horopter When the eyes are fixed upon a point in space, a number of other points can be located by calculation which are projected upon corresponding points of the two retinas (foveas). A line joining such points forms a circle called the *horopter* which passes through the fixation point and the nodal points of the eyes. The horopter will vary of course with the point of fixation of the eyes and does not exist unless the eyes act synergically (see fig 75 9). Points in the visual field lying outside the horopter do not fall on the corresponding points in the two retinas (peripheral retinas) and, as a consequence, actually cause a double impression. But this *physiological diplopia* as it is called does not thrust itself upon consciousness, it is suppressed or ignored and therefore does not cause confusion. Yet one can easily demonstrate for oneself that it exists. For example, when the eyes are fixated upon a near object such as a pencil tip held close to the face, a more distant object may, through a conscious effort, be observed in duplicate. For this reason it is also sometimes referred to as *introspective diplopia*.

The double image is always projected to the plane of the object upon which the eyes are fixed, and the doubling of the image is either homonymous (uncrossed) or heteronymous (crossed) depending upon whether the object which produces the double image is beyond the point of fixation or between it and the eyes. That is to say when the object (D in fig 75 10) whose images fall on noncorresponding retinal points is closer to the eyes than the object upon which the eyes are fixed, the images, I and I₁, are projected across the lines of sight the right hand image being formed by the left eye and the left hand image by the right eye. When the object is beyond the plane of fixation the projection of the images (I₁ and I) is homonymous, each being formed by the corresponding eye. The reader may demonstrate these facts for himself. When a pencil is held close to the eyes so as to form a double image while the eyes are focussed upon a more dis-

FIG 76 9 The horopter (Müller). *F* is the fixation point. The images of *A* and *B* fall upon the retinae at corresponding points as *aa'* and *bb'*. The projection of all such corresponding points lies upon the circumference of the dotted circle. It is obvious that there is a different horopter for each position of *F*. (After Duke Elder, *Text Book of Ophthalmology*.)

FIG 75 10 Illustrating the projection of retinal images that fall upon noncorresponding retinal points i.e. on different sides of the foveae—physiological diplopia. *I* heteronymous diplopia (crossed) homonymous (uncrossed) diplopia. *D* positions of object in relation to the fixation point. The images *I* and *I*₁ are projected to the plane of the object *F* upon which the eyes are fixed. LE, left eye, RE, right eye.

tant object closing the right eye causes the left hand image to disappear, whereas if the eyes are focussed upon the pencil and the object giving rise to the double image is more distant, closure of the right eye abolishes the right hand image. Closure of the left eye, of course, produces converse effects.

Depth Perception Stereoscopic Vision (Gr Stereos, Solid, Skopco, I View)

Our visual judgment of solidity, that is our recognition that the object has depth as well as height and width is due largely to the fact that vision is normally binocular and corresponding points in the two retinas receive slightly dissimilar images of any given object. If the reader will look at some object in front of him, first closing one eye and then the other, he will find that the view

FIG 75 11 Examples of aspect disparity *A* is a view seen from above of lines of sight when the eyes look at a solid object. Notice that the right eye sees some of the right hand side of the object, while the left eye sees some of the left hand side.

B is a front view of a cube seen by the left eye with the right eye closed. *C* is a front view seen by the right eye with the left eye closed. When both eyes are open, we see a fusion of *B* and *C* (After Graham)

FIG 75 12 Diagram of a tent and pine trees to show the impression of depth caused by the fusion of two dissimilar images. If the figures be gazed at steadily at a distance of about 5 inches from the eyes and a card held edgewise from the tip of the nose to the line of letters each horizontal pair of figures can, with a little practice be made to fuse. In *A* the aspect of the two scenes is practically the same and the fused picture appears quite flat. In *B*, the tent in the right hand figure is placed more toward the midline and upon fusion appears to be in front of the pines. In *C*, the disparity of the right hand figure is farther from the midline the tent is now projected to a point behind the pines.

seen by the right eye is slightly different from that seen by the left (fig 75 11). The right eye is able to see more of the right side of the object, the left eye more of the left side. The two slightly disparate images are fused in the brain, yet the composite image has hidden within it something of each separate one, upon this the stereoscopic effect to a large extent depends. The fusion of the dissimilar images by the brain, and the impression of depth and solidity produced thereby, lies in the field of psychology.

In order for two dissimilar images to be fused in consciousness, it is not necessary that they fall upon retinal points which correspond exactly, unification of the images results though there is some degree of noncorrespondence. Actually, there is a greater impression of depth when the dissimilar images do not fall on retinal points which fail to correspond perfectly, provided that the discrepancy is not so great as to prevent fusion. In figure 75 12 a scene of a tent and pine trees is represented diagrammatically. When the two scenes are fused the tent is projected closer or farther from the eyes according to its position in the two pictures in lateral relation to the pines. When in one or in both pictures it is moved toward the mid-line it appears to advance in front of the pine trees, when moved laterally it seems to recede. The three dimensional effect is enhanced by increasing the noncorrespondence, as when the tent in one or both pictures is moved, to or away from the mid line. But if moved too far the noncorrespondence is too great to permit fusion to occur, and the stereoscopic effect is lost.

The instrument known as a stereoscope produces an illusion of solidity by making use of the principle of simultaneous stimulation of the retinas by dissimilar images. A photograph taken with an ordinary camera appears flat because identical images are formed upon the retinas. A stereoscopic photograph, on the other hand, is taken by a camera provided with two lenses which are set, like the eyes, a short distance apart in the horizontal plane. Thus, an illusion of depth is produced. Two slightly dissimilar views are taken which, when looked at through the stereoscope, are projected by means of prisms, one to each eye, so as to fall on corresponding retinal points (fig 75 13). Depth perception cannot, however, be explained entirely upon the basis of dissimilar retinal images, for though the discrimination of depth (or distance) is much more acute in binocular vision it is not abolished when one eye is closed. For example, when two objects are placed one in front of the other and viewed binoc-

ularly from a distance of about 6 meters the least distance between them which can be perceived by average normal eyes is around 20 mm. When one eye is covered the least perceptible difference is increased to 120 mm. The ability to detect a small difference in distance from the eyes of two objects, and so to appreciate depth and solidity, is called *stereoscopic acuity*. It is expressed as the least difference between the angles formed by the lines of sight to two objects when one is just perceived to be farther away than the other (fig. 75 14). The difference in angles is known as *stereoscopic parallax*, and may, in a person with very high visual acuity, be as little as 2 seconds of arc.

Other factors, listed below, do not depend upon binocular vision, but play an important part in depth perception through one eye alone (monocular vision).

(1) *The apparent size of various objects in our field of vision*. We know from experience the approximate dimensions of the objects which we see, but the image which an object casts upon the fovea diminishes as its distance increases (p. 1361). For example, a church steeple at a distance casts an image upon the retina no larger, perhaps smaller, than would a pencil held a few inches from the eye. We know the relative sizes of the two objects and therefore infer that the steeple must be far away and the pencil near.

(2) *Accommodation of the eye*. Since a near object requires a greater effort of accommodation than does a more distant one for its image to be focused upon the retina, some cue may possibly be given as to the relative distance of two objects from the eyes. This factor however is of very minor importance and may be negligible.

(3) *The apparent change in color of an object with distance*. The atmosphere is not perfectly transparent or equally so for all wave lengths. Tree clad hills, which we know to be green, appear bluish in the distance, the colors of many other objects appear to fade with distance, their detail and outline being dimmed by haze. On rare occasions the atmosphere may be particularly clear and then distant hills, etc., will appear to be unnaturally near.

(4) *The blocking out of parts of a distant view by objects between it and the eyes* gives a sensation of depth for the overlapping of parts of farther ob-

jects by nearer ones gives an indication of their relative from the eyes.

(5) *Linear perspective*. Straight lines running into the distance which are actually parallel (or objects along imaginary straight lines) are convergent in the retinal image. When we look down a railway track, for example, the rails appear to converge towards some point beyond the horizon.

FIG. 75 13 Diagram to illustrate the principle of the stereoscope (Brewster's). A and B represent photographs of two scenes slightly dissimilar because they were taken from different positions. C, curved prisms, P, partition to prevent one eye seeing the picture opposite the other eye. LE, left eye; RE, right eye. When the two pictures are viewed through the instrument they are fused perfectly into one of apparently three dimensions, points in the background of which seem to be situated at V.

A similar stereoscopic effect is produced when two scenes are printed each in a different color, e.g., red and blue, and imperfectly superimposed so their outlines overlap. If they are viewed in the ordinary way, they appear as a flat jumbled picture, but if a red glass be held in front of one eye and a blue glass in front of the other, so as to sort out the separate scenes, one to each eye, a clear black and white view is seen in three dimensions. In the modern stereoscopic cinema it is usual to separate the two scenes by using polarized light beams set at right angles to each other, thus allowing color films to be shown stereoscopically.

FIG. 75 14 Stereoscopic parallax in the viewing of two objects T_1 and T_2 . It is expressed as the difference between the angles α_1 and α_2 .

This arrangement of lines in the retinal image we have come to associate with distance. It depends upon the fact that points at a constant distance apart subtend a smaller angle at the eye the farther they are removed. The artist draws objects along imaginary lines which run towards a point in the background of his picture.

(6) *Parallax*. When one moves in any direction, near objects appear to move in the opposite direction, those in the background in the same direction as ourselves. This apparent movement of near objects in relation to ones farther away is called parallax.

(7) *The distribution of light and shade over the surface of an object and the shadow which it casts upon its surroundings* is also an important factor in the judgment of distance.

Normally, the images formed by the two eyes are very nearly equal in size, varying by less than one per cent. When they differ in size to a degree which prevents perfect fusion with a consequent impairment of binocular vision the condition is spoken of as *aniseikonia*. Little interference with binocular vision results unless the inequality of the images is more than 4 or 5 per cent.

Ocular Movements

The Innervation of the Ocular Muscles

The nerves supplying the extrinsic muscles of the eye are the third (oculomotor), fourth (trochlear) and the sixth (abducent). The oculomotor nerve supplies all the extrinsic muscles of the eye bell except the superior oblique and the external rectus. It also supplies the striated portion of the

levator palpebrae superioris and conveys parasympathetic fibers to the sphincter pupillae (p 1410) and ciliary muscle. The deep smooth muscle component of the elevator of the lid is innervated by the sympathetic.

THE NUCLEUS OF THE THIRD NERVE is situated in the floor of the Sylvian (cerebral) aqueduct and subjacent to the superior colliculus. It is in close relation to the medial longitudinal fasciculus. It is composed of a group of five smaller nuclei (fig 75 15).

(a) The central nucleus (Perlia's nucleus) fuses with its fellow of the opposite side to form a single gray mass in the mid line. It is probably the center for convergence of the eyes (internal recti). (b) The caudal central nucleus lies in line with and behind the former. It also fuses with its fellow of the opposite side. Functionally it is considered a part of the central nucleus and is shown by Brouwer and others as actually continuous with the latter. (c) The dorsal lateral nucleus. It and the next two nuclei are paired. The dorsolateral nucleus probably the center for upward movements of the eyes (superior rectus and inferior oblique muscles). The striped muscle of the levator palpebrae superioris also, it is believed, receives its innervation from this nucleus. (d) The ventromedial nucleus lying medial, ventral end caudad to the preceding is thought to be concerned with downward movements (inferior rectus). (e) The Edinger Westphal nucleus lies on each side dorsal and lateral to the central nucleus. It is believed to supply fibers to the sphincter pupillae and ciliary muscles.

The axons arising from these cell groups pass for the most part into the nerve of the same side. A few fibers supplying the internal and inferior recti and inferior oblique muscles decussate with those of the opposite side.

The fibers after issuing from the oculomotor nucleus form a well defined tract (tract of the oculomotor nerve) which runs downwards and forwards through the tegmentum, traversing the red nucleus and medial portion of the substantia nigra. They emerge from the medial aspect of the cerebral peduncle.

THE NUCLEUS OF THE TROCHLEAR NERVE lies in the floor of the cerebral aqueduct adjacent to the posterior end of the ventri medial nucleus of the oculomotor nerve, and on a level with the inferior colliculus. It supplies the superior oblique, and with the ventri medial part of the oculomotor nucleus, forms a center for downward movements of the eye. The fibers arising from the trochlear nucleus differ from those of any other cranial nerve in that the great majority decussate with those of the opposite side. After leaving the nucleus the fibers curve dorsally around the central gray mass surrounding the aqueduct to reach the anterior medullary velum in which the decussation occurs. They emerge from the dorsal surface of the ante

TABLE 75 1

Muscle	Movement	Innervation	Diplopia due to Ocular Paralysis & Position of False Image in Relation to True when Right Eye Affected (Applicable to Left Eye if Right be Changed to Left and Vice Versa)	
Rectus	Superior	Elevation (IO), adduction (Inf R, Int R) intortion (SO)	Oculomotor	Above, to left of and tilted away from true image (crossed diplopia)
	Inferior	Depression (SO), adduction (Int R, SO) extortion (SO)	Oculomotor	Below, to left and tilted towards true image (crossed diplopia)
	Internal	Adduction	Oculomotor	Level with, parallel to and on the left of true image (crossed diplopia)
	External	Adduction	Abducens	Level with, parallel to and on the right of true image
Oblique	Inferior	Extortion (IR), elevation (SR), abduction (Ext R, SO)	Oculomotor	Above, to right of and tilted away from true image
	Superior	Intortion (SR), depression (Inf R), abduction (Ext R, SO)	Trochlear	Below, to right of and tilted towards true image
Levator palpi sup	Elevator of eyelid antagonizes the action of the palpebral part of the orbicularis oculi	Oculomotor		

nior medullary velum on one side of its frenulum and immediately behind the inferior colliculus

THE ABDUCENT NUCLEUS furnishes fibers to the external rectus. It lies in the pons close to the median line and subjacent to the upper part of the floor of the fourth ventricle. Its fibers pass downwards and forwards through the pons to emerge without crossing at the latter's lower border. The fibers of the facial nerve loop around the abducent nucleus (ch 65)

The nuclei of the three ocular nerves receive fibers from (a) the pyramidal tract of the opposite side, (b) the medial longitudinal fasciculus through which the three nuclei are connected with one another, with the vestibular nucleus, with the spinal cord and probably with the facial nucleus. It has been suggested that fibers from the oculomotor nucleus may enter the latter nucleus and be then conveyed in the facial to the orbicularis oculi and the corrugator supercilii, (c) tectobulbar tract which relays to the three nuclei, impulses entering the superior colliculus from the optic tract and the visual cortex

The eyes are said to be in a *position of rest* or in their *primary position* when their direction is maintained simply by the tone of the ocular muscles, that is, when the gaze is straight ahead and far away and not directed to any particular point in space. The visual axes are then parallel. When the eyes view some definite object they are turned by the contraction of the ocular muscles and converged so that the visual axes meet at the

FIG 75 16 Diagram of right eye from the front to illustrate the actions of the ocular muscles. O I, inferior oblique, OS, superior rectus, RE, external rectus, RI, internal rectus, OS, superior oblique, RI, inferior rectus (From Fuchs after Marquez)

observed object and an image of the object falls upon a corresponding point on each fovea (p 1412). The closer the object to the eye the greater the degree of convergence (p 1390). This movement of the eyes for the acute observation of an object is called *fixation*. The point where the visual axes meet is called the *fixation point* and the lines joining the latter to the fovea, i.e., the visual axes, are sometimes called the *fixation lines*. The widest limits of vision in all directions within which eyes can fixate is called the *field of fixation*. When surveyed by means of the perimeter it is found to be nearly circular with a diameter of about 100°. Its boundaries therefore lie well

within the limits of the binocular visual field (p 1402)

The eyeball is rotated in its socket (formed by the fascia bulbi) by the ocular muscles around one or other of three *primary axes* which intersect one another at right angles near the center of the globe. One axis is vertical, around it lateral movements (adduction and abduction) take place, i.e., in the horizontal plane. Another runs from before backwards and coincides with the visual axis, movements in the frontal plane (torsion or wheel movements) take place around it. The third is transverse, it is the axis of rotation for upward and downward movements, i.e., movements in the sagittal plane. Though the movements of the eyeball are essentially and for practical purposes rotary in character, a very slight translatory movement may take place as a result of movements of the lids and variations in the width of the palpebral fissure, closure and opening of the lids causing a displacement backward and outward, and forward and inward respectively. A slight displacement at right angles to the rotary movement also takes place during contractions of the ocular muscles: the eyeball therefore executing what has been described by Berlin as a screw movement. Also for this reason the center of rotation of the eyeball is not an absolutely fixed point but varies slightly. For general purposes however, it may be taken as the point of intersection of the primary axes. This point is on the visual axis about 13 mm. from the anterior surface of the cornea.

In table 75 1 the actions of the individual ocular muscles are given, but no normal movement is carried out by one of these muscles alone. Thus, when the eye is abducted, the external rectus and the two obliques act in unison to turn the eye outwards. The depressor and elevator components in the actions of the respective oblique muscles cancel one another. Similarly, adduction is effected by contraction of the internal rectus acting with the superior and inferior recti. Again, the depressor and elevating actions of the latter two muscles neutralize one another. In looking upwards the eye is elevated by the combined action of the superior rectus and the inferior oblique. In looking downwards the inferior rectus and the superior oblique act together, the subsidiary action of the inferior rectus in turning the eye inwards being offset by the opposite action of the superior oblique. This compound action of the ocular muscles makes for smooth and steady movement and rapid fixation of the eyeball. It will be seen from figure 75 16 that the obliques and the superior and inferior recti when contract-

ing individually produce a rotary or wheellike movement, outward (extortion) or inward (intortion). When acting in pairs the rotary actions being in opposite directions antagonize one another so that normally no such movement occurs.

The actions of the eye muscles follow the principle of reciprocal innervation. Thus, when the eye is turned outwards the external rectus and the two obliques contract while their antagonists (inferior, external and superior recti) are inhibited. The two eyes act in unison both turning in the same direction—*conjugate deviation*—and reciprocal innervation is extended to include muscle groups in the two eyes thus indicating their control from a single center. Thus, stimulation of the posterior part of the second frontal convolution causes conjugate deviation of the eyes to the opposite side. This involves contraction of the abductors and inhibition of the adductors of one eye and converse actions in the opposite eye (i.e. inhibition of the abductors accompanied by contraction of the adductors). Destruction of the cortical area results in the loss of the conjugate movement without paralysis of the individual muscles. The act of *convergence* in which both eyes are adducted, is due to the conjoint contraction of the internal recti. The center for this movement is probably in the central nucleus of the oculomotor nerve. A higher center for the movement is also situated in the frontal cortex.

The effects upon the eye movements of paralysis or weakness (pareisis) of the ocular muscles. (a) *Limitation of movement of the eye in the direction of the normal action of the affected muscle.* (b) *Paralytic strabismus or squint.* When an effort is made to turn the eyes in the direction of the paralyzed muscle, the affected eye remains stationary or makes a smaller movement than does the sound eye. That is, it deviates in relation to the latter in a direction opposite to that of the normal action of the paralyzed muscle. The visual axes, therefore, do not bear their normal relationship to one another. This is called the *primary deviation*. If a screen is placed in front of the sound eye while an attempt is made to fixate the affected eye upon an object situated towards the side of the paralyzed muscle, the sound eye deviates in the direction of action of the latter. This *secondary deviation* as it is termed is greater than the primary deviation of the paralyzed eye. The greater deviation of the sound eye is attributed to the unusual effort exerted in the attempt to fixate the paralyzed eye, an unnecessarily strong motor discharge being transmitted simultaneously to the muscle of the sound eye which normally acts conjointly (conjugate deviation) with the paralyzed muscle.

(c) *Diplopia, false projection of the visual field.* If, as a result of weakness or paralysis of the

muscles of one eye, or of an imbalance from whatever cause between the actions of the ocular muscles of the two eyes, the images do not fall upon corresponding retinal points, *diplopia* or *double vision* results. The image seen by the sound eye is called the *true image*, that seen by the affected eye is called the *false image*. The false image lies to one side, above or below the true image, depending upon the ocular muscle which is paralyzed. In the case of the oblique muscles and the superior and inferior recti, the false image lies above or below the true image—a little to one or other side and tilted towards or away from it (see table 75 I, p 1417). The false image is always displaced in the direction of the normal action of the paralyzed muscle. Thus, in paralysis of the right external rectus the right eye is not turned outwards when the subject attempts to look at an object towards his right side. The image of the object falls upon the temporal half of the left macula and is therefore projected into the nasal half of the visual field of that eye. But, in the affected eye the image falls upon the nasal half of the retina and is therefore projected into the temporal half of the right visual field. The image seen by the right eye (false image) therefore lies to the right of that seen by the left (true image). When the false image is on the same side of the true image as the affected eye the diplopia is said to be *simple* or *uncrossed*, if it lies on the opposite side of the true image the diplopia is said to be *crossed*.

If strabismus is congenital or of long standing, diplopia is not, as a rule, experienced. This is because though the images do not fall on anatomically symmetrical corresponding points in the two eyes, an area is developed in the peripheral retina of the squinting eye which assumes the function of a fovea. This pseudofovea or false macula, as it has been called, corresponds physio-

logically to the fovea of the sound eye. Fusion of the two images occurs and stereoscopic vision suffers little if at all. When squint of long standing is corrected surgically to bring the visual axes parallel, diplopia results since the true fovea of the corrected eye does not correspond functionally with fovea of the normal eye.

HEARING

Anatomy of the Auditory System

The ear, like the other sense organs, is a *transducer*, a device for converting energy from one form into another. The specialized function of the ear is to change the mechanical energy of the airborne vibrations that constitute sound into a form of electrochemical energy capable of stimulating the fibers of the auditory nerve. How the ear accomplishes its task has been the subject of speculation and investigation ever since the time of the early Greek philosophers. Only in the past century, thanks to the development of microcopy and to the rise of the sciences of acoustics and electronics, has it become possible to find even a partial answer to the question "How do we hear?"

ANATOMY OF THE EAR

The ear is divided into three parts: the external ear, consisting of the *pinna* and the *external meatus* or canal, ending blindly at the tympanic membrane, the *middle ear*, containing the three small auditory ossicles suspended in the air-filled tympanic cavity, and the fluid-filled *inner ear* or *labyrinth*, consisting of (1) the *cochlea*, which contains the *organ of Corti* with the endings of the cochlear division of the auditory nerve, (2) the *vestibule*, which contains the static organs the *utricle* and *sacculle* and (3) the three *semicircular canals* (fig. 76 1, A and B).

The *auricle* or *pinna* of the external ear consists of a thin, fibrocartilaginous plate, characteristically folded and ridged and covered with skin. In many animals it can readily be turned down to exclude unwanted sound. In man the small extrinsic and intrinsic muscles of the auricle are usually functionless. A depression called the *concha* forms the orifice of the *external meatus* or canal, which extends inward in a slightly curving course of about 25 mm to end at the *tympanic* or *drum membrane*. The wall of the outer third of the canal is formed by cartilage, that of the remainder by a tunnel in the temporal bone. The skin which lines the cartilaginous portion has

many *ceruminous glands* and laterally directed hairs, which discourage insects from entering the ear. The cerumen, however, can sometimes accumulate in such quantity as to block the canal and impede the passage of sound to the drum membrane.

The skin lining the osseous portion of the canal is thin, closely adherent to the periosteum, and extremely sensitive. It is continued as a delicate lamina, forming the outermost of the three layers: *cuticular*, *fibrous* and *mucous*, of which the tympanic membrane is composed.

The membrane lies obliquely across the end of the canal sloping downward, forward and medially. It is attached to a bony ring or *annulus* formed by the wall of the canal, and to the handle or *manubrium* of the malleus, which draws the center or *umbo* of the membrane inward by about 2 mm, so that its shape is that of a flat cone. The diameter along the line of the manubrium is about 9 mm, the diameter perpendicular to the manubrium is 8.5 mm. The total area of the membrane is approximately 69 sq mm.

When the normal drum membrane is illuminated and viewed through an ear speculum or otoscope, it appears pearl grey, pinkish or yellowish in color. Several landmarks can be seen. The *lateral process of the malleus* projects as a white spot near the upper anterior border of the membrane. Above it, bounded by two faint ridges, the *anterior* and *posterior malleolar folds*, which extend forward and backward, is a small triangular area in which the membrane is thin and slack. This area is called *Shrapnell's membrane* or the *pars flaccida*. The greater part of the membrane is taut and glistening, and is called the *pars tensa*. For convenience in describing the location of lesions in the membrane, it is subdivided into four quadrants by the manubrium of the malleus and its imaginary projection downward and backward, and by an imaginary line through the umbo at right angles to the manubrium. A brightly reflecting triangular area in the antero-inferior quadrant is called the *cone of light*. In the postero-superior quadrant, the *long crus of the incus* can usually be seen through the drum,

just behind and parallel to the handle of the malleus

The appearance of the membrane, its color, translucence, and degree of bulging or retraction, are of invaluable aid in diagnosing disease of the middle ear

The *middle ear* or *tympanic cavity* is a narrow air filled chamber in the mastoid portion of the temporal bone. It contains the chain of the miniature bones or *auditory ossicles*, which bear the fanciful descriptive names *malleus* (hammer), *incus* (anvil) and *stapes* (stirrup). The chain extends across the cavity from the drum membrane to the oval window of the cochlea on its inner wall.

The malleus, which more nearly resembles a club, has a handle (*manubrium*) attached to the drum membrane and a head (*capitellum*) which extends upward above the upper margin of the drum membrane into the *epitympanic recess*. It bears an articular facet for the body of the incus. The incus, shaped like a premolar tooth with spreading roots (*crura*), lies almost entirely in the epitympanum. It articulates with the head of the malleus by an articular surface on its body. The short crus is attached by a ligament in the *fossa incudis* of the epitympanum, whereas the long crus extends downward and medially parallel to the manubrium of the malleus. Its lower end is bent medially and bears a small knob of bone, the *lenticular process* which articulates with the head of the stapes.

The stapes, which actually resembles a stirrup, is the smallest of the ossicles. It consists of a head, a neck, an anterior and a posterior crus, and a footplate which fits into the oval or vestibular window of the cochlea. According to Bast and Anson, the stapes varies considerably in size and weight from one individual to another. In their series the height varied from 2.50 to 3.78 mm, with an average of 3.26 mm, the weight varied from 2.050 to 4.350 mg, with an average of 2.860 mg.

Five small ligaments connect the ossicles to the walls of the tympanic cavity. Three of them support the head and processes of the malleus and one supports the short crus of the incus. The fifth is the *annular ligament* of the stapes, which surrounds the footplate and connects its margin to the edge of the oval window. Two minute muscles also aid in controlling the movements of the ossicles. The larger, called the *tensor tympani*, issues from a canal parallel to the auditory tube. Its tendon bands laterally over a small

ridge of bone which serves as a pulley, and is inserted on the medial surface of the manubrium of the malleus. The smaller, called the *stapedius*, arises in a small, hollow, conical projection on the posterior wall of the tympanic cavity called the *pyramid*. Its tiny tendon is inserted on the posterior aspect of the neck of the stapes. When the tensor tympani, which is supplied by a branch from the mandibular division of the trigeminal nerve, contracts, it pulls the handle of the malleus inward and thus restricts the outward movement of the drum membrane. When the stapedius, supplied by a branch of the facial nerve, contracts, it pulls the neck of the stapes backward, thus tilting the anterior edge of the footplate outward and reducing its inward movement against the fluid in the cochlea. The function of the muscles and ligaments in modifying the movements of the ossicles will be considered in greater detail below.

The inner ear lies within the *periotic* or *bony labyrinth* in the petrous part of the temporal bone. It is divided into three main parts: the cochlea, the vestibule and the three semicircular canals. Suspended in the periotic labyrinth is an entirely closed system, the *otic* or *membranous labyrinth*, consisting of the *cochlear duct*, the *utricle* and *sacculle*, the three *membranous canals* and the various ducts which interconnect them (fig. 762). The otic labyrinth is filled by the *otic fluid* or *endolymph*. The spaces of the periotic labyrinth contain a delicate arachnoidlike tissue. Its interstices are filled with the *periotic fluid* or *perilymph*.

The cochlea, as its name implies, is coiled like a snail's shell. A section through its axis (fig. 763) reveals a central bony pillar, the *modiolus*, the base of which contains the internal auditory meatus with the auditory nerve. The periotic or osseous canal coils about the modiolus for approximately two and one-half turns, tapering in diameter from base to apex. A bony ledge, the *osseous spiral lamina*, projects into the canal, winding about the modiolus like the thread of a screw. It is widest in the basal coil, narrowing toward the apex.

The *basilar membrane* stretches from the tip of the osseous spiral lamina to a fibrous structure called the *spiral ligament* on the outer wall of the canal. A second partition known as *Reissner's membrane*, extends from the upper surface of the osseous lamina obliquely to the upper margin of the spiral ligament. In cross section the membranes enclose a triangular area, the

FIG 763 The cochlea and the cochlear nerve (A drawing by Max Brodel from 1940 *Year Book of the Eye, Ear, Nose and Throat*, edited by L. Bothman and S. J. Crowe, The Year Book Publishers, Inc.)

labyrinth, i.e., the scala vestibuli and scala tympani, the vestibule and the bony semicircular ducts. It is in direct communication with the cerebrospinal fluid in the arachnoid spaces surrounding the brain, by way of the perilymphatic duct. However, this may not represent its only source. Since radioactive sodium (Na^{24}) appears promptly in the perilymph after intravenous injection, it is clear that the perilymph must be an ultrafiltrate of the blood. It is thought to be resorbed into the capillaries of the spiral ligament.

The total volume of endolymph is small, and the difficulty of collecting an uncontaminated sample very great. Nevertheless it has been shown that the endolymph has an entirely different ionic composition from perilymph and cerebrospinal fluid, as demonstrated by the analyses of Smith, Lowry and Wu (table 761).

The inner ear obtains its blood supply by way of the internal auditory artery, which enters through the internal meatus with the auditory

nerve. The cells of the organ of Corti however, receive no direct blood supply, but appear to be entirely dependent upon the stria vascularis for oxygen and nutrients.

The neuroepithelium of the cochlea, known as the *spiral organ of Corti*, rests upon the lip of the osseous spiral lamina and the basilar membrane. It is made up of an orderly arrangement of the actual sensory elements, the *hair cells*, and their various *supporting cells*, and is covered by a stiff cuticle, the *lamina reticularis*, which looks, from above, like a regularly patterned mosaic. A prominent feature is the triangular *tunnel of Corti*, formed by the inner and outer *pillar cells* or *rods of Corti*. The flat, expanded bars of the inner pillar cells rest on the lip of the osseous spiral lamina, those of the outer pillars on the basilar membrane. Their narrow bodies slope towards each other, so that their broader upper ends join to support the lamina reticularis. The pillars increase progressively in height from the basal coil to the apex.

FIG 76 4 Cross section of the cochlear partition in the guinea pig (lower part of second turn) (From Davis *et al*, *J Acoust Soc Am* 1953, 25, 1180)

On the medial side of the tunnel, i.e., toward the modiolus, a single row of inner hair cells is arrayed, closely parallel to the inner pillars. They are surrounded by supporting elements, the inner border cells and phalangeal cells. On the lateral side of the tunnel are three or four parallel rows of outer hair cells. These are supported by the cells of Deiters, which actually rest on the basilar membrane and send stiff phalangeal processes upwards between the hair cells to form part of the lamina reticularis. The outer hair cells are surrounded by fluid spaces, the space of Nuel, lying between the first row and the pillar cells, and the outer tunnel, lying between the last row and the supporting cells of Hensen. Processes from these cells also contribute to the formation of the lamina reticularis. Beyond the Hensen cells is a series of cuboidal cells of Claudius. They are of simple structure, resembling the inner sulcus cells lying medial to the inner hair cells.

An eminence, the limbus spiralis, rests on the osseous spiral lamina medial to the inner sulcus. The thin membrane of Reissner is anchored at its inner margin. At its outer or vestibular lip the

TABLE 76 1

Protein	21.0	50.0	15.0

Mammalian endolymph does not show the high viscosity that has often been attributed to it by analogy with that of the shark, which sets into a jelly after withdrawal.

tectorial membrane is attached. This membrane is composed of a gelatinous substance similar to that of the cupula of the semicircular canals and the otolithic membranes of the utricle and saccule. It arches over the inner sulcus and overlies the lamina reticularis. Whether the hairs of the hair cells actually penetrate the substance of the tectorial membrane has not been determined, but it is certain that they are in contact with it.

The lateral wall of the cochlear duct is formed by the *outer sulcus cells*, the *stria vascularis* and, beyond these, the *spiral ligament*, in which the fibers of the basilar membrane are anchored. The stria, with its pigmented granular cells and its rich vascular supply, is thought to be responsible for the secretion of the cochlear endolymph.

The outer hair cells number about 12,000 according to Retzius (1884), the inner hair cells only 3,500. The outer hair cells are cylindrical in shape, with a thickened cuticular layer at the upper end, bearing 60 to 70 sensory hairs (stereocilia) about $4\ \mu$ long, arranged in a regular pattern. The density of the cuticle is similar to that of the reticular lamina. The intracellular structures of the hair cells as revealed by electron microscopy are described by Engstrom and Wersäll. Figure 76.5 shows an outer hair cell in schematic form, and its relationship to the Deiters' cell supporting it.

The inner hair cells differ significantly in form from the outer hair cells. They are more rounded,

and their hairs are fewer and somewhat coarser. The nucleus is smaller and more centrally located, and the intracellular structures differ in detail. These cytological differences are consistent with important differences in function as suggested by physiological studies.

Innervation. About the base of each hair cell (between it and the Deiters' cell) is a cluster of nerve endings. They are of two types: the smaller 0.5 to $1.0\ \mu$ in diameter, with a sparse granulation, and the larger as much as $5\ \mu$ long and 1 to $3\ \mu$ in diameter, with a dense granulation. The region of contact between a nerve ending and the hair cell membrane resembles a synapse. Characteristic membranous structures are seen in the 'synaptic region' of the hair cell where it is in contact with the large nerve endings but not with the small ones. It has been suggested that the two types of nerve endings may serve separate functions, the smaller afferent (presynaptic), the larger efferent (postsynaptic).

The nerve fibers within the fluid spaces of the organ of Corti are completely bare, with no myelin or neurilemma sheath. Those from the outer hair cells pass between the rods of Corti and cross the tunnel. On the inner side they join the fibers from the inner hair cells and enter a channel in the osseous spiral lamina. Their bipolar cells are located in the spiral ganglion of the modiolus. Central to the ganglion the fibers enter the internal meatus to form the auditory nerve trunk. The fibers from the apical region of the organ of Corti run a straight course, whereas the others are twisted about them like the strands of a rope.

The nerve supply of the organ of Corti provides for both a diffuse and a point-to-point type of innervation of the hair cells. Three main systems of fibers are recognized. *External spiral fibers* run for several millimeters in both directions along the basilar membrane. Each fiber has endings on many outer hair cells, and each hair cell receives endings from many fibers, so that there is much overlapping of innervation. *Radial fibers* supply mainly the inner hair cells, but some outer cells as well, in a more discrete fashion, with one or at most a few cells per fiber. At least half of the fine *internal spiral fibers* may be efferents. They give multiple innervation to the inner hair cells.

Major nuclear masses of the auditory pathway are located in the medulla, the midbrain and the thalamic region. The pathway terminates in the cortex of the temporal lobe. At each of these

FIG 76.6 The central ascending and descending auditory pathways. Numbers indicate orders of neurons. (From Galambos: *Ann Otol Rhin and Laryng* 1956, 65, 1053.)

levels an orderly spatial arrangement of the neurons has been found, indicating that the organ of Corti is represented or "unrolled" again and again in the brain. The pathways are both crossed and uncrossed so that each cochlea is represented in both sides of the brain (fig 76.6).

The fibers of first-order afferent neurons of the cochlear nerve enter the medulla and immediately divide, sending branches to the dorsal and ventral cochlear nuclei. Many second-order neurons pass medially from these to the superior olives of both sides, forming the trapezoid body, whereas others enter the lateral lemniscus directly, to terminate at the nuclei of the lateral lemniscus. The third-order neurons from the superior olive ascend in the lemniscus to the inferior colliculus, whereas those from the nuclei of the lemniscus proceed to the medial geniculate. From the geniculate, the auditory radiations pass in the internal capsule to the primary auditory area in the superior transverse temporal gyrus, or gyrus of Heschl (area 41 of Brodmann). In the carnivores this area is represented in the middle ectosylvian gyrus.

In addition to the direct pathway, there are numerous reflex connections with cranial motor

nuclei. A cerebellar auditory center has been found in the tuber vermis, which receives fibers from the dorsal cochlear nucleus.

Since a cat with a complete transection at the midbrain level of the classical auditory pathways on both sides can easily be aroused from sleep by sounds, a second auditory route to the cortex has been postulated in the reticular formation of the midbrain, the only structure spared by the operation.

The existence of descending pathways from the cortex to the cochlea is strongly indicated (fig 76.6). The best established of these is the olivocochlear tract of Rasmussen, sending efferent fibers from the superior olive to the contralateral cochlea by way of the bundle of Corti in the eighth nerve and the internal spiral fibers, at least as far as the inner hair cells.

The Nature of Sound

Sound may be characterized as a form of wave motion, a transmitted vibratory disturbance in the air or in some other elastic medium like water, wood, steel or bone. Although in this electronic era the sound waves used in the study of hearing usually come from a loudspeaker, an

FIG. 767 Above, sound waves in air, with regions of compression and rarefaction, produced by a tuning fork. Below, the sinusoidal variation in pressure. $\lambda = 1$ wave length.

earphone or other type of electromechanical transducer, the nature of sound can best be understood by considering one of the simplest sound producing instruments, the tuning fork. The motion of the fork, like that of all sounding bodies, is determined by three essential physical properties: *inertia*, *elasticity*, and *resistance*.

When the tuning fork is struck, the kinetic energy of the blow overcomes the *inertia* of the prong and displaces it to one side. The *elasticity*, or *stiffness*, tends to restore the prong to its original position, but the inertia keeps it moving beyond the position of rest until the elasticity brings it to a stop and causes it to swing back once more. At the end of its swing, the velocity of the fork is zero, and its energy is entirely in the potential form. As it passes through the equilibrium position, its velocity is maximal and its energy is entirely in the kinetic form. These alternating transformations continue until the energy is dissipated, partly in the form of heat due to internal and external frictional *resistance*, partly in the form of sound.

The rate at which the fork vibrates when struck is called its *natural frequency*. The greater its inertia or mass (m), the lower this frequency will be, whereas the greater the stiffness (s), the

higher the frequency. If the resistance is assumed to be negligible, this relationship may be expressed by

$$f = \frac{1}{2\pi} \sqrt{\frac{s}{m}}$$

Although the natural frequency is actually reduced somewhat by the effect of resistance, it remains constant as the amplitude of vibration decreases continuously until the fork comes to rest.

As the fork vibrates, it transfers a part of its energy to the molecules of air surrounding the prongs and forces them to vibrate also. Movement of a prong in one direction momentarily pushes the air molecules in its path together, whereas movement in the opposite direction pulls them away from each other. Although these movements of the individual air molecules are exceedingly small, the alternate compressions and rarefactions of the air are transmitted in all directions as waves of air borne sound.

Like a pendulum swinging through a small arc, the prongs of the tuning fork and the molecules of air execute a form of vibratory motion called *simple harmonic motion*. A body showing this type of motion is said to obey Hooke's law, since

FIG. 76.8 Two sinusoidal waves generated by the projection of circular motions, differing in frequency, amplitude and phase (Reprinted by permission from Stevens and Davis, *Hearing* John Wiley and Sons, Inc., 1938)

the force required to displace the body is proportional to the amount of the displacement. Simple harmonic motion is equivalent to the projection of the motion of a point which moves around a circle at a constant rate, as illustrated in figure 76.8. Here R is the projection of the point P , which moves in a counterclockwise direction around the circle. As P rotates at a constant angular velocity ω (in radians per second), R moves up and down on the vertical axis, executing the same type of motion as the prong of the tuning fork. If we plot the position of R as a function of the angular displacement of P , we have in effect spread out its motion in time. The resulting (solid) curve is called a sinusoid, since the distance OR is proportional to the sine of the angle POM , which is measured by ωt , the product of the angular velocity and the time elapsed since the point P was at M . A writing point attached to a tuning fork vibrating against a revolving smoked drum makes a similar tracing. It may be represented by the equation

$$y = A \sin \omega t$$

where y is the displacement OR , and A is the length of the radius vector OP . The crest, where the angle ωt is $\pi/2$, represents the region of compression, and the trough, where ωt is $3\pi/2$, represents the region of rarefaction of a longitudinal sound wave. At these points y is at its maximum value A , called the *amplitude* of the wave.

In one revolution of P the sinusoid completes one *cycle*. The number of cycles per second is called the *frequency*, f , its reciprocal, the duration of one cycle, is called the *period*, T . Since there are 2π radians in a circle, the relation of the angular velocity ω to the frequency f is given by the equation

$$\omega = 2\pi f$$

A body may execute two forms of harmonic motion at the same time. This motion is represented in figure 76.8 by a second sinusoid of twice the frequency but smaller amplitude. It is also represented by the rotation of point P' about the smaller circle at twice the angular velocity of P . At the instant illustrated, P' leads in phase by the angle ϕ . Adding the two curves would give a third curve showing the resultant motion of the body. The addition of other harmonic motions of various amplitudes and phases would give a resultant wave-form of greater and greater complexity.

A sound consisting of a single frequency is called a *pure tone*. A tone having 5 per cent of its energy at other frequencies than the lowest or the *fundamental frequency* is said to have "5 per cent distortion," or to be "95 per cent pure." Although the sounds used in measuring hearing often approximate pure tones, those of musical instruments are always more or less complex. They consist of a fundamental frequency or *first harmonic*, and a number of higher harmonics or *partials*, which are simple multiples of the fundamental frequency. The higher harmonics give to the tone of the instrument its characteristic quality.

In a sound wave, the individual molecules of air move to and fro in simple harmonic motion for very short distances. Their speed of movement is called the *particle velocity*. It is zero at the troughs and crests of the waves, and reaches a maximum of a fraction of a millimeter per second as the particle passes its position of rest. The *velocity of propagation* of the sound wave is much greater, varying with the density and elasticity of the medium. In air at 0°C it is 331 meters per second, increasing somewhat at higher temperatures. In water the velocity is over 1400 meters per second, and in a rigid solid

such as ivory, which has physical properties resembling those of the petrous bone, it is 3000 meters per second. The *wave length* of sound, the distance travelled by sound in one period, is equal to the velocity of sound divided by its frequency. Thus a 1000-cycle tone in air has a wave length of about 0.33 meter, whereas a 100 cycle tone has a wave length of 3.3 meters. In water the wave lengths are about four times as great.

When sound in air encounters an obstacle in its path which is small relative to the wave length the sound waves are *diffracted* around the obstacle. It is this process of *diffraction* that enables us to hear around corners. Only if the obstacle is relatively large does it cast a significant "sound shadow." A part of the energy is *reflected*, and in suitable conditions gives rise to an *echo*. The multiple reflections of sound from the walls of a room are called *reverberations*. A third portion of the energy is absorbed and transmitted by the obstacle. The amount of energy transmitted depends upon the relationship of the *specific acoustic resistances* of the medium and the obstacle. These are $R_1 = \sqrt{\rho_1 S_1}$ and $R_2 = \sqrt{\rho_2 S_2}$, where ρ_1 and ρ_2 are the densities of the medium and the obstacle, and S_1 and S_2 are their respective elasticities. If r is used to represent the ratio R_2/R_1 , then the fraction of the energy transmitted is expressed by

$$T = \frac{4r}{(r+1)^2}$$

whereas the remainder $1 - T$ represents the energy reflected. If the specific acoustic resistances are similar, then r approaches 1 and T approaches 1. Most of the energy is transmitted, and very little is reflected. If, on the other hand, the properties of the medium and the obstacle are very different, then r becomes large and T becomes small, so that the obstacle becomes a sound mirror, and the greater part of the energy is reflected.

A body at rest can be forced to vibrate if it is coupled to another vibrating body, either directly or through the medium of the air. Thus the motion of a tuning fork can be transmitted to a table top by pressing the base of the fork firmly against the table. If a body is forced to vibrate at its natural frequency, the transmitted effect is greatly enhanced, and the body is said to *resonate*. Resonance may be illustrated by singing a brief note while pressing the loud pedal of a piano, so that the dampers are lifted and the

strings are allowed to vibrate freely. Those strings with the same natural frequencies as the voice resonate in response, and the note is still heard faintly after the singing has stopped.

Since the ear functions only in response to forced vibration, it is important to examine this phenomenon further. In the example of the tuning fork we have seen that when a body is caused to vibrate by applying a momentary force, it vibrates at its own natural frequency. Because of damping the amplitude of the vibrations decreases exponentially, and they gradually die out. When a periodic force is suddenly applied to a body at rest, it gives a similar *transient* response at its natural frequency. The transient dies out more or less rapidly depending upon the degree of damping, but a *steady state* response at the frequency of the driving force remains. Since we are not troubled by the persistence of transient responses in our own ears, it is clear that the damping of the ear must be very great.

The response of a vibrating body to an external force is limited by the mechanical impedance of the body. The amplitude of motion is directly proportional to the applied force, and inversely proportional to the mechanical impedance. The mechanical impedance is a complex function made up of three terms: the *mass reactance*, the *elastic reactance*, and the *frictional resistance*, all measured in mechanical ohms. The first two terms are dependent upon the frequency, but the third is not. In mathematical symbols, the expression for mass reactance is

$$X_m = 2\pi f m$$

where $2\pi f$ is the angular frequency and m is the mass (in grams). The elastic reactance is

$$X_e = \frac{S}{2\pi f},$$

where S represents the stiffness in dynes per centimeter. The complete expression for mechanical impedance, Z , is

$$Z = \sqrt{\left(2\pi f m - \frac{S}{2\pi f}\right)^2 + R_m^2}$$

where R_m is the frictional resistance in ohms.

Mechanical impedance is directly analogous to electrical impedance in alternating current circuits, where inductance corresponds to mass, capacitance to the reciprocal of the stiffness (compliance) and the electrical to the frictional resistance. We shall see the importance of the

impedance concept when we come to consider the transmission of sound across the middle ear to the cochlea

The Dimensions of Sound

WAVEFORM AND SPECTRUM

In order to investigate hearing, we must be able to measure and specify the sound stimulus that give rise to hearing. Sound waves in air consist in minute variations in pressure above and below the existing atmospheric pressure. If we plot these variations as a function of time for the simple case of a pure tone, we obtain a sinusoidal curve representing the pressure waveform for the tone (fig. 76.9). It has two dimensions, amplitude and time. Frequency is expressed by the number of cycles per second, in this instance 1000 c.p.s. The same information can be presented by plotting amplitude against frequency to show the spectrum, which for a pure tone consists of a single component. It is represented in the figure 76.9 by a vertical line, the height of which indicates the maximum amplitude or peak pressure of the tone.

Fourier (1822) discovered that any waveform, however complex, can be analyzed into a series of simple sinusoids. An example of frequency

analysis is given in figure 76.9. On the left, two frequencies of 12 and 15 c.p.s. are shown, and the complex wave produced by combining them. On the right, the spectrum of each indicates the amplitudes and frequencies of the respective components. Figure 76.10 (L-2) also shows the waveforms of several types of auditory stimuli, with the spectrum of each. The square wave (B) has a line spectrum, consisting of a fundamental of 1000 c.p.s. and a series of odd numbered harmonics (3000, 5000, 7000 etc., c.p.s.), of decreasing amplitudes. The train of pulses (C) shows both odd and even harmonics, but the amplitudes are smaller. Furthermore, the phase is shifted by 90° because the pulses are not symmetrical about the baseline as the square waves are. The single pulse (D) consists of a uniform, continuous spectrum. The amplitude of each component is extremely small, and again the phase is shifted by 90° .

"White" noise (E) gets its name from the fact that, like white light, it consists of a random mixture of all frequencies. The spectrum is continuous, with uniform amplitude and random phase. White noise we have always with us, in the thermal agitation or Brownian movement of the air molecules, just below the threshold of hearing. The random movements of electrons in

FIG. 76.9. Waveforms and spectra for various types of auditory stimulus. (Reprinted with permission from Licklider in *Handbook of Experimental Psychology*, edited by S. S. Stevens, John Wiley and Sons, Inc., 1951.)

FIG 76-10 Frequency analysis of a complex wave consisting of two components of different amplitude (Reprinted with permission from Licklider in *Handbook of Experimental Psychology*, edited by S S Stevens, John Wiley and Sons, Inc., 1951)

conductors and vacuum tubes also produce white noise, which is audible as the characteristic background "shh" from a phonograph or radio.

The spectrum for the short tone of 3000 cps (P) shows that when the tone is turned on and off other frequencies appear above and below 3000 cps. This is always the case when a tone is changed in frequency, amplitude or phase. Only a tone of infinite duration is ideally pure.

The sounds of speech form a constantly changing pattern of complex tones, noise and transients. Although measurements of the average spectra show that frequencies below 1000 cps carry most of the energy, it is the transients of higher frequency that provide most of the perceptual clues to the listener.

THE MEASUREMENT OF SOUND INTENSITY

The amplitudes of movement of the air particles in sound waves are exceedingly small, varying from about 10^{-5} cm for sounds that are barely audible to 10^{-2} cm for sounds sufficiently intense to injure the inner ear. Although the velocity of the air particles can be determined with great accuracy by noting the force that they exert on a light disk suspended in the path of the sound waves (Lord Rayleigh, 1882), the most convenient measure of sound intensity is the alternating pressure produced by the motion of the particles. This value is readily determined by measuring the electric current generated by a suitably calibrated condenser microphone placed in the sound field (For measuring the sound pressure in a confined space such as the external canal, a narrow calibrated probe tube is attached to the microphone.) Sound pressure can be expressed as the maximum or peak pressure (P_{max}) or as the root-mean square (rms) pressure

which represents an average of all the pressures from moment to moment. For a sine wave, the rms pressure

$$P_{rms} = \frac{P_{max}}{\sqrt{2}} = 0.707 P_{max}$$

For noise or speech the peak pressures may vary from one instant to the next over a wide range. The rms values are more stable and are therefore generally used for expressing sound pressures. The pressures of ordinary sounds amount to no more than a fraction of 1 dyne/cm², in contrast to the atmospheric pressure of about 10^6 dynes/cm².

We use the term intensity loosely to mean sound pressure, particle velocity or amplitude of movement, sound energy or power. Strictly speaking it should apply only to power or energy. We must now examine some of the relationships among these various quantities. If we know the sound pressure P and the specific acoustic resistance R of the medium then the particle velocity, u , measured in centimeters per second is

$$u = \frac{P}{R}$$

This is clearly analogous to the relationship of electric current to electromotive force and resistance, as expressed by Ohm's law

$$I = \frac{E}{R}$$

For plane waves, the amplitude of particle movement, or displacement (in centimeters)

$$d = \frac{P}{2\pi f R}$$

where f is the frequency

The power J is equal to the pressure times the velocity, or

$$J = P v = \frac{P^2}{R}$$

J is measured in ergs per second per cm^2 or in microwatts per cm^2 , since 10 ergs per second = 1 microwatt. Similarly, the energy is proportional to the square of the sound pressure, just as electric energy and power are proportional to the square of the electromotive force.

THE DECIBEL NOTATION

In practice, measurements of sound intensity are not expressed as absolute magnitudes. Instead, a given intensity is compared with a standard value by expressing the ratio between the two. Because of the enormous range of intensities involved, it is convenient to express these ratios as logarithms. If one intensity is 10 times as great as another, their ratio is 10 and the logarithm (to the base 10) of the ratio is 1. The two intensities are said to differ by 1 *bel* (named for Dr. Alexander Graham Bell, inventor of the telephone). A more practical unit is one-tenth of a bel, the *decibel* (db). We may therefore express the number of decibels corresponding to a ratio between two intensities as

$$N_{(\text{db})} = 10 \log_{10} \frac{J}{J_0}$$

where J_0 is a standard or reference intensity.

Since power is proportional to the square of the sound pressure, we can also write

$$\begin{aligned} N_{(\text{db})} &= 10 \log_{10} \frac{P^2}{P_0^2} \\ &= 20 \log_{10} \frac{P}{P_0} \end{aligned}$$

Therefore, if one sound has a pressure 10 times as great as another, they are said to differ by 20 db. The ratio of the powers is 100, but the difference between them in decibels is still 20 db. The decibel notation is also used in comparing electric powers, voltages and currents.

Like all logarithmic scales, the decibel scale is particularly convenient because it is compressed. The intensity ratio between sounds that are dangerous to the organ of Corti and those that are just at the threshold of hearing is approximately one hundred million million or 10^{14} . Yet this vast range is expressed by only 140 db. Furthermore, if we multiply the power with an

amplifier or divide it with an attenuator, we add or subtract decibels. If a sound 60 db above the reference level is amplified by 20 db (corresponding to a 100-fold increase in its power), its new intensity is $60 + 20 = 80$ db. We must always remember, however, that the decibel scale has no absolute zero point. When we write 0 db, we are simply expressing a power or pressure ratio of 1. Therefore the reference level must always be given if decibel readings are used to represent absolute values. Some investigators use a "zero level" of 1 dyne/cm². The standard reference level adopted by the Acoustical Society of America is 10^{-16} watt per cm². This corresponds to a 0 db pressure level of 0.000204 dyne/cm². Sound level meters are usually calibrated to measure sound pressure levels in decibels above 0.0002 dyne/cm². This value approximates the least intensity that can be heard by the average person. A decibel scale showing the approximate

DECIBELS

HEARING: MECHANICAL AND NEUROPHYSIOLOGICAL CONSIDERATIONS

Sensitivity and Dynamic Range of the Ear

The range of frequencies to which the normal human ear is sensitive is usually said to extend from about 20 to 20,000 c p s, covering approximately ten octaves. The upper and lower limits are not sharply defined, but depend to some extent upon the intensity of sound available. For the common laboratory mammals, the upper limit seems to be at least an octave higher. Bats, however, emit and hear frequencies as high as 150,000 c p s when flying in the dark, catching insects and avoiding obstacles in accordance with the patterns of echoes they receive. Porpoises use very high frequencies in a similar type of echolocation or "sonar" system to find their prey in the water.

The threshold of audibility for young adult human subjects with "normal" hearing, as determined at the Bell Telephone Laboratories by Svirian and White, is shown in the lowest curve of figure 77.1. This curve represents the minimum audible field pressures which the subjects could hear when placed in a sound field produced by a loudspeaker in an otherwise quiet, nonreverberant environment. The pressure measurements were made by replacing the subject with a condenser microphone in the exact position occupied by the subject's head.

The region of greatest sensitivity lies between 2000 and 3000 c p s. This is also the region of the broad resonance peak of the external canal. Here the threshold is 6 to 8 decibels (db) below 0.0002 dyne/cm², i.e., 0.0001 dyne/cm² or less.

Above 5000 c p s the threshold curve rises at first slowly, then abruptly, below 2000 c p s the rise is more gradual. At 15,000 c p s and at 100 c p s the threshold intensity is approximately 40 db higher than at 3000 c p s.

The values shown in this curve represent very sensitive ears having almost ideal hearing. According to an extensive survey by the U. S. Public Health Service, only 1 per cent of the population can hear sounds at or below the levels

represented by the second curve, whereas half the population can hear the sounds represented by the fifth curve.

As the intensity of a sound is increased above the threshold value, the loudness or magnitude of the sensation increases. At about 120 db (or 0.0002 dyne/cm²) the sound is not only heard but begins to be felt as a vague sensation of discomfort in the ear. This "threshold of feeling" is indicated as the uppermost curve in figure 77.1. Still higher levels cause a tickling or pricking sensation, and may produce definite pain if they exceed 140 db. These are the levels which readily cause temporary impairment of hearing. The area enclosed by the threshold and the "feeling" curves is sometimes called the *auditory area*. Any sound lying within this area produces an auditory sensation in a normal listener. How the ear encompasses this enormous dynamic range is one of the major questions of auditory research.

Transmission of Sound to the Cochlea

THE EXTERNAL EAR. In many animals the shape and mobility of the external ear give it a directional and sound-gathering function which is of great assistance in localizing the source of a sound. In man the acoustical properties of the external ear are more or less unimportant, although the shape of the concha does serve to funnel sounds of relatively short wavelength (11 cm or less, i.e., 3000 c p s and higher) into the canal. Because the canal is a closed tube, it resonates at a wave length corresponding to four times its own length. Wiener and Ross made probe-tube measurements and found a broad resonance peak in the external canal, centering about 3800 c p s, which has a wave length of 9.2 cm, or four times the average length of the canal. The chief physiological importance of the canal seems to be protective. Not only do its length and shape help to shield the drum membrane from damage by blows or penetrating objects, but it also helps to maintain a favorable

environmental temperature and humidity for the membrane

THE MECHANICAL IMPEDANCE OF THE EAR Part of the sound energy reaching the drum is reflected back, whereas the rest is absorbed by the drum, setting it in motion How much energy is reflected and how much is absorbed are functions of the mechanical impedance of the ear If the drum behaved like a rigid plug offering an infinite impedance, all of the energy would be reflected If, on the other hand, its impedance were precisely matched to that of the air in the external canal, all of the energy would be absorbed and none would be reflected Impedance measurements by

Tröger (1930) and other investigators have shown that the characteristics of the ear vary with frequency At the low frequencies the impedance is determined chiefly by the stiffness, and at the higher frequencies chiefly by the mass At intermediate frequencies the frictional resistance alone is the determining factor With the data of Tröger and others, the impedance of the ear can be expressed as transmission loss in decibels The curve for transmission loss as a function of frequency shows that the impedance is greatest at the low frequencies (100 to 200 cps) and gradually declines to a broad minimum between 1000 and 2000 cps The data do not extend be-

3000 c p s, but presumably the impedance increases again at higher frequencies, as the broken portion of the curve suggests

THE TYMPANIC MEMBRANE Békésy has made direct measurements of the amplitude of movements of the drum membrane as small as 10^{-6} mm. For this purpose he used a small capacitative probe, with its fixed plate 2 to 3 mm in diameter and placed 0.5 mm from the drum membrane, which itself formed the other plate. A high frequency voltage of 100,000 c p s was then applied across this condenser. When the drum vibrated, its movements varied the capacity and thus modulated the high frequency current. By measuring the modulated current he was able to calculate the displacement of the drum membrane.

Using this probe to measure the amplitude of motion of different portions of the drum membrane in response to a constant stimulus, Békésy found that, at all frequencies up to 2400 c p s, the whole central conical portion of the drum and the handle of the malleus move as a unit about an axis of rotation passing through the anterior and lateral processes. Figure 77.3 shows the contours of equal amplitude of movement for a tone of 2000 c p s. The amplitude is greatest near the inferior

FIG 77.3A Vibration patterns of the human drum membrane for a 2000 c p s tone (Békésy, 1941, reproduced by permission from Békésy and Rosenblith in *Handbook of Experimental Psychology*, Ed by S. S. Stevens, John Wiley and Sons, Inc., New York, 1951)

FIG 77.3B Vibration of the drum membrane as a rigid cone at low frequencies (Békésy, 1941, reproduced by permission from Békésy and Rosenblith in *Handbook of Experimental Psychology*, Ed by S. S. Stevens, John Wiley and Sons, Inc., New York, 1951)

FIG 77.4 The distribution of the mass of the ossicles about their axis of rotation (Békésy, 1941, reproduced by permission from Békésy and Rosenblith in *Handbook of Experimental Psychology*, Ed by S. S. Stevens, John Wiley and Sons, Inc., New York, 1951)

edge of the membrane. Above 2400 c p s the membrane no longer vibrates as a stiff cone but in segments, with the manubrium lagging behind the adjacent portions of the membrane.

THE TRANSFORMER ACTION OF THE MIDDLE EAR Sound waves do not pass readily from one medium to another of different acoustical resistance, but are largely reflected at the boundary between the two media. Between air with an acoustical re-

sistance of only 41.5 mechanical ohms per sq cm and sea water with a resistance of 161,000, the impedance mismatch is obviously very great. Only 0.1 per cent of the energy of sound would be transmitted, representing a loss of 30 db. A similar loss would occur in the transmission of sound from the air in the external canal to the fluids in the cochlea, if the middle ear mechanism did not act as a transformer to match the widely different impedances. This change from a slight pressure exerted over the large area of the drum to a greater pressure exerted over the smaller area of the stapes footplate is accomplished by the acoustical lever system formed by the drum and ossicles. The total area of the drum membrane is about 63 sq mm and its effective area is about 43 sq mm, whereas the area of the footplate is only 3.2 sq mm. This 13-fold reduction in area gives a corresponding increase in pressure at the oval window. Since an additional mechanical advantage of approximately 1.3 is available because the handle of the malleus is longer than the long process of the incus, the pressure exerted by the footplate is approximately 17 times as great as that at the drum membrane.

An additional virtue of the middle ear mechanism is that it provides for selective delivery of sound energy to one cochlear window rather than to both. If both windows were equally exposed to sound, little transfer of energy would occur because it would be opposed by the inertia and

incompressibility of the cochlear fluids contained in the unyielding bony capsule. As it is, the fluids offer much less resistance because the round window is free to move outward as the stapes footplate moves inward, and *vice versa* (fig. 77.5).

MECHANICS OF THE OSSICLES The mass of the malleus and incus is evenly distributed above and below their axis of rotation, as shown in figure 77.4. Since they are suspended by elastic ligaments and closely bound together they move in and out as a unit. In response to moderate pressures the stapes follows them, so that the whole chain vibrates as a single mass. The footplate of the stapes rocks about its lower, posterior pole, moving like a bell crank lever rather than a piston (fig. 77.5). When the intensity of a low frequency tone rises above a critical value, this mode of vibration suddenly changes and the footplate now rotates about its long axis. The amplitude of motion is decreased and less pressure is transmitted to the cochlea, thus reducing the risk of damage to the organ of Corti.

The intra aural muscles provide another means of partial protection against intense sounds of low frequency. When the tensor tympani contracts, it pulls the handle of the malleus and the drum membrane inward. When the stapedius contracts, it pulls the footplate outward from the oval window. The effect of simultaneous contractions is to restrict the motion of the ossicular chain. Wiggers has shown in animal experiments

FIG. 77.5 Schematic diagram of movements of the tympanic membrane, the ossicles and the basilar membrane. (Reproduced by permission from H. Davis in *Hearing and Deafness*, Holt, Rinehart and Wilson, Inc. 1960.)

that the transmission of low frequencies to the cochlea is sharply reduced, whereas that for frequencies around 1300 c p s is slightly increased, as if the stiffness of the middle ear mechanism had been increased by the contractions. Higher frequencies are unaffected. The muscles respond reflexly to sound, much as the eyelid and the sphincter of the iris respond reflexly to light. Just as in the eye, the reflex is consensual, so that a sound stimulus applied to one ear elicits muscle contractions in both ears. The protection offered against intense sounds is only partial at best. According to B. Versall, the reflex latency in the decorticate rabbit is 10 msec for the stapedius and 17 msec for the tensor tympani. Maximum tension is attained by the two muscles only after 63 and 132 msec and in this time the ear can suffer severe injury from the initial waves of the noise of an explosion. The suggestion has been made that the intra-aural muscles may 'tune' the ear by facilitating the transmission of the higher frequencies at the expense of the lower, but this possibility has received little support from experimental studies.

The Cochlea

FREQUENCY ANALYSIS Many attempts have been made to explain the role of the cochlea in the process of hearing and particularly in the perception of pitch. Some investigators have held that the cochlea performs a frequency analysis of sound, whereas others have reserved that function to the brain. In formulating the *resonance theory* (1863), Helmholtz postulated a series of resonators in the cochlea, each tuned to a different frequency. He first suggested that the rods of Corti with their varying heights might serve as the resonators. Later he proposed the fibers of the basilar membrane, which he compared to the strings of a harp or pianoforte, postulating that the shorter fibers near the oval window respond to higher frequencies and the longer fibers near the apex to lower frequencies. In opposition to the resonance theory Rutherford (1880) put forward his *telephone theory* ascribing to the cochlea the role of a telephone transmitter. He thought of it as transforming sounds into nerve impulses of the same frequency which were then analyzed in the central nervous system.

The resonance theory continued to encounter the difficulty that no individual resonators could be identified. Gradually it evolved into the more widely accepted *place theory* which holds that the entire cochlea is a tuned structure with different portions of the basilar membrane and organ of

Corti responding to sounds of different frequency. The corresponding nerve fibers then report to the brain which portions of the organ of Corti are being stimulated. The telephone theory on the other hand made it necessary to assume that the auditory nerve fibers have the unique property of responding at much higher rates than the theoretical maximum of 1000 impulses per second attributed to other nerve fibers of large diameter. At the same time it left entirely unexplored the question of how the brain might perform a frequency analysis. The implications and shortcomings of these two major theories and of variants put forward by other students of hearing have been reviewed by Wever (1949). He has shown that the two theories so long thought to be irreconcilably opposed to each other, can be combined in his *resonance volley theory* which uses the telephone or volley principle to explain the response of the whole cochlea to low frequencies and the place or resonance principle to explain the cochlear analysis of higher frequencies. Both principles now have a solid basis of experimental fact derived from two types of investigation: (a) the study of the mechanics of the cochlear partition and (b) the study of the electrical potentials of the organ of Corti.

MECHANICS OF THE COCHLEAR PARTITION Békésy has shown, by painstaking evaluation of the physical properties of the various membranes and tissues that make up the cochlear partition and by direct microscopic observation of their patterns of movement under stroboscopic illumination that the place principle is correct. The cochlea is a tuned structure which performs a frequency analysis of sound. Part of the tuning is provided by the increasing width of the basilar membrane from 0.04 mm at the stapes to 0.5 mm at the helicotrema, and part by the gradual increase in the mass of the organ of Corti in the same direction. The most important factor is the graded stiffness of the basilar membrane which is greatest at the stapes and decreases steadily towards the apex. As a result the stiffness, or 'volume elasticity,' of the cochlear partition as a whole is about 100 times as great at the stapes as it is at the apex.

The basilar membrane may be thought of as a gelatinous sheet covered by a thin, homogeneous layer of fibers, forming a continuous structure with the organ of Corti. Surprisingly enough, the membrane is not under tension, and therefore does not in any way resemble the strings of a piano as Helmholtz thought. Coupling between adjacent portions is both elastic and frictional,

FIG 776 Amplitude of displacement of the cochlear partition at various frequencies (Békésy, *J Acoust Soc Am*, 21, 245, 1949)

FIG 777 The dashed curve represents the amplitude of displacement of a point 30 mm from the stapes at different frequencies. The solid curve shows the phase lag behind the motion of the stapes. At frequencies over 150 cps, the phase angle is greater than π , indicating that motion is due to travelling waves and not to a simple resonance (Békésy, *J Acoust Soc Am*, 21, 245, 1949)

and much of the frictional coupling is furnished by the endolymph and perilymph. As a result of the gradation in stiffness, the resonant frequency of the cochlear partition is highest at the stapes and decreases along its length, but because of the coupling the various portions cannot respond independently as separate tuned resonators.

Observing the movements of the cochlear partition under the microscope, von Békésy found that each part shows a maximum displacement for

a certain frequency of sound. This maximum displacement moves towards the stapes as the frequency is raised (fig 77 6), and towards the apex as the frequency is lowered. The amplitude of vibration at a given point plotted as a function of frequency resembles a resonance curve, but there is a vital difference. For a simple resonator like a pendulum, the phase angle changes from $\pi/2$ to $-\pi/2$ as the driving frequency is changed, and at the point of resonance the phase angle is zero. When the phase relations of the cochlear partition are measured, it is seen that the basilar membrane, the organ of Corti, the tectorial and Reissner's membranes all move together in phase. However, the phase lag between the movement of the stapes and that of a point on the basilar membrane near the helicotrema increases from 0 to 3π as the frequency is increased (figs 77 7 and 77 8). Békésy has pointed out that this phase shift indicates the presence of travelling waves rather than a simple resonance.

The travelling waves are generated because the stiffest portion of the cochlear partition near the stapes in a sense drives the more flexible portions. Near the stapes the partition vibrates in response to all frequencies. As the waves move along the partition their amplitude gradually increases and reaches a maximum at the point where the natural frequency of the partition is the same as the driving frequency. Beyond this point the amplitude decreases rapidly as the velocity of travel diminishes and the wavelength grows shorter and shorter in the more flexible portions of the membrane. So great is the retardation that a single wave set up by a sudden, brief sound requires about 5 msec to travel from the stapes to the helicotrema.

The travelling waves are demonstrable in the human cochlea only at frequencies above 150 cps. At lower frequencies the basilar membrane moves more and more as a unit, so that below 50 cps the entire cochlear partition is moving in phase and the maximum amplitude occurs very close to the helicotrema.

On the basis of his measurements of the physical characteristics of the cochlear partition, von Békésy constructed models of the cochlea in which the travelling waves could readily be demonstrated. One of the most instructive of these models consisted of a plastic tube cast around a brass tube with a slit. When the tube was filled with fluid and the fluid set in motion by a vibrating piston at one end, travelling waves were set up with broad maxima that shifted with frequency over a two-octave range. When the

Fig 77.8 The travelling wave pattern on the basilar membrane showing the primary and secondary waves and the shortening of the wave length as the travelling wave pattern nears the apex (Reproduced by permission from H Davis in *Hearing and Deafness*, Holt, Rinehart and Wilson, Inc, 1960)

Fig 77.9 Left, organ of Corti and tectorial membrane at rest Right bending of hairs by shearing action between reticular lamina and tectorial membrane Based on von Békésy's description (From Davis in *Physiological Triggers* American Physiological Society, Inc, 1966)

forearm was placed lengthwise along the vibrating membrane it provided a sensory surface representing the organ of Corti. As the frequency of vibration was changed the maximum could be felt to move along the arm. Although the maximum was quite broad and flat, the sensation of vibration was much more concentrated, so that any frequency shift could readily be recognized by a shift in the place of stimulation. Even with very brief tones lasting for only two cycles, the "pitch" discrimination was excellent. Some inhibitory process in the cutaneous innervation on either side of the maximum was presumably responsible for "sharpening" the pattern of stimulation. A similar mechanism is thought to act in the organ of Corti to aid in the discrimination of pitch.

The Organ of Corti

THE FINE MOVEMENTS Although the gross pattern of movement of the cochlear partition permits the cochlea to perform a frequency analysis,

it does not account for the actual transfer of energy to the hair cells. This stimulation occurs as the result of a double transformation, first of the up-and-down movement of the basilar membrane into a rocking motion of the rods of Corti and reticular lamina, and then into a shearing motion between the lamina and the tectorial membrane. The shearing motion causes a bending of the hairs, which are embedded at one end in the cuticular plates of the hair cells, firmly held by the reticular lamina, and extend at the other end into the tectorial membrane. Von Békésy has studied these fine movements under the microscope by stroboscopic illumination. He has observed that the direction of bending of the hairs varies from one side of the position of maximal amplitude of vibration to the other. On the side toward the stapes the hairs are bent radially, i.e., toward the Hensen cells. Further toward the apex, the hair cells move up and down only, whereas still further along, where the wave length of the

FIG. 77.10 The distribution of the DC endocochlear (positive) potential and the intracellular (negative) potentials. The heavy line represents the boundary of the endolymphatic space. The fluid in the tunnel of Corti may be perilymph or Engstrom's "cortilymph" (From Tasaki *et al.* J Acoust Soc Am 1954, 26, 765)

travelling wave is shorter, the direction of bending is longitudinal. Although the bending of the hairs is the essential mechanical step in stimulating the hair cells, the significance of the different directions of bending is not yet understood.

THE ELECTRICAL RESPONSES Attempting to observe the patterns of impulses in the auditory nerve in response to sound, Wever and Bray (1930) made the surprising discovery that the electrical potentials picked up from the nerve reproduced almost perfectly the frequencies and wave-forms of the sounds reaching the ear. Although this finding seemed at first to support Rutherford's telephone theory, it was soon demonstrated by Davis and Saul that two distinct types of potentials were involved: the cochlear microphonic potential (CM) and the action potentials of the auditory nerve fibers (AP). Although the AP response showed the typical threshold and refractory period, and differed in no way from the action potentials of other nerves, the CM response which preceded it in time had no all-or none properties, but closely reproduced

the wave form and polarity of the stimulus. More recent studies by von Békésy and by Davis and his collaborators have shown that five different types of electrical potentials can be recorded from the cochlea by means of fine electrodes inserted into the scalae. Two of these are DC resting potentials. The others are responses to sound stimuli.

Intracellular potentials Like other cells, the cells of the organ of Corti and the auditory nerve fibers have a negative intracellular potential. As recorded with a microelectrode, these potentials range from -20 to -80 mv referred to the perilymph.

Endocochlear potential The endolymph in the cochlear duct shows a remarkable positive potential of 80 mv referred to the perilymph in the vestibular and tympanic scalae. This high potential is a unique property of the cochlea, since the potential of the endolymph in the utricle is only $+5$ mv. It depends, not upon the ionic composition of the endolymph, but upon the metabolic activity of the stria vascularis. During asphyxia it decreases, and returns to its normal

Fig 77-11 Intensity functions of the cochlear microphonic (CM), action potential (AP) and negative summing potential (SP-), in response to brief tones of 7000 cps, as recorded by intra-cochlear electrodes from the basal turn in the guinea pig. The voltage of CM is proportional to the sound pressure level up to 80 db SPL, then grows more slowly to a maximum of almost 1 mv at about 105 db SPL. AP grows rapidly from threshold then more slowly. The growth of SP- approximately parallels that of CM (Unpublished, reproduced by special permission of Dr. Halliwell Davis).

level only when oxygen is readmitted. Injection of azide or cyanide into the scala media abolishes the potential completely. The positive potential can be modified by movements of the basilar membrane. It is increased when the membrane is pushed "downward" towards scala tympani, by inward movement of the stapes, or by injecting fluid into the cochlear duct. Conversely, it is decreased by outward movement of the stapes, causing an "upward" movement of the basilar membrane. Movement of the tectorial membrane with respect to the organ of Corti causes similar changes in the endocochlear potential, suggesting a close relationship between the endocochlear and the cochlear microphonic potentials.

Cochlear microphonic potential. Unlike the DC intracellular and endocochlear potentials, the microphonic potential is an immediate response to acoustic stimulation. For many years it has been known to be associated with the hair cells, and at one time it was thought to be produced by compression and elongation of these cells in

much the same way as the piezo-electric potentials are produced in the crystal of a microphone. Recent studies have shown that the essential movement is the bending of the hairs as a result of vibration of the tectorial membrane. The response has no true threshold or refractory period, but closely reproduces the wave form of the stimulus. Its amplitude is linearly proportional to the displacement of the cochlear partition, and therefore to the sound pressure of the stimulus from moment to moment. As the stimulus intensity is increased, the amplitude of the response grows proportionately (Fig 77-11). At higher levels the response becomes nonlinear, goes through a maximum, and eventually declines. Using intra-cochlear electrodes to record from individual turns of the guinea pig cochlea, Davis and his collaborators have shown that the basal turn responds to all frequencies, whereas the third turn responds only to frequencies below 3000 cps. This is further evidence of the broad tuning of the basilar membrane (Fig 77-12).

FIG 77 12 Cochlear microphonic responses re producing the sinusoidal wave form of the stimulus as recorded with intracochlear electrodes in scala vestibuli and scala tympani of the basal and third turns in the guinea pig. The basal turn re sponds to all frequencies but the third turn only to frequencies below about 3000 c p s (From Davis, *Laryngoscope*, 68, 359, 1958.)

FIG 77 13 Above the stimulus a brief tone of 21 500 c p s. Below the response, including coch lear microphonic summating and action potentials recorded from the round window in the guinea pig. CM is at the frequency of the stimulus. SP is the downward displacement of the baseline and the action potentials are the peaks and valleys on the descending limb of SP (From Festalozza and Davis, *Am J Physiol*, 185, 595, 1956.)

The microphonic potential is dependent upon an adequate oxygen supply. During anoxia it falls to a very low level which may persist for some time after death. The precise relationship of the microphonic to the endocochlear potential is

not known, in spite of some evidence suggesting that the microphonic may be simply a modulation of the latter by movements of the cochlear partition. In any case it furnishes an excellent means for the experimental study of events in the middle ear, the transmission of sound energy in the cochlea and the effects of toxic agents on the organ of Corti.

Summating potentials. Two DC potential re sponses to acoustic stimulation can be recorded, the positive and negative summating potentials. As seen in figure 77 13, these potentials reproduce the envelope of a brief burst of tonal stimulation and are proportional to the root-mean-square value of the stimulus. They apparently represent a rectifier or detector action resulting from longi tudinal movement of the tectorial membrane accompanied by a persistent bending of the hairs in the same direction. The summating potentials appear at levels where the microphonic potential is becoming nonlinear. The positive summating potential, which is more sensitive to oxygen lack, is thought by Davis to originate in the outer au ricles, whereas the more resistant negative po tential which actually increases in amplitude after mild injury to the organ of Corti, is at tributed to the inner hair cells.

Action potentials. Although the action po tentials can easily be recognized among the mix ture of potentials recorded from the round window membrane, special electrode placements or can cellation procedures are required to record them uncontaminated by the microphonic potentials. They show the typical all-or none behavior of axon spike potentials of myelinated nerve fibers having a definite threshold and a refractory period. The response to a click at a moderate intensity level consists of three successive volleys of "spike" potentials, called N_1 , N_2 and N_3 , representing synchronous repetitive firing in many fibers. These action potentials are readily "masked" by noise, which stimulates the fibers in random fashion, so that the click finds many of them refractory and therefore unable to re spond synchronously.

Synchronous volleys of action potentials occur in response to the sound waves of a steady tone of low or middle frequency. Above 1000 c p s fibers may be responding in alternation or in rotation since the refractory period of about 1 msec prevents a given fiber from responding to each successive sound wave. At higher frequen cies, synchronization of the action potentials

decreases, to disappear completely above 4000 cps

The action potential lags behind the microphonic potential by 0.55 to 1.0 msec. This latency suggests a "synaptic delay" between the hair cells and the nerve endings, but it may also be ascribed to the conduction time of the nonmedullated fibers within the organ of Corti. Other properties of the action potentials also support the hypothesis that a synaptic type of transmission occurs at this point. Their sensitivity to oxygen lack greatly exceeds that of the microphonic response. Furthermore, they can be fatigued, and their recovery after masking is not as prompt as it should be if masking reflected only the refractory state of the nerve fibers. Whether a neurohumoral step occurs between the hair cell and the nerve fiber has not been ascertained. Davis's view is that the cochlear microphonic and negative summing potential excite the nonmedullated dendritic terminals directly.

The responses of single auditory nerve fibers have been studied by Tasaki by means of extremely fine pipette electrodes. Some fibers gave single and others repetitive responses, some had low, others high thresholds. Most of them responded to a wide range of frequencies below a sharp cut-off frequency, above which the fiber would not respond no matter how much the intensity was increased. As the frequency was increased, fibers would stop firing abruptly, and the higher the frequency, the smaller became the number of active fibers. These findings are in full accord with Békésy's description of the behavior of the travelling waves and their sharp decline just above the point of maximum amplitude of vibration of the partition.

The action potentials can be inhibited by stimulation of the olivocochlear tract of Rasmussen in the medulla, but the microphonic potentials are unaffected. The functional significance of this efferent inhibitory action is unknown, but it furnishes an example of the control of the responses of a sense organ by the central nervous system and presumably represents a sort of feedback mechanism.

The Central Auditory Pathway

RESPONSES OF MEDULLARY NEURONS The responses of the second order neurons of the cochlear nucleus as recorded with microelectrodes closely resemble those of the auditory nerve fibers. Galambos and Davis have observed that each unit responds to a limited range of frequencies,

which is narrow at threshold but gradually broadens as the intensity of the stimulating tones is increased. As in the nerve, the high frequency cut-off is sharp (fig. 77-14). Many of the units show a "spontaneous" rhythmical discharge, which may be inhibited when a tone is sounded. Furthermore, when a unit is responding to a tone, presentation of a second tone may inhibit the discharge. The effect of this inhibition is to sharpen the cut-off at the low frequency end. A tonal stimulus therefore increases the activity in some units and decreases or abolishes activity in others. Galambos suggests that each tonal frequency produces a characteristic pattern of "islands" of active and inactive neurons. In this way the broad tuning of the basilar membrane may be made more precise by a place principle operating at the medullary level superimposed upon the repeated point-to-point projection of the organ of Corti which has been found in anatomical studies.

RESPONSES OF HIGHER AUDITORY CENTERS The neurons of the inferior colliculus and medial geniculate body follow in general the patterns of activity seen in the cochlear nucleus. Discharge is increased by certain tones and suppressed by others, and the response areas of individual units are sharply defined. The point-to-point "tonotopic" projection of the cochlea is less firmly established at these levels, but the physiological evidence tends to support it.

The responses of the cortical auditory area have been most extensively studied in the cat. In this species and in the dog the area is located on the temporo-parietal surface of the hemisphere. It is bounded on three sides by the suprasylvian sulcus and extends ventrally almost to the rhinal fissure. On the basis of anatomical and electrophysiological data, as well as behavioral studies before and after cortical ablations, the six subdivisions shown in figure 77-15 have been delimited. AI receives the major projection of the medial geniculate body (*pars principalis*), and it is from this area that "onset responses" to clicks and pure tones are most easily recorded in anesthetized animals. According to Tunturi's experiments in the dog, using strychnine to sensitize 1 mm² areas of the cortex, subdivision AI shows a tonotopic organization. Individual tones activate narrow bands of cortex 8 mm long with the lower frequencies represented more caudally and the higher frequencies more rostrally. A weak suprathreshold tone presented to the contra-

FIG 77 14 Response areas of four neurons in the cochlear nucleus of the cat. Each neuron has a specific frequency at which a minimal acoustic energy is required to excite it. Each responds also to lower frequencies at higher intensity, but shows a sharp cut off for higher frequencies, in accordance with the pattern of vibration of the basilar membrane described by Békésy (From Galambos and Davis, *J Neurophysiol*, 6, 1943, 1933)

FIG 77 15 The cortical auditory areas of the cat as described by various authors. AI and AII, first and second auditory areas, EP, posterior ectosylvian area, SII, second somatic area, IN, insular region, TE, temporal area (Reproduced by permission from H. W. Aides in *Handbook of Physiology*, Section I. Neurophysiology, Vol. 1, American Physiological Society, Inc., 1959)

lateral ear activates the entire band. The same tone presented to the ipsilateral ear activates only the dorsal portion of the band, but as the in-

tensity is increased more and more of the band is activated. Thus it would appear that pitch alone is represented in the contralateral cortex, but pitch and loudness are both represented in the ipsilateral cortex. A roughly similar tonotopic organization in the cat was revealed by the studies of Woolsey and Walzl, who stimulated nerve fibers at various points in the osseous spiral lamina of the cochlea and recorded the responses from the cortex. On the other hand, single unit studies with microelectrodes have revealed that relatively few cortical units respond selectively to tones, whereas more respond to noise and clicks only. Galambos has recently reported single units which appear to be sensitive to auditory stimuli only when a cat "pays attention" to the sound source.

The auditory cortex is not necessary, in the cat at least, for learning responses to tones or for discrimination between tones. It is required, however, for the recognition of simple auditory patterns, such as the difference between two different sequences of three tones each, the first *high-low-high*, and the second *low-high-low*. This

type of discrimination depends upon the integrity of the insular (IN) and temporal (TL) areas (Diamond and Neff)

AUDITORY LOCALIZATION IN THE CORTEX Both ears are represented about equally in the right and left auditory pathways, thanks to the trapezoid fiber crossing in the medulla, and to other intercommunications in the midbrain and corpus callosum. A sound applied to either ear alone evokes equal electrical responses in both cortices. On the other hand, when a sound is presented to both ears simultaneously, the responses of the two sides are equal only if the sound is in the median plane. As the source is moved to one side of the head, the response of the contralateral cortex becomes greater, and that of the ipsilateral cortex less (Rosenzweig). In spite of this important cortical correlate, auditory localization persists after bilateral destruction of the auditory areas.

Summarizing our still unsatisfactory knowledge of the auditory functions of the central nervous system, we may say that the rather broad frequency analysis performed by the cochlea is sharpened in the cochlear nucleus, where information concerning place of stimulation along the basilar membrane and frequency of stimulation is processed. Although a more or less point-to-point projection of the cochlea at various levels seems to be the rule, the frequency sensitive units become proportionately fewer and more sharply tuned, whereas more and more units appear which have other functions.

Loudness has long been assumed to be correlated with the rate of discharge in individual fibers of the auditory nerve and with the total number of fibers discharging. At the same time, according to the volley principle, the rate of discharge signals the frequency for low tones. To resolve this apparent conflict, the suggestion has been made that loudness is not a simple function of the total number of impulses per second, and that the inner hair cells, with their higher thresholds, may make a significantly greater contribution to loudness than the more sensitive outer hair cells. How loudness is mediated in the central nervous system is still quite unknown. One of the few hints that we have comes from the studies of Bremer on the *encéphale isolé* in the unanesthetized cat. In this preparation a sustained activation of area AI occurs in response to tones. Raising the intensity of stimulation causes an increase

in the frequency of the rhythmical cortical discharge.

Thus far no auditory function has been found to have an exclusively cortical representation in animals except the discrimination of tonal patterns. This fact does not in any way call into question the importance of the auditory cortical areas. It does suggest that the experimental questions which we have been asking of the cortex may have been too simple.

THE MEASUREMENT OF AUDITORY SENSATION: DEAFNESS

Audiometry

Pure tones In the previous chapter the measurement of the absolute threshold of hearing was discussed, i.e., the smallest amount of acoustical energy that the ear can detect when pure tones of various frequencies are presented in quiet surroundings. An adaptation of this type of measurement is most commonly used in the clinic. The basic instrument, the *audiometer*, is an electroacoustic device consisting of an oscillator, an amplifier, an attenuator for controlling intensity, and an earphone. Its frequency range usually extends from 125 to 8000 c.p.s., in discrete steps of an octave or less, whereas its intensity range covers approximately 100 decibels (db) in steps of 5 db. It must be remembered that the "zero-db" level of the audiometer is not the same as the standard reference level of 0.0002 dyne/cm². Instead, it varies from frequency to frequency, representing the average normal threshold for each frequency, as determined in extensive hearing surveys conducted by the U. S. Public Health Service. The present American audiometer standard corresponds closely to the 50 per cent contour in figure 76. It is 10 db higher than the British and the proposed International Standard, which correspond closely to the thresholds of normal young adults as measured in ideal conditions in the laboratory.

A subject who is just able to detect all of the frequencies at 0 db is said to have normal hearing. If he can hear certain frequencies only when their intensity is increased by 30 db, he is said to have a hearing loss of 30 db at those frequencies. A graph showing the audiometric threshold plotted as a function of frequency is called an audiogram. The shape of the audiogram of a patient who is hard of hearing gives the otologist important evidence about the nature of the hearing impairment (figure 78.1).

OTHER FORMS OF AUDIOMETRY Von Békésy has invented an audiometer which enables the patient to control the stimulus and at the same time to

have his audiogram recorded automatically. So long as the patient hears the tone, he presses a button which causes it to diminish in intensity. When the tone disappears below his threshold, he releases the button and it grows again in intensity until he hears it and presses the button once more. At the same time the frequency gradually increases. The recording pen therefore moves up and down on the intensity scale, writing the patient's reports of the disappearance and reappearance of the tone, and at the same time moves from left to right on the frequency scale. In this way a complete audiogram can be recorded in a few minutes. The size of the excursions of the pen also gives an indication of the rate of increase in loudness. As shown below, an abnormally rapid increase in loudness called *recruitment* is characteristic of certain forms of sensory neural deafness.

GSR and EEG audiometry Two other forms of audiometry are available for use with very young children or with patients who cannot understand or carry out the instructions for routine hearing tests. In one type of test the patient is conditioned to expect a mild electric shock whenever he hears a tone. The shock evokes the galvanic skin response (GSR), a sudden transient change in the electrical resistance of the skin and the tone, as the conditioned stimulus, comes to have the same effect. By recording the skin response and noting whether a change occurs when tones are sounded at various levels, the operator can determine the patient's threshold of hearing. In the EEG test, a change in the electroencephalographic pattern in response to sound, the so-called electroencephalic response (EER), which occurs in light sleep, is used as an indication that a given tone has been heard. Both of these tests require considerable skill in the interpretation of the records.

Speech audiometry The frequencies of greatest importance for the understanding of speech are those in the middle of the audiometer range. If the hearing for 500, 1000 and 2000 c.p.s. is sig-

Broken line shows improvement of hearing after fenestration. (By permission from *The Inner Ear* by H. G. Kobrak. Copyright 1959. The University of Chicago Press.)

FIG 782 Von Békésy audiogram showing hearing impairment for high frequencies (nerve deafness) caused by dihydrostreptomycin. (By permission from L. J. Ranta. *Acta Oto laryng. Suppl.* 136. Stockholm 1958.)

nificantly impaired, the hearing for speech is also affected. The average hearing loss for these three frequencies usually gives a reasonably close estimate of the hearing loss for speech.

The hearing loss for speech can be measured directly using phonographic recordings of especially selected test words. These may be familiar

words of two syllables equally stressed (spondees), such as *baseball* and *railroad*. Groups of six words are presented at successively lower intensity levels in steps of 4 db until the patient can no longer hear them. The intensity at which he can repeat half of the words correctly is taken as his threshold for speech, and the difference between this value and the average threshold for normal listeners represents his *hearing loss for speech*.

Additional information can be obtained by the use of the phonetically balanced (PB) lists of monosyllabic words. In these lists of 50 words each the various speech sounds occur with approximately the same frequency as in normal conversational English. Each list is presented at a uniform intensity and the percentage of words the patient is able to repeat correctly is his *articulation score*. His average articulation score for

quiet (55 db), normal (70 db) and loud (85 db) conversational speech is a useful measure of his ability to hear in everyday situations. Davis has given it the name *Social Adequacy Index (SAI)*. For a person with normal hearing the SAI lies between 94 and 100. A score of 33 represents the lower limit for "socially adequate" hearing.

Patients with hearing impairment due to purely conductive lesions (see below) can usually attain an articulation score of 100 per cent if the speech is made sufficiently intense. Other patients with lesions in the end organ or nerve may not achieve a score of better than 60 per cent no matter at what intensity the speech is presented. The difference between this maximum articulation score and 100 per cent is called the *discrimination loss* (DL). From it and the hearing loss for speech the SAI can be estimated.

Bone conduction audiometry Sound can be transmitted to the cochlea in two ways: by *air conduction*, through the external canal and across the middle ear, and by *bone conduction* as a result of vibrations of the skull. Bone conduction furnishes a means of testing the integrity of the cochlear mechanism in patients with damage to the middle ear. Bárány and von Békésy have shown that there are in fact two forms of bone conduction. When a vibrator is placed on the forehead, the skull can move as a rigid body, especially in response to frequencies below 800 c/s. The ossicles, however, are suspended in the middle ear cavity. They do not move with the skull because of their inertia. The cochlea and oval window therefore move with respect to the stapes, but the result is the same as if the footplate of the stapes itself were vibrating. Stimulation of the cochlea by this means is called *inertia bone conduction*. The second form, *compression bone conduction*, occurs at higher frequencies, where the skull no longer moves as a rigid body but vibrates in sections. The vibrations are transmitted directly to the cochlea. As its bony walls vibrate and set the fluids in motion the round window membrane moves more freely than the stapes in the oval window, and thus the basilar membrane is made to vibrate and stimulate the hair cells.

A calibrated bone conduction vibrator is usually furnished with the audiometer. The vibrator is applied to the mastoid process or to the forehead. Since the vibrations are transmitted to both inner ears, it is necessary to apply a masking noise to the ear not being tested in order to avoid confusion. The diagnostic use of bone conduction audiometry and the classical tuning fork tests are discussed later in this chapter.

DIFFERENTIAL THRESHOLDS Discrimination, as in the understanding of speech, means the recognition of differences between sounds in terms of intensity, frequency, pattern, etc. Considerable interest has attached to the measurement of the

differential threshold, also called the *difference limen* (DL) or *just noticeable difference* (JND) for the intensity and frequency of pure tones. Weber's law (1834) states that the increment of a stimulus that is just noticeable is a constant fraction of the intensity of the stimulus itself. In other words, for intensity, the fraction $\Delta I/I$ (or ΔI in db, which expresses the ratio) must be a constant if Weber's law holds. Actually the law does hold reasonably well over a considerable part of the intensity range, although the actual size of ΔI varies with frequency. For tones near threshold ΔI is relatively large, but it declines rapidly to reach a more or less constant value above a sensation level of 50 db (Sensation level SL means *decibels above threshold*). Thus for a 1000 c/s tone at 5 db SL, ΔI is 3 db, whereas at 50 db SL, it is only 0.5 db. For white noise, ΔI is less than 0.5 db at 20 db SL, and remains almost constant at least up to 100 db SL.

For frequencies above 1000 c/s at a sensation level of 40 db or more, the relative DL ($\Delta I/I$) remains almost constant at about 0.003 as the frequency is increased. At 1000 c/s the normal listener can detect a change of 3 c/s, but at 5000 c/s he would fail to notice a change of less than 15 c/s.

MASKING In spite of the ability of the ear to analyze complex tones and separate out individual frequencies, weak sounds may be completely inaudible in the presence of sounds of greater intensity. This familiar phenomenon is called *masking*. White noise is particularly effective in masking other acoustic stimuli.

The degree of masking is measured as the number of decibels by which the intensity of the masked sound must be increased above the quiet threshold to become just audible in the presence of the masking noise. Fletcher has shown that when a tone is masked by noise, the frequencies effective in masking it are those lying in a relatively narrow band centered about the frequency of the masked tone. These frequencies make up the *critical band*. For a tone of 300 c/s, the critical band is about 50 c/s wide, for 2000 c/s it is 100 c/s wide, and for 5000 c/s, it is 500 c/s wide. Beyond these limits, further increase in the width of the band of frequencies does not increase the degree of masking.

The masking of tones by other pure tones has been extensively studied, but it is complicated by the fact that tones close together in frequency interfere with each other and cause fluctuations in loudness, or *beats*, which make the degree of

masking difficult to judge. In general, low tones are much more effective in masking high tones than vice versa. This finding is in accord with the patterns of excitation of the basilar membrane described by Békésy, who noted that low tones affect the whole length of the membrane, whereas high tones affect only a limited region near the stapes.

Masking by noise is frequently used in clinical audiometry to "block" the better ear so that it will not respond to loud sounds or to bone-conducted sound used in testing the worse ear and thus give a false result.

LOUDNESS Loudness is the psychological attribute of sound most closely associated with the physical property of intensity. Being a subjective quantity, loudness cannot be specified directly in terms of physical units, but must be expressed in terms of special psychophysical scales. One of these is the scale of *Loudness Level*, which is based upon judgments of equal loudness. If the experimenter takes a tone of 1000 c.p.s. at 40 db in intensity level and asks the subject to adjust the intensity of other frequencies until each is equal in loudness to the 1000-c.p.s. tone, he obtains an equal loudness contour. The loudness level of the 1000 c.p.s. tone is said to be 40 *phons*, and all

other frequencies on the contour have the same loudness level. We may therefore define the loudness level (in *phons*) of any tone as the intensity level (in db) of the 1000 c.p.s. tone which is equal to it in loudness. A set of equal loudness contours is shown in figure 78.3. From the spacing of the curves it is evident that the loudness level of low frequency tones grows much faster than that of medium and high frequency tones.

A loudness scale can also be based on judgments of loudnesses that are multiples and fractions of a standard loudness. Stevens has set up such a scale, using as a unit the *sone*, which is defined as the loudness of a 1000 c.p.s. tone at 40 db intensity level. A tone that sounds twice as loud has a loudness of 2 *sones*, whereas one that sounds one-half as loud has a loudness of 0.5 *sone*. Stevens has shown that the relationship between loudness in *sones* (*S*) and sound pressure (*p*) is a simple power function $S = kp^{0.6}$. When plotted in the form shown in fig. 78.4, this equation gives a straight line. The plot shows that for each increase of 10 db in sound pressure level the loudness is approximately doubled.

An abnormally rapid increase in loudness can often be demonstrated in cases of unilateral hearing impairment due to injury or degeneration of

FIG. 78.3 Equal loudness contours showing the relation between intensity level and frequency for tones at different loudness levels. All of the sounds represented by a given curve sound equally loud. The figures 0 to 110 represent loudness level in *phons*. The 0 phon contour is the normal free field threshold curve. Figures in parentheses show the loudness in *sones*. (Reprinted with permission from Stevens and Davis, *Hearing*, 1938, John Wiley and Sons, Inc., New York.)

FIG. 78.4 Loudness in sones for octave bands of noise as a function of the sound pressure level of the bands (By permission from S. S. Stevens, *J. Acoust. Soc. Am.* 28, 807-832, 1956.)

the organ of Corti. If an alternate binaural loudness balance is carried out, it is seen that even though the threshold of the abnormal ear may be much higher than that of the normal, loudness increases so rapidly in the abnormal ear that at higher intensities both ears bear the same loudness when both are stimulated at the same intensity level. This phenomenon is called *recruitment of loudness*. It is of diagnostic importance in cases of perceptive deafness (fig. 78.5).

PITCH. Although we usually think of *pitch* as a function of frequency only, Stevens has shown that pitch can change with intensity. For frequencies below 1000 c.p.s., pitch decreases as intensity is increased, whereas for tones above 3000 c.p.s. pitch increases with intensity. For tones in the middle range, slight changes may occur in either direction, depending upon the intensity level.

Stevens and Volkman have established a numerical scale of pitch by a fractionation method similar to that used for the scale of loudness. The unit of pitch is called the *mel*. A pitch of 1000 mels is assigned to a 1000-c.p.s. tone, a pitch of

500 mels to the tone which sounds one half as high in pitch, and so on. Pitch intervals 50 mels wide sound to the ear to be equal in subjective extent. It may be noted that there is close agreement between the width in cycles of the 50-mel pitch intervals and the width of the critical bands which are effective in masking pure tones.

The same frequency does not necessarily produce the same sensation of pitch in both ears. In cases where a unilateral partial loss of hearing has occurred as a result of localized damage to the organ of Corti, a tone may sound higher in pitch in the abnormal than in the normal ear. This sensation of false pitch of which the patient is usually unaware, is called *diplacusis*. A small difference in tuning can sometimes be demonstrated even in "normal" ears.

LOCALIZATION. Judgment of the direction from which a sound is coming demands the use of both ears. The important cues are differences in time of arrival (or phase) in the case of frequencies below 1200 to 1400 c.p.s., and differences in intensity in the case of higher frequencies. When two tones differing only in intensity are led sep-

arately to each ear of an observer, he will localize the source on the side of greatest intensity. If the tones differ only in phase, he tends to localize it on the side of the leading phase. A sound which arrives simultaneously at the two ears and is equally loud in both is localized in the median plane. Slight head movements producing changes in these interaural differences are also important in localizing the source. With earphones, the source is judged to be in the center of the head if the sounds they produce at the two ears are synchronous and of equal intensity. If the sound in one earphone is made slightly more intense or is advanced slightly in phase, the source seems to move toward that side of the head.

DEAFNESS Any abnormal condition or disease which interferes with the conduction of sound to the inner ear, with the setting up of nerve impulses in the cochlea, or with their transmission to the appropriate levels of the nervous system can cause an impairment of hearing. The otologist distinguishes between *conductive deafness*, caused by interference with the passage of sound waves through the external and middle ear, and *sensorineural (nerve) deafness*, caused by damage to the cochlear mechanism or to the auditory nerve. *Central deafness* involving the auditory pathways of the nervous system, is also recognized. *Conductive deafness* has many causes. One of the commonest of these is an accumulation of hard dry wax in the external canal. Fortunately, it is a condition that can easily be corrected. The tympanic membrane itself may be altered by disease resulting either in 'hardening of the eardrum' with fibrous and calcareous deposits, or in a perforation. The effect of a perforation upon hearing depends upon its position and size, but it usually involves the low frequencies. Stiffening or interruption of the ossicular chain by destruction of an ossicle can occur in chronic otitis media. The hearing loss may amount to 30 db or more, when the drum membrane, malleus and incus are absent, it may be as great as 65 db.

Otosclerosis (or *otospongiosis*) is a localized disease of the bony capsule of the labyrinth and a common cause of conductive deafness. It involves destruction of bone in the neighborhood of the windows and replacement by new bone, which may be deposited around the stapes footplate in such a way as to interfere with its motion and ultimately to fix it in the oval window. The increasing stiffness causes a progressive loss of hearing for the low frequencies, usually beginning between puberty and the early thirties. Later the

FIG 78.5 Binaural loudness matching. Curve A represents two normal ears in which the same hearing level in the right ear as in the left produces equal loudness. Curve B represents a right ear with a neural impairment showing recruitment matched against a normal left ear. The right ear requires a 40 db greater hearing level at threshold but the loudness increases more rapidly with intensity than in the normal ear so that a tone at 80 db sounds equally loud to both ears. Curve C shows a right ear with a 40 db conductive impairment. The loudness increases at the same rate as in the normal left ear. (By permission from *The Measurement of Hearing* by I. J. Harsh, Copyright 1932, McGraw Hill Book Company, Inc., New York.)

high frequencies may be affected by pathological changes in the cochlea itself.

In recent years, two surgical procedures have been perfected for the restoration of hearing in otosclerosis. One is *Lempert's fenestration* operation, in which a new window is made between the middle ear and the lateral semicircular canal. In this way the immobile ossicular chain is bypassed, and sound is once more permitted to reach the inner ear via the round window and the new "oval window." The second procedure is that of *stapes mobilization*, developed by Rosen. In this operation the ankylosed margins of the footplate are cut through with fine picks or chisels. The operation is performed under local anesthesia, and the restoration of hearing is sometimes dramatically sudden. A serious problem in the development of both operations has been the tendency of deafness to recur with closure of the fenestra or re-ankylosis of the footplate. An example of otosclerotic deafness and the improvement in hearing after fenestration is shown in figure 78.1.

Tympanoplasty, the surgical reconstruction of the sound conducting system, is another example

of middle ear surgery. It may be recommended in cases where the middle ear mechanism has been damaged by chronic otitis media. The operation must necessarily take various forms, depending upon the degree of injury found. In some cases a single ossicle between the drum and the oval window, resembling the avian *columella*, is substituted for the defective ossicular chain.

In all types of conductive deafness, the amplification provided by an electronic hearing aid may be of great assistance to the patient. The ear phone is usually inserted in the external canal, but in some cases a bone conduction oscillator placed on the mastoid process may be preferable.

A temporary conductive deafness can occur when the drum membrane is strongly retracted (and its stiffness therefore increased) by a negative pressure in the middle ear. This condition is commonly experienced in aircraft during descents from altitude. When the external pressure exceeds that in the middle ear, the Eustachian tube, the only means by which the two pressures can be equalized, remains tightly closed, and the weak dilator muscle at its pharyngeal orifice, the *tensor veli palatini*, is unable to open it. The drum membrane does not rupture unless the pressure difference amounts to 100 to 500 mm Hg. Usually the retraction persists for only a short time until the pressure difference is relieved by repeated swallowing, or by making a forced expiration with the nose and mouth closed (Valsalva's maneuver).

When the tube remains closed for any length of time, air trapped in the middle ear is gradually absorbed. If the partial pressure of oxygen in the cavity is reduced below the level of the hydrostatic pressure in the capillary bed, fluid leaves the capillaries and enters the middle ear, which may fill in minutes. Such an accumulation of fluid increases the friction of the system, and thus decreases the transmission of sound.

Sensori neural (nerve) deafness. Deafness due to interference with the process of excitation in the cochlea or with the transmission of impulses by the auditory nerve may be caused in many ways. In its mildest, reversible form it appears as a temporary threshold shift after exposure to sound or noise of more than ordinary intensity. If the exposure is very intense or occurs day after day, as in a noisy industrial situation with sustained levels in the neighborhood of 100 db, it can result in the permanent impairment called *acoustic trauma*. Hearing for the upper frequencies is more affected than for the lower, and a "dip" in the audiogram at 4000 cps is a common finding.

The reason for the special vulnerability of this region of the basilar membrane is unknown.

In the temporary nerve deafness after exposure to a pure tone, the maximum loss is found about half an octave above the frequency of the exposure tone, but never below it. This result fits well with the known shape of the travelling wave. A loss of 40 to 60 db at one or more frequencies is usually accompanied by a ringing or sizzling *tinnitus* or subjective noise, presumably representing a sustained spontaneous discharge of injured hair cells. Recruitment of loudness is present so that in spite of the elevation of threshold for certain frequencies, the loudness of sounds at higher intensity may be normal. Diplacusis with an upward shift of pitch in the region of the hearing loss can usually be demonstrated (Davis *et al*). In animals exposed to intense tones degenerative changes are found in the hair cells of the organ of Corti. The outer hair cells are more susceptible to such injury than the inner, and the region of damage is usually localized in the basal half of the cochlea (Lurie *et al*).

Nerve deafness can occur at any age. In childhood it can result from meningitis, or occasionally from certain virus infections such as mumps. A form of nerve deafness accompanied by violent attacks of vertigo is *Ménière's syndrome* which occurs most frequently in middle aged persons. Hearing for the low frequencies is affected and a roaring *tinnitus* is often present. The attacks are attributed to an increased hydrostatic pressure of the endolymph (hydrops), causing a bulging of the walls of the cochlear duct which has been demonstrated *post mortem*. The function of the auditory nerve may also be impaired by the pressure of a tumor in the cerebello-pontine angle. Finally, a gradual perceptible loss for the high frequencies occurs with advancing age and is called *presbycusis*.

A new hazard to hearing is found in the antibiotics of the streptomycin group, especially *dihydrostreptomycin*, *kanamycin* and *neomycin*, all of which can cause profound deafness by their ototoxic action. The hearing loss starts with the highest frequencies and may progress even after antibiotic therapy is discontinued. In experimental animals, the antibiotics have been shown to cause degeneration of the hair cells and disappearance of the organ of Corti. The electrical responses are diminished, especially the cochlear microphonic potential.

Bone conduction audiometry plays an important part in the diagnosis of nerve deafness. Be

cause cochlear function is affected, the bone conduction audiogram shows the same pattern of loss as that for air conduction. In conductive deafness on the other hand, hearing by bone conduction may be perfectly normal, in contrast to the loss shown in the air conduction audiogram. The comparison can also be made in the classical *Rinne* test using the tuning fork. The vibrating fork is first placed on the mastoid process. When the patient reports that he can no longer hear its tone by bone conduction, it is removed from the bone and the vibrating prongs are held up to the open ear canal. The normal ear should then hear the fork by air conduction and continue to hear it for about 45 seconds. This "positive" *Rinne* test is also characteristic of partial nerve deafness. If the fork is heard longer by bone conduction, the test is negative, and a conductive deafness is present.

In the *Schwabach* test, the patient's bone conduction hearing is tested against the presumably normal hearing of the examiner. If there is a conductive lesion, the patient will be able to hear the fork longer than the examiner, because the presence of the lesion excludes masking noise. If a neural lesion is present, the patient will hear the fork for a shorter time than the examiner. The bone conduction test made with an audiometer is essentially similar to the *Schwabach* test.

The *occlusion* or *Bing* test consists in placing the fork on the vertex of the skull and determining the effect of gently occluding the canal on the thresholds for low frequencies. If the ear is normal or nerve deaf, sensation at low frequencies is increased because the bone conducted sound sets up vibrations in the air enclosed in the canal which are transmitted to the cochlea and reinforce the vibrations reaching it directly. If a conductive lesion is present, occlusion of the canal has no effect on the sensation.

The *Weber* test is valuable in the diagnosis of otosclerosis and highly reliable in spite of the difficult theoretical problem it has always raised. It consists simply in placing the vibrating fork on the patient's head and asking him to report in which ear he hears it. If one ear has a nerve lesion, the sound will be heard in the opposite, i.e., the *better* ear. If, however, one ear has a fixed stapes, the sound will be heard in the same, i.e., in the *worse* ear. Many hypotheses have been put forward attempting to explain this paradoxical result, but none has yet been generally accepted. One of the most attractive is that of *Langenbeck*, who has pointed out that only compression bone conduction can be effective in stimulating the cochlea of an ear with a fixed stapes and has shown how the localization of the sound may depend upon a difference in phase between the com-

FIG 78-6 The four classical bone conduction tests with tuning forks. Arrows indicate that the sound is heard for a longer period of time when the fork is moved from one position to the other. THE SENSES OF TASTE AND SMELL; COMMON CHEMICAL SENSE

Taste, Gustation

Taste is a chemical sense, that is to say, the receptors (chemoreceptors) for this sense respond adequately to chemical stimuli. In order, therefore, for a substance to arouse a sensation of taste it must be dissolved—either taken in solution or dissolved in the saliva, a solid taken into a perfectly dry mouth is tasteless. For this reason the organs of taste or *taste buds* are present only upon a moist surface, being confined to the mouth region of all air breathing vertebrates, but may be anywhere upon the body surface of aquatic forms.

THE ORGANS OF TASTE The taste buds of man are mainly situated on the tongue but a few are also found in the mucous membrane covering the palate, fauces, epiglottis and the larynx in the region of the arytenoid cartilages. Taste buds are more widely distributed in children and are especially plentiful over the anterior part of the tongue. In the adult they are much fewer at the tip of the tongue and are almost absent from the middle third. In most fishes the skin of the general body surface is plentifully supplied with taste receptors, and in the catfish and certain other species of fish they are contained in the filiform processes known as barbels projecting from the snout and angles of the mouth. In insects (flies, bees) taste receptors are located at the end of the proboscis antennae or upon the tarsal segments of the legs.

The mucosa of the human tongue is studded with large numbers of small elevations—the *lingual papillae*—caused by projections of the lamina propria and called *secondary papillae*. The papillae are of three main types, filiform, fungiform and vallate. The *filiform papillae* are very minute conical structures covering the anterior two thirds or so of the dorsal surface of the tongue. They are arranged in rows running roughly parallel with the rows of vallate papillae. The *fungiform papillae* are considerably larger than the preceding type, round in shape and situated mainly at the tip and edges of the tongue. The *vallate papillae* are much larger and become especially

prominent posteriorly where from 6 to 12 are arranged conspicuously in the form of a V with its limbs open anteriorly. A vallate papilla consists of a central round elevation with perpendicular sides and surrounded by a culcus, the taste buds are situated in the mucosa forming the walls of this circular trench. The filiform papillae rarely contain taste buds but each fungiform papilla usually holds from 8 to 10 embedded in the epithelium covering its free surface.

A section of a taste bud is shown in figure 79 1. It measures about 70 μ long and 50 μ broad and lies with its long axis perpendicular to the epithelial surface. It consists of groups of *supporting cells* (*peripheral supporting cells*) shaped somewhat like the sections of a musk melon and arranged side by side to enclose a small oval chamber which opens superficially through a circular gap—the *inner taste pore*—surrounded by the converging ends of the supporting cells. The inner taste pore usually leads into a short canal which opens in turn through the *outer taste pore* upon the surface of the tongue. The cavity of the taste bud is occupied by other supporting cells (*central supporting cells*) in the intervals between which the taste receptors (taste cells) are lodged. The taste cell is spindle-shaped and provided with a fine hairlike process which projects through the inner taste pore into the short canal mentioned above. The taste bud contains a variable number of these sensory cells usually from 5 to 18. Nerve fibers after losing their medullary sheaths penetrate the bud and arborize upon the surface of the taste cells.

The total number of taste buds varies widely between different species from an estimated 800 in the bat to 35 000 in the ox, there are about 9,000 in man.

The chief nerves of taste are the *chorda tympani* branch of the facial nerve and the *glossopharyngeal nerve* (see fig. 79 2). The former nerve supplies the taste buds over the anterior two thirds of the tongue, the latter is distributed to the posterior third. The *vagus nerve* innervates the taste buds present on the pharyngeal aspect of the tongue, on the soft palate, epiglottis and the region of the arytenoid cartilages. The *trigeminal nerve* mediates

FIG 791 Vertical section through a taste bud

FIG 792 Diagram of the course of the gustatory fibers (Modified from Brodal, after Ronboham)

common chemical sense (p 1469) and sensations of touch, temperature and pressure (common sensibility) from the entire buccal mucosa, it does not contain taste fibers. Cushing observed, for example, that removal of the Gasserian (trigeminal) ganglion did not cause any permanent loss of taste. Section of the nerves of taste in animals is followed by degeneration and gradual disappearance of the taste buds. Olmsted has shown in experiments upon the catfish that taste buds reappear upon regeneration of the nerve fibers. The latter evidently exert a formative influence, possibly through the medium of a chemical substance, upon the development of the taste organs.

The central connections of the nerves of taste are described in chapters 64 and 66 (see fig 79 2)

THE SENSATIONS OF TASTE

There are four simple, primary or fundamental tastes—sweet, sour (acid), salty and bitter. Two others are sometimes added, namely, alkaline and metallic.¹ The various other tastes which we ex-

¹ Opinions differ as to the nature of these two sensations, most investigators contending that the former is a compound sensation, resulting from the excitation of several types of end organs, including those for sweetness and for touch. Similarly, the metallic taste caused by the salts of heavy metals, copper, silver, mercury, etc., is believed to be a complex of sour and sweet. Some maintain indeed that it is due chiefly to the stim-

perence are (a) blends of two or more of the primary sensations or (b) combinations of the latter with sensations aroused by the stimulation of the nerves of common sensibility. For example, ginger is recognized not only by its taste (i.e., through impulses from the taste buds), but also by the burning sensation caused by the excitation of the ordinary sensory nerves of the mouth and also, we may add, by its odor. Many other substances, such as fats and oils and pungent condiments, are "felt" as well as tasted.

Many of the finer flavors are in reality sensations of smell, and olfaction enters very largely into many of the sensations which we generally class as tastes. For this reason when the nose is held or the nasal passages blocked, as during a common cold, the sense of taste is blunted. It may then be impossible if two bland foods are of the same consistency to distinguish between them, thus an apple and a pear, or a turnip and a potato, taste pretty much alike. On the other hand, certain substances which we think that we detect by smell are actually tasted. The sweetish smell of chloroform is an example, the vapor reaches the taste buds in the inspired air.

The four primary gustatory sensations are not aroused with equal intensity over all parts of the tongue. Apparently there is a functionally distinct type of receptor for each primary taste, and the distribution of each type is not uniform over the lingual mucosa. End organs sensitive to sweet and salty materials are most plentiful at the tip, those responsive to acid are distributed mainly along the margins, whereas those aroused by bitter substances are towards the base of the tongue and in the region of the epiglottis. These facts are recognized generally in practice, for one would not more think of sipping beer than he would of gulping a glass of wine, and a child prefers to lick rather than munch a stick of candy. The taste receptors adapt rather rapidly, for this reason food which we enjoy is moved over the surfaces of the tongue and mouth and brought into contact continually with fresh receptors. Some substances stimulate two types of taste bud. For example, sodium salicylate, rhamnose and parabrom-benzoic sulfinate, a substance related to saccharine, give a sweet taste when applied to the tip of the tongue but when swallowed, and thus brought into contact with the vallate papillae, taste bitter. Ortho benzyl benzoate, on the other hand, gives a bitter followed by a sweet taste. Magnesium and sodium

ulation of olfactory receptors. Stimulation of the tongue by an electric current causes a metallic taste.

sulfates are salty bitter, causing a salty taste at the tip of the tongue and a bitter taste at the base. When the papillae are explored individually with different sapid substances it is found that the filiform type are insensitive. Of the fungiform papillae, some respond to both sweet and salty compounds, others to acid and sweet and others again to bitter and acid. A few respond to all four types of stimulus. These results indicate the existence of functionally distinct types of taste receptors and that different types are present in the same fungiform papilla. Only taste buds responsive to bitter substances are present in the vallate papillae (fig. 79.3).

The sense of taste may be aroused by substances reaching the taste buds in the blood stream. Thus the intravenous injection of histamine causes a metallic taste, glucinum a sweet taste, and in jaundice a bitter taste may be experienced as a result of the high concentrations of biliary constituents in the blood.

Theories of taste perception. The results of experiments in which action potentials were recorded from single nerve fibers when sapid substances were applied to the tongue strongly support the conception of four specific types of taste receptor. Pfaffman identified three types of nerve fiber in the cat: (a) those which responded to acid, (b) those which responded to acid and salt, and (c) those which responded to acid and quinine. Although fibers responsive to sweetness were not found by this investigator, others using an improved method have obtained responses with sucrose. No difference was observed in the character of the impulses which might serve to distinguish the type of stimulus employed. Such a finding is in accord with what we know of other sense organs, namely, that the quality of sensation is determined by the central connections of the nerve fiber, i.e. upon the part of the brain where the impulses set up in the receptor organ by an adequate stimulus, are delivered.

It is quite evident that stimulation of the different types of receptor in suitable proportions accompanied by the excitation of nongustatory nerves of the lingual and oral mucosa as well as of the olfactory receptors, could account for the wide range of taste sensations that are experienced.

The mechanism through which the taste receptor is stimulated, and an impulse set up in the nerve fiber is unknown, but a theory has been proposed based upon the inhibition of enzyme systems in the taste cells by the sapid substance. Bourne, for example, found in various mammals

FIG. 79.3 Showing distribution of primary taste sensations on one side of the tongue.

a relatively high concentration of alkaline phosphatase in the epithelium overlying the taste buds, and El Baradi and Bourne have demonstrated that a 0.05 per cent concentration of vanillin strongly inhibits the action of this enzyme. Also a simple esterase is present in the taste buds in fairly high concentration; it is inhibited by quinine but not by salt or sugar.

Discrimination of differences in intensities of stimulation is relatively crude for taste and smell. In order for a change to be produced in either of these sensations the intensity of stimulation must alter by about 30 per cent, whereas the eye can detect a change in illumination of 1 per cent and the ear a change in sound intensity of 10 per cent.

TASTE SENSATIONS AND CHEMICAL CONSTITUTION. The sweet taste is associated predominantly with organic compounds, especially the *sugars* (e.g., sucrose, maltose, glucose, etc.), certain *polysaccharides*, *glycerol* and other *alcohols*, *aldehydes* and *ketones* of the aliphatic series, and *saccharine*, *dulcine* and *chloroform*. But certain inorganic substances, such as *lead acetate* (sugar of lead) and *alkalis* in high dilution, are also sweet to the taste.

Substances which arouse an acid or a salty taste are always electrolytes, but bitter or sweet substances may be either electrolytes or nonelectrolytes.

Several attempts have been made to relate the sweet taste to chemical constitution. Oertly and Myers, for example, from a study of a large number of sweet organic compounds have proposed the theory that every sweet molecule contains two particular types of radical or an atom upon which the sweet taste depends. One of these they call a *glucophore*; the other an *auxogluc*. A glucophore makes a given compound a potential taste stuff, if it is bound to an auxogluc a sweet compound is produced. Some six glucophores and nine auxogluces have been identified, four of each are listed in the following table.

Glucophores

Auxogluces

- | | |
|--|--------------------------------|
| (1) $-\text{CO}-\text{CHOH}-(\text{H})$ | (1) H |
| (2) $\text{CO}_2\text{H CH}_2\text{NH}_2-$ | (2) CH_2CH_3 |
| (3) $\text{CH OH CHO}-$ | (3) CH_2OH |
| (4) CH O NO_2- | (4) $\text{CH}_2\text{OH CHO}$ |

Thus the hexoses contain the glucophore (1) and the auxogluce (4), glycerol the glucophore (2) and the auxogluce (3), and amino acetic acid the glucophore (2) and the auxogluce (1).

The *salty* taste is evoked primarily by inorganic compounds, notably the *chlorides of sodium, potassium, magnesium, ammonium and lithium*, by certain *sulfates, bromides and iodides* and by *sodium and potassium nitrates*. The saline taste of such compounds is attributed to the anions (Cl , Br , I , SO_4 and NO_3), a conclusion arrived at from a comparison of their tastes when in high dilution with that of an equally weak solution of sodium acetate. For example, a 0.04 molar solution of NaCl , of KCl or of LiCl has a slightly salty taste, whereas sodium acetate in equal or somewhat lower dilution is tasteless or at least is not salty. Similarly sodium bromide, iodide or nitrate loses its saline taste at a much higher dilution than does the acetate. Of the halogens the dilution at which the salty taste is just perceptible is highest for the chloride, next for the bromide and lowest for the iodide ion. The saline taste is not confined to inorganic compounds. Certain organic compounds, such as the *hydrochlorides of monomethylamine and diethylamine* also possess this property.

The *sour* taste is produced by acids or acid salts. It is generally agreed that the effective agent is the *hydrogen ion*. This statement would seem to be contradicted by the fact that solutions of certain organic acids such as acetic, tartaric, citric, etc. are more acid to the taste than a solution of a mineral acid having a considerably greater hydrogen ion concentration. For example, the acid taste of a solution of acetic acid is about equal to one of HCl in a dilution one third as great yet as compared with the latter solution, the solution of HCl , since this acid is highly dissociated, is from four to five times as great. The greater effectiveness of acetic acid for a given H ion concentration is attributed to its greater power of penetrating the tissues and therefore to its greater effectiveness in raising the hydrogen ion concentration within the taste buds. The *astringent* taste is attributed to acid in very high dilution, that is, to a greatly attenuated sensation of sourness.

The *bitter* taste, like sweetness, is associated chiefly with organic compounds especially the *alkaloids (quinine, strychnine, morphine, etc.)* and

certain *glucosides*. *Puric acid, dextromannose and bile salts* are among the other bitter organic compounds. Of inorganic substances with a bitter taste are *magnesium, ammonium, and calcium salts*. The bitterness of these salts is due to the cation. A slight change in the chemical constitution of a substance often alters its taste from bitter to sweet. Saccharine, for example, is intensely sweet, but some of its derivatives are bitter, dulcin is some 500 times sweeter than cane sugar yet *phenylthiocarbamide*, in which one oxygen atom in the dulcin molecule is replaced by a sulfur atom, is bitter to most persons. Phenylthiocarbamide is peculiar in that to 3 persons out of 10 it is tasteless. The taste deficiency ("taste blindness") in respect to this substance is hereditary, being transmitted as a Mendelian recessive. Many organic compounds having a bitter taste contain NO_2 groups. If the molecule contains two such groups the compound is usually, although not necessarily, bitter, if three are present it is invariably so.

INADEQUATE STIMULI. Of agents other than chemical which are capable of evoking a sensation of taste, by far the most effective is the electrical current. Electrical stimulation by means of the constant current using a pair of electrodes placed upon the tongue causes, upon breaking the current, a metallic taste which persists for a little time. If one electrode is placed in contact with the surface of the tongue and the other upon some indifferent part of the body a constant current during its passage causes an acid or alkaline taste, depending upon the direction of the current. If the lingual electrode is the anode an acid taste is experienced whereas if the cathode is the stimulating electrode the taste is alkaline. Two factors apparently, are concerned in the production of the acid or alkaline taste, namely, direct electrical stimulation of the taste cells and the production of H and OH ions at the anode and cathode, respectively, as a result of electrolysis of the buccal fluids. That a gustatory response can be produced by direct electrical stimulation is evident from the fact that it is more readily aroused by a rapidly alternating current which has no appreciable electrolytic action, than by a direct current. Furthermore, when two persons are connected each to a pole of a battery and the circuit completed by bringing the tips of their tongues together, they experience different taste sensations: one acid the other alkaline. Now the two sets of taste buds must be exposed to the action of the same ions, the only condition of the experiment which is different in respect to the taste organs of the two persons is the direction of the current. The

electrical taste evoked by a constant current is a rather complex sensation and cannot be described as purely acid or alkaline in quality. It frequently has a bitter metallic component which, as mentioned above, is usually the only taste caused by a single break shock. Very probably electrolytic products as well as the direct stimulating effect of the current are responsible for evoking the complex response. The gustatory sensation caused by a single shock is apparently due purely to direct electrical stimulation, since a current of such brief duration would not have any electrolytic action.

Thermal and mechanical types of stimulation may arouse faint sensations of taste but, as a rule, are ineffective.

Thresholds of the primary taste sensations. Minimum concentrations of the four main groups of sapid substances which will evoke the corresponding sensations are given in table 79 1.

AFTER TASTE AND TASTE CONTRASTS. The sense of taste exhibits phenomena analogous to positive after images and successive and simultaneous contrast, which have been described for vision (pp 1341, 1372). It is a familiar experience that the tastes of certain substances (e.g., quinine) "cling" to the tongue. But it is unlikely that the persistent taste is a true after sensation comparable with an after image, it is most probably due simply to the continued action of the stimulating agent which, having entered the taste pore, is removed with difficulty by the saliva or even by rinsing the mouth with water. On the contrary, the metallic taste which outlasts a single break shock is in all likelihood an example of the persistence of sensation.

Several observations exemplifying *successive contrast* can be cited. A sweet taste is enhanced by a preceding salt or bitter taste and *vice versa*. In the same way sour and sweet tastes intensify one another. Even distilled water tastes sweet after rinsing the mouth with a weak solution of sulfuric acid, and lemon juice seems much more acid following a sweet stimulus. Other examples which should probably be placed under the heading of successive contrast are the sweet taste which is experienced upon smoking a cigar or cigarette after washing out the mouth with a weak solution of copper sulfate, and the bitter taste caused by smoking if the tongue or buccal mucosa has been treated with a solution of silver nitrate. *Simultaneous contrast* is also demonstrable. For example, if one border of the tongue is rubbed with salt the sensitivity of the opposite border to a sweet stimulus is increased. This contrast effect must, of course, be of cerebral origin. Salt and acid also show simultaneous contrast, but

TABLE 79 1

Sensation and substance	Concentration
<i>Sweet</i> cane sugar	1 part in 200
dulcin	1 part in 100,200
a antialdoxine	
perillaldehyde	1 part in 600,000
<i>Salty</i> , sodium chloride	1 part in 400
<i>Acid</i> , hydrochloric	1 part in 15,000
<i>Bitter</i> , quinine	1 part in 2,000,000
atrychoise	1 part in 2,500,000

the phenomenon cannot be demonstrated for the bitter taste.

The effects of drugs upon taste. Certain drugs have a selective action upon the taste sensations, abolishing some while leaving others unaffected. For example, after the application of a decoction of the leaves of *Gymnema sylvestre* to the tongue, sweet and bitter substances cannot be tasted, but saline and acid tastes are retained, and are only slightly if at all depressed. *Stoaine* acts similarly to *Gymnema* but is less effective. *Cocaine* abolishes all taste as well as common sensibility, the several sensations disappearing in the following order, pain, bitter, sweet, saline, acid and touch.

Smell, Olfaction

THE OLFACTORY EPITHELIUM. The mucous membrane lining the greater part of the nasal cavity has no true olfactory function. The olfactory receptors are confined to the nasal mucosa over a relatively small region—the *olfactory area*. This area comprises, on each side, the walls of a narrow niche (fig. 79 4) formed by the superior nasal concha, the upper part of the septum and the roof of the nose (cribriform plate of the ethmoid bone). The olfactory epithelium differs both in its gross appearance and histologically from the rest of the nasal mucosa. It is yellowish or brownish yellow in color, its total area, i.e. on both sides of the nose, is about 500 square millimeters.¹

¹ The *vomeronasal organ* (organ of Jacobson) is a short tubular structure which, although well developed to certain lower vertebrates, is rudimentary in primates. It can be identified in a vestigial form in infants but, although it may persist throughout life, it is commonly absent in the adult. When present it is situated in the lower anterior part of the nasal septum and opens into the cavity of the nose by a minute pore a short distance within the external nares. In the dog and cat it receives both olfactory and trigeminal fibers and contains epithelium similar to that of the olfactory area. The function of the vomeronasal organ is not known with certainty but its general structure and innervation suggest very strongly that it is a subsidiary olfactory sense organ.

FIG 79 4 (Upper) sagittal section through skull to show position of olfactory area (b), (a) frontal bone, (c) nasal conchae (Lower) coronal section through the nasal cavity: (a) crista galli, (b) olfactory area, (c) nasal conchae, (d) maxillary sinus, (e) nasal septum

The olfactory epithelium is composed of three types of cell (a) supporting cells, (b) basal cells and (c) bipolar nerve cells. The supporting cells are of a very high columnar type with large oval nuclei. Superficially, they form a continuous epithelial surface, except for small round gaps between them through which the olfactory vesicles with their tufts of hairs project (see below). Their cytoplasm contains granules of a golden brown pigment to which the color of the olfactory epithelium is due. Proximally, the supporting cell tapers into a long slender process which extends as far as the lamina propria (fig 79 5). The basal cells are squat conical structures which extend for only a short distance above the lamina propria. They are believed to develop into supporting cells, thus serving as a reserve from which the latter when destroyed can be replaced.

The bipolar nerve cells are the essential olfac-

tory sense organs. Their two processes arise from opposite poles of the fusiform cell body, the dendrite from its superficial and the axon from its deep aspect. The dendrite is a long straight and relatively stout cylindrical process. It extends to the epithelial surface and projecting through one of the gaps between the supporting cells, expands slightly to form the olfactory vesicle. The latter contains from six to eight granules each of which gives rise to a hairlike protoplasmic process. The axon of the bipolar cell proceeds centrally from the deep aspect of the perikaryon and after traversing the lamina propria joins with the central processes of neighboring cells to form some 20 nerve strands—the *fila olfactoria* or *olfactory nerves*. The latter ascend in grooves in the ethmoid bone and entering the skull through perforations in the cribriform plate end within the olfactory lobe (bulb) in a tuft of delicate filaments which synapse with dendrites of the mitral cells (fig 79 5). The synapses form conspicuous spherical structures called the olfactory glomeruli. The axons of the mitral cells constitute the olfactory tract. Most of the fibers of the latter are continued into the lateral olfactory stria which conveys the impulses to the cortical center for smell (ch 67). The olfactory nerves are nonmedullated but possess a neurilemma. The lamina propria of the olfactory mucous membrane contains glands of the tubuloalveolar type—the glands of Bowman. They secrete a serous fluid which bathes the epithelial surface, thus providing a solvent for odorous material.

FIG 79 5 Left, diagram showing olfactory epithelium and connections of olfactory nerve fibers 1, olfactory tract, 2, mitral cells, 3, glomeruli, 4, cribriform plate, 5, olfactory nerves, 6, olfactory epithelium. Right, enlarged drawing of cells, B, basal cell, R, olfactory receptor cell, S, supporting cell.

The fluid is delivered by fine ducts which take a perpendicular course to the surface.

It will at once be recognized from the foregoing description that the end organs of smell differ from those of any other sense in that the cell body of the primary neuron is situated in the peripheral organ itself and is stimulated directly without the intervention of a specialized receptor cell. No other sensory mechanism possesses both these features. Although the primary neuron of the visual pathway is situated in the retina the stimulus is received by the rods and cones; pain sensations are subserved by bare nerve endings; the cell bodies of the pain fibers are located in the posterior root ganglia. It is also important to remember that here as nowhere else the nervous system is in direct contact with the external environment. The terminations of the dendrites of the olfactory cells, namely the olfactory hairs, are covered only by a layer of fluid. Furthermore the sheaths of the olfactory nerves are continuous with the subarachnoid space. Experimental work indicates that the olfactory nerves constitute one pathway through which the virus of anterior poliomyelitis may reach the central nervous system. Schultz and Gebhardt have shown for example that monkeys are protected against the intranasal injection of poliomyelitis virus by a previous section of the olfactory nerves. Intranasal sprays consisting of solutions of zinc sulfate and other substances have been employed in monkeys with the purpose of blocking these channels. The encouragement derived from the success of these experiments in protecting animals from the disease has led to the trial of similar measures in poliomyelitis epidemics but unfortunately they do not appear to have any value in reducing the number of cases. It is very difficult especially in children to bring the solution into contact with the olfactory epithelium and this is probably the reason that reliance cannot be placed upon intranasal spraying as a preventive. The recent experiments of C. G. Smith are enlightening. The olfactory areas of rats were treated with a 1 per cent solution of zinc sulfate and examined histologically at periods of from 2 days to 2 months thereafter. In animals so treated destructive changes amounting even to sloughing of the entire olfactory epithelium were found and in all cases the bipolar cells showed widespread degeneration. Regeneration of non-sensory cells (supporting and basal) subsequently occurred but of course the nerve cells were not restored. It would appear from these experiments that zinc sulfate solution if it is to be effective in protecting against the virus of poliomyelitis must entail permanent loss of the sense of smell.

THE PHYSIOLOGY OF THE SENSE OF SMELL

OLFACTORY SENSATIONS. Smell is very closely allied to taste and has been aptly described as "taste at a distance." In many animals the sense of smell is almost incredibly acute, a relatively large part of the brain being given over to it. In the life of such macrosmatic animals the olfactory sense is of paramount importance, warning the animal of the approach of its enemies, guiding it in the quest for food and motivating the sex reflexes. Certain species of moth (e.g., great peacock and banded moth) are credited with a degree of olfactory acuity which seems almost mythical to microsmatic man, the female being able it is claimed to attract the male by the odor of its secretions from a distance of a mile or more. The olfactory organs of moths and most other insects are located in the antennae. Even man in whom smell is a comparatively rudimentary sense can detect certain substances (e.g., mercaptan and artificial musk) in a dilution of 1 part in several billion parts of air. Smell is therefore much more acute than the sense of taste.

The adequate stimulus for the olfactory receptors as for those of taste is chemical.² An odorous material continuously emits particles of molecular size which reach the olfactory area through the air. Substances which pass readily into the gaseous state such as turpentine, gasoline, the essential oils etc. have strong odors whereas non-volatile materials e.g., the heavy metals, are nearly or quite inodorous. Arsenic which ordinarily is odorless gives off a characteristic smell however, when heated to a temperature at which it volatilizes and Elsberg, Brewer and Levy found that the olfactory coefficients (p. 1467) of a number of odorous liquids vary directly with their boiling points. The niche at the roof of the nose which is lined by the olfactory epithelium constitutes a blind pocket from which the main air currents caused by the ordinary respiratory movements are excluded. Experiments upon the human cadaver have shown that the respired air does not come into direct contact with the olfactory area. A head was bisected in the median plane and the nasal septum replaced by glass. When smoke was forced back and forth through the nose by means of bellows neither during the artificial inspiratory nor expiratory movement was the current ob-

² An electric current acts as an inadequate stimulus. When the nose is filled with normal saline and a constant current passed through the solution an odor which is difficult to describe is experienced upon opening or closing the current.

served to enter the olfactory region. The air flow takes a curved course, the highest point being about the middle of the nose and below the superior concha. The stream reaches a lower level during expiration than in inspiration. In order to excite the olfactory cells the odorous particles must, therefore, be carried upward from the respiratory passages either by diffusion or by eddy currents. In the aforementioned experiment eddy currents were observed both during the inspiratory and expiratory movements. In the living subject it is probable that the ascending currents are more pronounced during inspiration, at this time air movements caused by convection are likely to occur, due to the mixing of the cooler ingoing stream with the warmer air within the nose. But, however produced, whether by convection or simply as a result of the mechanical mixing of the inspired air with that within the nasal passages, eddy currents constitute the main factor in the stimulation of the olfactory endings, and a sharp inspiration is the most effective means by which such currents are set up. When, for example, we wish to smell some particular scent more acutely we automatically make a sharp inspiration or "sniff." Diffusion is a relatively slow process and is probably of minor importance in bringing the odorous material to the olfactory endings. Even though the nose is filled with odor-laden air we cannot smell while the breath is held. It is during expiration that odorous materials liberated from the food as it is masticated and swallowed enter the nose through the posterior nares and ascend to the olfactory area.

It will be recalled that the olfactory hairs are immersed in a layer of fluid secreted by Bowman's glands. The odorous particles must therefore enter into solution before they can come into contact with and stimulate the sense organs. This fact emphasizes again the similarity between the senses of taste and smell. It is probable that odorous materials before they can act as stimuli must also be dissolved in the substance of the olfactory hairs themselves. These structures, since they are stained best by osmic acid, are believed to be composed largely of lipid material. One would expect, therefore, that odorous substances must be soluble in oil as well as in water, and that those which are most freely soluble in both media would be the most potent in arousing an olfactory sensation.

The mechanism of the "sniff" appears to be a compressing together of the septum and the outer wall of the nose at the front of the respiratory passages so as to divert the inspired air to the olfactory area (Ogle).

tion. This supposition is borne out to some extent by experiment. Ethyl and methyl alcohols, for example, which are freely soluble in water but only slightly in oil, have weak odors as compared with butyl alcohol which dissolves very freely in oil and is also soluble in water. *Chlorobenzol*, *brombenzol*, *ether*, *citral* and many other substances with strong odors are soluble in both water and oil. It would appear that high solubility in oil is of more importance for olfactory stimulation than high water solubility, because, taking two substances, one with a high solubility in oil but sparingly soluble in water, and the other possessing solubilities of a converse kind, the former has the most powerful odor.

Although it is no longer questioned that the olfactory nerves subserve the sense of smell, some of the earlier investigators (e.g., Magendie) contended that olfaction was a function of the trigeminal nerve. The confusion arose from the fact that certain agents, e.g., *ammonia nitric acid fumes*, *chlorine*, *pepper*, *menthol*, *peppermint* and many others, cause nasal sensations, usually described as pungent, acid, irritating or cooling. These are not true olfactory sensations but are due to the stimulation of the trigeminal, which is the nerve mediating chemical sense and common sensibility in the respiratory part of the nasal mucosa. It is often very difficult, however, to dissociate these sensations from smell when the two types of ending are stimulated concurrently. A similar confusion arises, as already mentioned in the case of taste.

Strong reflex effects, e.g., sneezing, lachrymation, respiratory inhibition, vasomotor reactions, etc., result from irritation of the trigeminal endings, whereas reflexes initiated from the olfactory receptors are as a rule mild in character, and in man are concerned mainly with salivary and gastric secretion. In animals olfactory reflexes play their most important role in the reactions of sex and in self preservation—the search for food and protection from enemies. Olfaction is paramount among the senses in its power to awaken a train of associations in consciousness. Everyone is familiar with the strange reminiscent aura of long past events which is aroused by certain familiar scents.

THRESHOLD STIMULI. Among the most effective olfactory stimuli are *artificial musk*, *mercaptan*, *butyric acid*, *iodoform* and *oil of peppermint*. For example, methyl mercaptan (garlic odor) is perceptible to the average person in a concentration of 1/23,000,000,000 mg per cu cm of air. Assum-

ing that 50 cc of air is required for arousing an olfactory sensation, this would mean that 1/460,000,000 mg of the substance is an effective stimulus. The sense of smell is therefore many thousand times (about 25,000 times in the case of ethyl alcohol) more acute than the sense of taste. The minimum perceptible concentrations of various odorous substances are given in table 79 2.

SENSORY ADAPTATION. The olfactory receptors adapt fairly rapidly. It is a common experience that a disagreeable odor which when first smelled is almost overpowering soon becomes imperceptible. But although lost for one particular odor the sense of smell is retained for others, the phenomenon therefore is not due to fatigue of the olfactory mechanism (although it is often referred to as such) but is an example of sensory adaptation (p 1147). The rate of adaptation varies for different odors. The receptors become insensitive to oil of orange or to oil of lemon after an exposure of from 2.5 to 11 minutes (average 3 minutes) whereas eumarin (0.2 per cent aqueous solution) cannot be smelled longer than from 1.75 to 2.3 minutes and adaptation for the odor of benzoin is more rapid than for that of rubber.

Olfactory adaptation commences to develop from the moment that the odor is first smelled the threshold rising gradually until complete insensitivity to that particular odor is reached. Even a previous period of exposure to a given odor raises the minimum concentration at which it is perceived for a considerable length of time afterwards. Elsberg found for example, that the olfactory coefficients (p 1467) for peppermint, camphor and sassafras were increased to double their normal values if the subject had previously been smelling these substances, and the sensitivity of a person who had been for a time in the operating theater to the odor of ether was below normal several hours later.

CHEMICAL CONSTITUTION IN RELATION TO OLFACTORY STIMULATION. Generally speaking the olfactory potency of chemical compounds belonging to an homologous series increases progressively from the lowest members of the series to a maximum and then undergoes a gradual reduction in the upper members. The odors of the monatomic alcohols, for example, increase in strength from methyl through ethyl, propyl and butyl to amyl, the relative potencies of methyl and amyl alcohols are as 1 to 10,000. Also, compounds which as a group resemble one another in their chemical and physical properties tend to have odors possessing certain common characteristics. For example, the elements sulfur, selenium and tellurium, which belong to the sixth group in Mendeljeff's periodic table, when combined with hydrogen, methyl or ethyl, etc., have

TABLE 79 2

Substance	Mg per liter of Air
Ethyl ether	5.83
Chloroform	3.30
Pyridine	0.032
Oil of peppermint	0.024
Iodoform	0.018
Butyric acid	0.009
Propyl mercaptan	0.006
Artificial musk	0.00004

(From Allison and Katz.)

strong disagreeable smells. Similarly members of the seventh group, chlorine, bromine and iodine have kindred odors, the odors of chloroform and iodoform compounds of the first and third elements respectively, are linked together by that of bromoform in which the fragrance of chloroform and the unpleasant odor of iodoform can be detected. Of chemically allied organic substances ethyl, propyl and butyl acetates have an acetic odor whereas amyl acetate has not nevertheless the smell of the lowest of the series is linked with that of the highest through the two intermediate compounds.

Thus—

Ethyl acetate acetic odor

Propyl acetate acetic odor with slight pineapple flavor

Butyl acetate, slight acetic odor with pineapple flavor

Amyl acetate no acetic odor, strong pineapple flavor

Though the foregoing are interesting examples of chemical olfactory correlation it is not possible to make anything more than broad generalizations in respect to chemical structure and smell, for compounds which closely resemble one another chemically may have quite different odors and others which show little resemblance in their chemical or physical properties (e.g. hydrocyanic acid and nitrobenzene, garlic and certain arsenical compounds, and artificial and natural musk) may smell very much alike. Many nitrile compounds have an odor resembling bitter almonds or hydrocyanic acid whereas certain compounds of phosphorus and bismuth, as well as of arsenic, have a garlicky smell. An attempt has been made in the case of aromatic compounds to relate odor to a particular radical on the benzene ring. Hydroxyl, aldehyde, ketone, ester, nitro and nitril grouping—the so-called *osmophoric groups*—have been suggested as determining the character of the odor, it is believed, however, that the latter is dependent not so much upon which particular radical is present as upon the position which any one of them occupies in the

benzene ring and the general architecture of the molecule

A physical property common to many odors is their strong absorption of infrared rays. The significance of this fact, first remarked upon by Faraday, is unknown

OLFACTOMETRY The most widely known method of investigating the sense of smell is that of Zwaardemaker. His olfactometer consists of two glass tubes sliding one within the other, as shown in figure 79 6. The inner tube (a) is graduated in sections 0.7 cm. long. The inner surface of the outer tube carries a faintly odorous substance. The curved end (c) of the inner tube is introduced into a nostril, the opposite one being closed, the subject breathes quietly. The outer tube is gradually withdrawn, thus exposing a greater area of its inner surface to the air current and thereby increasing the concentration of the odorous particles in the inspired air. The highest figure visible on the inner graduated tube when the odor is just perceived indicates the subject's threshold for smell in units termed *olfacties*. This method gives not the best only approximate results, chiefly because the volume of inspired air drawn through the tubing varies considerably from subject to subject and in the same person at different times or even during a single period of observation. In the *blast method* of Elsberg and Levy this factor is controlled. Thirty cubic centimeters of an odorous liquid (e.g., benzene citral, oil of orange, oil of turpentine, butyric acid, etc.)

are placed in the bottle shown in figure 79 7. The right hand tube is connected to a double nosepiece which fits into the nostrils. By means of a syringe connected to the other tube a measured volume of air is forced from the bottle in one blast at a constant pressure while the subject holds his breath. An equivalent volume of odor laden air is thus forced into the nose. The volume of the injections is gradually increased in successive blasts until the odor is just perceived and can be named. The smallest volume necessary for identification is called the *minimum identifiable odor (MIO)* or the *olfactory coefficient*.

This method has been employed by Elsberg as an aid in the localization of tumors in the anterior part of the skull. In this situation a tumor (e.g., of the frontal lobe) is likely through direct pressure to involve the olfactory lobe or tract of one or of both sides, or the olfactory nerves may be torn in fractures through the cribriform plate. Unilateral involvement of the olfactory nerves lobe or tract raises the MIO or completely abolishes the sense of smell on the affected side. A tumor involving both olfactory lobes or tracts will result in lowered acuity of smell or complete anosmia on both sides. Elsberg states that tests for olfactory 'fatigue' give valuable localizing aid, the "fatigue" phenomenon is prolonged beyond the normal limits by tumors within the substance of the temporal lobe, but not by those situated extracerebrally (e.g., beneath the frontal lobe). In cases of a generalized increase of intracranial pressure due to other causes the MIO is often lowered.

CLASSIFICATION OF ODORS The division of odors into categories has proved an extremely difficult problem. There are no basic quantities of olfaction comparable to sweet, salty, sour and bitter tastes. The number of different and distinct smells is legion, and no comprehensive classification upon the basis of chemical constitution or physical properties can be even attempted. The earliest classification of odors was made by the Swedish botanist Linnæus (1750). The following one proposed by Zwaardemaker, which is little more than an elaboration of that proposed by Linnæus, consists of nine categories. It has a purely subjective basis and is therefore of little scientific value.

- 1 *Ethereal odors*, e.g., of fruits, beeswax, ethers
- 2 *Aromatic or resinous odors*, e.g., of camphor, bitter almonds, cloves, lavender
- 3 *Fragrant or balsamic odors*, e.g., of flowers, extracted or artificial perfumes

FIG 79 6 Diagram of Zwaardemaker's olfactometer. See text.

FIG 79 7 Illustrating the blast method of olfactometry. (After Elsberg and Levy.)

- 4 *Ambrosial odors*, e.g. of musk, ambergris
- 5 *Garlic odors* e.g., of garlic onions and of sulfur and selenium compounds
- 6 *Burning odors*, e.g., of burning feathers, tobacco, roasted coffee and meats
- 7 *Goat odors*, e.g., caproic acid, sweat and ripe cheese
- 8 *Repulsive odors* e.g., of hyocyanus and several of the family of the deadly night shade, bedbug
- 9 *Unpleasant odors* e.g., of excrement, decaying meat and vegetable matter

ACTION POTENTIALS FROM THE OLFACTORY PATHWAYS Gerard and Young have recorded the action currents from the olfactory bulb of the frog. A spontaneous rhythmical discharge occurs in this part of the isolated brain at the rate of about 4 per second. The discharge is taken as representing true automatic activity of the nerve cells of the bulb itself, for the possibility that it was due to the irritation of traumatized structures seems to have been excluded.

In certain fishes (catfish, carp and tench) the olfactory bulb is connected with the forebrain by a nerve strand (the *olfactory stalk*) which measures about 2 cm. long and is composed of from 500 to 1000 medullated fibers. Adrian and Ludwig studied the action potentials in the olfactory stalk of the catfish during stimulation of the olfactory end organs. The latter are contained in a small sac which opens through a nipple upon the surface of the skin above the mouth. Potential changes of small amplitude pass up the stalk as long as the preparation survives, although nothing but distilled water has been introduced into the sac. This *resting discharge* is of very low frequency. When the sac was irrigated with fluid containing containing small fragments of some odorous material, e.g. putrefying earthworms, a burst of impulses occurred at high frequency after a latent period of from 0.5 to 5 seconds or longer. It was found that the irrigation was more powerfully stimulating if the fluid contained small fragments of the material than if it had been filtered.

THE QUESTION OF OLFACTORY DISCRIMINATION The great multitude of distinguishable odors brings up a question for which no answer is forth coming, namely "What is the mechanism underlying olfactory differentiation?" "How do we detect the difference between two scents such as those of the violet and the rose?" Or, to make the question still more difficult, "How does a dog recognize the smell of his master among the smells of other persons?" Were there a limited number of basic odors, as there are of fundamental tastes, the problem would not be difficult. A theory of color vision can be conceived (ch. 62) based upon the existence of receptors responsive to different

wave lengths, and which discharge impulses along specific nerve paths (pp. 1148, 1149). The resonance valley theory explains the pitch-discriminating function of the ear (p. 1439), and four functionally distinct types of taste bud, each with its specific nerve fiber, for the perception of the fundamental sensations of taste. But it is not conceivably possible that every one of the immense number of different odors is subserved by a specific type of end organ with its own nerve fiber. Furthermore new and distinct odors are being created in industry every day.

Theories of the mechanism through which an odorous substance sets up an impulse in an olfactory nerve fiber are of necessity almost wholly speculative. The following catalytic theory of olfaction has been proposed by Kistiakowsky similar to that already described for gustation. He postulates a series of catalytic reactions which may be represented as, $A \rightarrow A' \rightarrow A''$, $B \rightarrow B' \rightarrow B''$, $C \rightarrow C' \rightarrow C''$, etc. Each step is effected by a specific enzyme, and each compound formed A' , B' , C' , etc., stimulates an olfactory receptor and gives rise to a corresponding distinct 'basic odor'. Presumably, the odoriferous substance itself inhibits one or more of the enzyme systems. This would lead to differences in the combination of the stimulating compounds, and even a slight change in their relative concentrations could arouse an olfactory sensation. The difficulty here is in defining a basic odor and having to assume an unreasonable number of functionally different receptor cells, for the nerve impulses themselves possess no differentiating characteristics which could serve the brain as cues. But if in addition, areas with different physical or chemical properties were distributed over the olfactory membrane which permitted a selective penetration or adsorption of the odorous substance to or upon the receptors, some sort of pattern of excitation might be established which could be interpreted by the cerebral cortex as a smell of a certain kind, or the different areas might possess specific affinities for certain chemical groups. A mechanism of this nature would not require an immense number of different types of receptor.

From what we know of other senses we can presume that the intensity of the olfactory sensation is related to the frequency of the impulses discharged to the olfactory center. This is borne out by the experiments of Adrian and Ludwig just described.

THE EFFECT OF ONE ODOR UPON THE PERCEPTION

of another. Strong odors tend to mask weaker ones. If two scents are of about equal strength a blend of the two is smelled or both are identified, but if one is considerably stronger than the other it alone, as a rule, is smelled. On the other hand, certain pairs of odors in appropriate relative concentrations are antagonistic, and when the two are sniffed together both are diminished. Iodoform, for example, is antagonized by balsam of Peru, musk by bitter almonds and ammonia by acetic acid. Other pairs of neutralizing odors are cedarwood and rubber, beeswax and balsam of Tolu, benzoin and rubber, and camphor and eau de Cologne. Although the neutralizing effect may in some cases be simply chemical or physical in nature, in others there seems to be a true physiological antagonism, for the phenomenon is observed when mixing is avoided by leading the two odors directly one to each nostril.

ANOMALIES OF OLFACTION. Loss of the sense of smell or anosmia is not infrequent as a temporary condition, e.g., as a result of inflammation of the nasal mucosa or of the local application of cocaine or adrenaline. Complete and permanent anosmia is rare in otherwise normal persons and is usually due to absence of the olfactory bulb or olfactory nerves, but bilateral or unilateral olfactory deficiencies are frequently associated with lesions in the region of the olfactory lobes. Albinoes are said to be anosmic, which suggests that the pigment in the supporting cells of the olfactory epithelium, which possibly serves an essential function, is lacking. Inability to smell certain odors is not uncommon. Some persons, for example, cannot smell hydrocyanic acid, the odor of nignonette, benzoin, methyl alcohol or vanillin cannot be smelled by others. Even such a strong, disagreeable smell as that of a rotten egg or of feces may not be sensed. Partial anosmia for all scents may result from excessive smoking. *Hyperosmia* is not unusual in hysteria, in certain cerebral diseases in raised intracranial pressure and during the initial stage of the action of cocaine. Olfactory hallucinations may occur in lesions of the temporal lobe (ch 67). In cerebral tumors, especially of the frontal or temporal lobes an odorous material introduced into one nostril may be referred to the other. This phenomenon, known as *olfactory alloesthesia*, is analogous to *allocheiria* mentioned on page 1140.

Common Chemical Sense

The general body surface of fish and many other aquatic forms is sensitive to various types of chemical irritant, as are also the moist skins

of amphibians. The elicitation of reflex responses from the foot of a pithed frog stimulated by a weak solution of sulfuric acid is a well known laboratory exercise. In man the common chemical sense is restricted to surfaces which are kept constantly moist, namely, the buccal and nasal mucous membranes, the conjunctivae and the mucosa of the anal canal. The common chemical sense of the first three is subserved by the trigeminal nerve, that of the anal canal by the pudendal nerve. It has already been pointed out that the sense organs subserving this sense in the mouth and nose are distinct from the gustatory and olfactory endings, and apparently they are not identical with those subserving pain for dissociation of chemical and pain sensations can be effected by cocaine, the latter being abolished before the former. Thus, after the application of a 1 per cent solution of the anesthetic to the foot of the frog no response is given to pinching, pricking or scratching, whereas reactions to chemical agents can for a time be elicited.
